`tsscons` forces the total sum of squares to be computed as though the model has a constant, that is, as deviations from the mean of the dependent variable. This is a rarely used option that has an effect only when specified with `noconstant`. It affects the total sum of squares and all results derived from the total sum of squares.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`ols`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

`vce(ols)`, the default, uses the standard variance estimator for ordinary least-squares regression.

`regress` also allows the following:

`vce(hc2)` and `vce(hc3)` specify an alternative bias correction for the robust variance calculation. `vce(hc2)` and `vce(hc3)` may not be specified with `svy` prefix. In the unclustered case, `vce(robust)` uses $\widehat{\sigma}_j^2 = \{n/(n-k)\}u_j^2$ as an estimate of the variance of the jth observation, where u_j is the calculated residual and $n/(n-k)$ is included to improve the overall estimate's small-sample properties.

`vce(hc2)` instead uses $u_j^2/(1-h_{jj})$ as the observation's variance estimate, where h_{jj} is the diagonal element of the hat (projection) matrix. This estimate is unbiased if the model really is homoskedastic. `vce(hc2)` tends to produce slightly more conservative confidence intervals.

`vce(hc3)` uses $u_j^2/(1-h_{jj})^2$ as suggested by Davidson and MacKinnon (1993), who report that this method tends to produce better results when the model really is heteroskedastic. `vce(hc3)` produces confidence intervals that tend to be even more conservative.

See Davidson and MacKinnon (1993, 554–556) and Angrist and Pischke (2009, 294–308) for more discussion on these two bias corrections.

Reporting

`level(#)`; see [R] **estimation options**.

`beta` asks that standardized beta coefficients be reported instead of confidence intervals. The beta coefficients are the regression coefficients obtained by first standardizing all variables to have a mean of 0 and a standard deviation of 1. `beta` may not be specified with `vce(cluster` *clustvar*`)` or the `svy` prefix.

`eform(`*string*`)` is used only in programs and ado-files that use `regress` to fit models other than linear regression. `eform()` specifies that the coefficient table be displayed in exponentiated form as defined in [R] **maximize** and that *string* be used to label the exponentiated coefficients in the table.

`depname(`*varname*`)` is used only in programs and ado-files that use `regress` to fit models other than linear regression. `depname()` may be specified only at estimation time. *varname* is recorded as the identity of the dependent variable, even though the estimates are calculated using *depvar*. This method affects the labeling of the output—not the results calculated—but could affect subsequent calculations made by `predict`, where the residual would be calculated as deviations from *varname* rather than *depvar*. `depname()` is most typically used when *depvar* is a temporary variable (see [P] **macro**) used as a proxy for *varname*.

`depname()` is not allowed with the `svy` prefix.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

The following options are available with `regress` but are not shown in the dialog box:

`noheader` suppresses the display of the ANOVA table and summary statistics at the top of the output; only the coefficient table is displayed. This option is often used in programs and ado-files.

`notable` suppresses display of the coefficient table.

`plus` specifies that the output table be made extendable. This option is often used in programs and ado-files.

`mse1` is used only in programs and ado-files that use `regress` to fit models other than linear regression and is not allowed with the `svy` prefix. `mse1` sets the mean squared error to `1`, forcing the variance–covariance matrix of the estimators to be $(\mathbf{X}'\mathbf{D}\mathbf{X})^{-1}$ (see *Methods and formulas* below) and affecting calculated standard errors. Degrees of freedom for t statistics is calculated as n rather than $n-k$.

`coeflegend`; see [R] **estimation options**.

Remarks and examples

Remarks are presented under the following headings:

Ordinary least squares
Treatment of the constant
Robust standard errors
Weighted regression
Instrumental variables and two-stage least-squares regression
Video example

`regress` performs linear regression, including ordinary least squares and weighted least squares. For a general discussion of linear regression, see Draper and Smith (1998), Greene (2012), or Kmenta (1997).

See Wooldridge (2013) for an excellent treatment of estimation, inference, interpretation, and specification testing in linear regression models. This presentation stands out for its clarification of the statistical issues, as opposed to the algebraic issues. See Wooldridge (2010, chap. 4) for a more advanced discussion along the same lines.

See Hamilton (2013, chap. 7) and Cameron and Trivedi (2010, chap. 3) for an introduction to linear regression using Stata. Dohoo, Martin, and Stryhn (2012, 2010) discuss linear regression using examples from epidemiology, and Stata datasets and do-files used in the text are available. Cameron and Trivedi (2010) discuss linear regression using econometric examples with Stata. Mitchell (2012) shows how to use graphics and postestimation commands to understand a fitted regression model.

Chatterjee and Hadi (2012) explain regression analysis by using examples containing typical problems that you might encounter when performing exploratory data analysis. We also recommend Weisberg (2005), who emphasizes the importance of the assumptions of linear regression and problems resulting from these assumptions. Becketti (2013) discusses regression analysis with an emphasis on time-series data. Angrist and Pischke (2009) approach regression as a tool for exploring relationships, estimating treatment effects, and providing answers to public policy questions. For a discussion of model-selection techniques and exploratory data analysis, see Mosteller and Tukey (1977). For a mathematically rigorous treatment, see Peracchi (2001, chap. 6). Finally, see Plackett (1972) if you are interested in the history of regression. Least squares, which dates back to the 1790s, was discovered independently by Legendre and Gauss.

Ordinary least squares

▷ Example 1: Basic linear regression

Suppose that we have data on the mileage rating and weight of 74 automobiles. The variables in our data are `mpg`, `weight`, and `foreign`. The last variable assumes the value 1 for foreign and 0 for domestic automobiles. We wish to fit the model

$$\texttt{mpg} = \beta_0 + \beta_1\texttt{weight} + \beta_2\texttt{foreign} + \epsilon$$

This model can be fit with `regress` by typing

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress mpg weight foreign
```

Source	SS	df	MS	Number of obs =	74
				F(2, 71) =	69.75
Model	1619.2877	2	809.643849	Prob > F =	0.0000
Residual	824.171761	71	11.608053	R-squared =	0.6627
				Adj R-squared =	0.6532
Total	2443.45946	73	33.4720474	Root MSE =	3.4071

mpg	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
weight	-.0065879	.0006371	-10.34	0.000	-.0078583	-.0053175
foreign	-1.650029	1.075994	-1.53	0.130	-3.7955	.4954422
_cons	41.6797	2.165547	19.25	0.000	37.36172	45.99768

`regress` produces a variety of summary statistics along with the table of regression coefficients. At the upper left, `regress` reports an analysis-of-variance (ANOVA) table. The column headings `SS`, `df`, and `MS` stand for "sum of squares", "degrees of freedom", and "mean square", respectively. In this example, the total sum of squares is 2,443.5: 1,619.3 accounted for by the model and 824.2 left unexplained. Because the regression included a constant, the total sum reflects the sum after removal of means, as does the sum of squares due to the model. The table also reveals that there are 73 total degrees of freedom (counted as 74 observations less 1 for the mean removal), of which 2 are consumed by the model, leaving 71 for the residual.

To the right of the ANOVA table are presented other summary statistics. The F statistic associated with the ANOVA table is 69.75. The statistic has 2 numerator and 71 denominator degrees of freedom. The F statistic tests the hypothesis that all coefficients excluding the constant are zero. The chance of observing an F statistic that large or larger is reported as 0.0000, which is Stata's way of indicating a number smaller than 0.00005. The R-squared (R^2) for the regression is 0.6627, and the R-squared adjusted for degrees of freedom (R^2_a) is 0.6532. The root mean squared error, labeled `Root MSE`, is 3.4071. It is the square root of the mean squared error reported for the residual in the ANOVA table.

Finally, Stata produces a table of the estimated coefficients. The first line of the table indicates that the left-hand-side variable is `mpg`. Thereafter follow the estimated coefficients. Our fitted model is

$$\texttt{mpg_hat} = 41.68 - 0.0066\,\texttt{weight} - 1.65\,\texttt{foreign}$$

Reported to the right of the coefficients in the output are the standard errors. For instance, the standard error for the coefficient on `weight` is 0.0006371. The corresponding t statistic is -10.34, which has a two-sided significance level of 0.000. This number indicates that the significance is less than 0.0005. The 95% confidence interval for the coefficient is $[-0.0079, -0.0053]$.

◁

▷ Example 2: Transforming the dependent variable

If we had a graph comparing `mpg` with `weight`, we would notice that the relationship is distinctly nonlinear. This is to be expected because energy usage per distance should increase linearly with weight, but `mpg` is measuring distance per energy used. We could obtain a better model by generating a new variable measuring the number of gallons used per 100 miles (`gp100m`) and then using this new variable in our model:

$$\texttt{gp100m} = \beta_0 + \beta_1\texttt{weight} + \beta_2\texttt{foreign} + \epsilon$$

We can now fit this model:

```
. generate gp100m = 100/mpg
. regress gp100m weight foreign
```

Source	SS	df	MS	Number of obs =	74
				F(2, 71) =	113.97
Model	91.1761694	2	45.5880847	Prob > F =	0.0000
Residual	28.4000913	71	.400001287	R-squared =	0.7625
				Adj R-squared =	0.7558
Total	119.576261	73	1.63803097	Root MSE =	.63246

gp100m	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
weight	.0016254	.0001183	13.74	0.000	.0013896	.0018612
foreign	.6220535	.1997381	3.11	0.003	.2237871	1.02032
_cons	-.0734839	.4019932	-0.18	0.855	-.8750354	.7280677

Fitting the physically reasonable model increases our R-squared to 0.7625.

◁

▷ Example 3: Obtaining beta coefficients

`regress` shares the features of all estimation commands. Among other things, this means that after running a regression, we can use `test` to test hypotheses about the coefficients, `estat vce` to examine the covariance matrix of the estimators, and `predict` to obtain predicted values, residuals, and influence statistics. See **[U] 20 Estimation and postestimation commands**. Options that affect how estimates are displayed, such as `beta` or `level()`, can be used when replaying results.

Suppose that we meant to specify the `beta` option to obtain beta coefficients (regression coefficients normalized by the ratio of the standard deviation of the regressor to the standard deviation of the dependent variable). Even though we forgot, we can specify the option now:

```
. regress, beta
```

Source	SS	df	MS	Number of obs =	74
				F(2, 71) =	113.97
Model	91.1761694	2	45.5880847	Prob > F =	0.0000
Residual	28.4000913	71	.400001287	R-squared =	0.7625
				Adj R-squared =	0.7558
Total	119.576261	73	1.63803097	Root MSE =	.63246

gp100m	Coef.	Std. Err.	t	P>|t|	Beta
weight	.0016254	.0001183	13.74	0.000	.9870255
foreign	.6220535	.1997381	3.11	0.003	.2236673
_cons	-.0734839	.4019932	-0.18	0.855	.

◁

Treatment of the constant

By default, `regress` includes an intercept (constant) term in the model. The `noconstant` option suppresses it, and the `hascons` option tells `regress` that the model already has one.

▷ Example 4: Suppressing the constant term

We wish to fit a regression of the `weight` of an automobile against its `length`, and we wish to impose the constraint that the weight is zero when the length is zero.

If we simply type `regress weight length`, we are fitting the model

$$\texttt{weight} = \beta_0 + \beta_1\,\texttt{length} + \epsilon$$

Here a `length` of zero corresponds to a `weight` of β_0. We want to force β_0 to be zero or, equivalently, estimate an equation that does not include an intercept:

$$\texttt{weight} = \beta_1\,\texttt{length} + \epsilon$$

We do this by specifying the noconstant option:

```
. regress weight length, noconstant
      Source |       SS       df       MS              Number of obs =      74
-------------+------------------------------           F(  1,    73) = 3450.13
       Model |  703869302      1  703869302             Prob > F      =  0.0000
    Residual |  14892897.8     73  204012.299           R-squared     =  0.9793
-------------+------------------------------           Adj R-squared =  0.9790
       Total |  718762200     74  9713002.7             Root MSE      =  451.68

------------------------------------------------------------------------------
      weight |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
      length |   16.29829   .2774752    58.74   0.000     15.74528    16.8513
------------------------------------------------------------------------------
```

In our data, length is measured in inches and weight in pounds. We discover that each inch of length adds 16 pounds to the weight.

◁

Sometimes there is no need for Stata to include a constant term in the model. Most commonly, this occurs when the model contains a set of mutually exclusive indicator variables. hascons is a variation of the noconstant option—it tells Stata not to add a constant to the regression because the regression specification already has one, either directly or indirectly.

For instance, we now refit our model of weight as a function of length and include separate constants for foreign and domestic cars by specifying bn.foreign. bn.foreign is factor-variable notation for "no base for foreign" or "include all levels of variable foreign in the model"; see [U] 11.4.3 Factor variables.

```
. regress weight length bn.foreign, hascons
      Source |       SS       df       MS              Number of obs =      74
-------------+------------------------------           F(  2,    71) =  316.54
       Model |  39647744.7      2  19823872.3           Prob > F      =  0.0000
    Residual |  4446433.7      71  62625.8268           R-squared     =  0.8992
-------------+------------------------------           Adj R-squared =  0.8963
       Total |  44094178.4     73  604029.841           Root MSE      =  250.25

------------------------------------------------------------------------------
      weight |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
      length |   31.44455   1.601234    19.64   0.000     28.25178    34.63732

     foreign |
    Domestic |  -2850.25   315.9691    -9.02   0.000    -3480.274   -2220.225
     Foreign |  -2983.927   275.1041   -10.85   0.000    -3532.469   -2435.385
------------------------------------------------------------------------------
```

❑ Technical note

There is a subtle distinction between the hascons and noconstant options. We can most easily reveal it by refitting the last regression, specifying noconstant rather than hascons:

```
. regress weight length bn.foreign, noconstant
```

Source	SS	df	MS	Number of obs =	74
				F(3, 71) =	3802.03
Model	714315766	3	238105255	Prob > F =	0.0000
Residual	4446433.7	71	62625.8268	R-squared =	0.9938
				Adj R-squared =	0.9936
Total	718762200	74	9713002.7	Root MSE =	250.25

weight	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
length	31.44455	1.601234	19.64	0.000	28.25178	34.63732
foreign						
Domestic	-2850.25	315.9691	-9.02	0.000	-3480.274	-2220.225
Foreign	-2983.927	275.1041	-10.85	0.000	-3532.469	-2435.385

Comparing this output with that produced by the previous regress command, we see that they are almost, but not quite, identical. The parameter estimates and their associated statistics—the second half of the output—are identical. The overall summary statistics and the ANOVA table—the first half of the output—are different, however.

In the first case, the R^2 is shown as 0.8992; here it is shown as 0.9938. In the first case, the F statistic is 316.54; now it is 3,802.03. The numerator degrees of freedom is different as well. In the first case, the numerator degrees of freedom is 2; now the degrees of freedom is 3. Which is correct?

Both are. Specifying the hascons option causes regress to adjust the ANOVA table and its associated statistics for the explanatory power of the constant. The regression in effect has a constant; it is just written in such a way that a separate constant is unnecessary. No such adjustment is made with the noconstant option.

❑

❑ Technical note

When the hascons option is specified, regress checks to make sure that the model does in fact have a constant term. If regress cannot find a constant term, it automatically adds one. Fitting a model of weight on length and specifying the hascons option, we obtain

```
. regress weight length, hascons
(note: hascons false)
```

Source	SS	df	MS	Number of obs =	74
				F(1, 72) =	613.27
Model	39461306.8	1	39461306.8	Prob > F =	0.0000
Residual	4632871.55	72	64345.4382	R-squared =	0.8949
				Adj R-squared =	0.8935
Total	44094178.4	73	604029.841	Root MSE =	253.66

weight	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
length	33.01988	1.333364	24.76	0.000	30.36187	35.67789
_cons	-3186.047	252.3113	-12.63	0.000	-3689.02	-2683.073

Even though we specified `hascons`, `regress` included a constant, anyway. It also added a note to our output: "note: hascons false".

❑

❑ Technical note

Even if the model specification effectively includes a constant term, we need not specify the `hascons` option. `regress` is always on the lookout for collinear variables and omits them from the model. For instance,

```
. regress weight length bn.foreign
note: 1.foreign omitted because of collinearity
```

Source	SS	df	MS	Number of obs =	74
				F(2, 71) =	316.54
Model	39647744.7	2	19823872.3	Prob > F =	0.0000
Residual	4446433.7	71	62625.8268	R-squared =	0.8992
				Adj R-squared =	0.8963
Total	44094178.4	73	604029.841	Root MSE =	250.25

weight	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
length	31.44455	1.601234	19.64	0.000	28.25178	34.63732
foreign						
Domestic	133.6775	77.47615	1.73	0.089	-20.80555	288.1605
Foreign	0	(omitted)				
_cons	-2983.927	275.1041	-10.85	0.000	-3532.469	-2435.385

❑

Robust standard errors

`regress` with the `vce(robust)` option substitutes a robust variance matrix calculation for the conventional calculation, or if `vce(cluster` *clustvar*`)` is specified, allows relaxing the assumption of independence within groups. How this method works is explained in [U] **20.21 Obtaining robust variance estimates**. Below we show how well this approach works.

▷ Example 5: Heteroskedasticity and robust standard errors

Specifying the `vce(robust)` option is equivalent to requesting White-corrected standard errors in the presence of heteroskedasticity. We use the automobile data and, in the process of looking at the energy efficiency of cars, analyze a variable with considerable heteroskedasticity.

We will examine the amount of energy—measured in gallons of gasoline—that the cars in the data need to move 1,000 pounds of their weight 100 miles. We are going to examine the relative efficiency of foreign and domestic cars.

```
. gen gpmw = ((1/mpg)/weight)*100*1000
. summarize gpmw
```

Variable	Obs	Mean	Std. Dev.	Min	Max
gpmw	74	1.682184	.2426311	1.09553	2.30521

In these data, the engines consume between 1.10 and 2.31 gallons of gas to move 1,000 pounds of the car's weight 100 miles. If we ran a regression with conventional standard errors of `gpmw` on `foreign`, we would obtain

```
. regress gpmw foreign
      Source |       SS       df       MS              Number of obs =      74
-------------+------------------------------           F(  1,    72) =   20.07
       Model |  .936705572     1  .936705572            Prob > F      =  0.0000
    Residual |  3.36079459    72  .046677703            R-squared     =  0.2180
-------------+------------------------------           Adj R-squared =  0.2071
       Total |  4.29750017    73  .058869865            Root MSE      =  .21605

------------------------------------------------------------------------------
        gpmw |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
     foreign |   .2461526   .0549487     4.48   0.000     .1366143    .3556909
       _cons |   1.609004   .0299608    53.70   0.000     1.549278     1.66873
------------------------------------------------------------------------------
```

`regress` with the `vce(robust)` option, on the other hand, reports

```
. regress gpmw foreign, vce(robust)
Linear regression                               Number of obs =      74
                                                F(  1,    72) =   13.13
                                                Prob > F      =  0.0005
                                                R-squared     =  0.2180
                                                Root MSE      =  .21605

------------------------------------------------------------------------------
             |               Robust
        gpmw |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
     foreign |   .2461526   .0679238     3.62   0.001     .1107489    .3815563
       _cons |   1.609004   .0234535    68.60   0.000      1.56225    1.655758
------------------------------------------------------------------------------
```

The point estimates are the same (foreign cars need one-quarter gallon more gas), but the standard errors differ by roughly 20%. Conventional regression reports the 95% confidence interval as $[0.14, 0.36]$, whereas the robust standard errors make the interval $[0.11, 0.38]$.

Which is right? Notice that `gpmw` is a variable with considerable heteroskedasticity:

```
. tabulate foreign, summarize(gpmw)
           |        Summary of gpmw
  Car type |      Mean   Std. Dev.       Freq.
-----------+------------------------------------
  Domestic | 1.6090039   .16845182          52
   Foreign | 1.8551565   .30186861          22
-----------+------------------------------------
     Total | 1.6821844   .24263113          74
```

Thus here we favor the robust standard errors. In [U] **20.21 Obtaining robust variance estimates**, we show another example using linear regression where it makes little difference whether we specify `vce(robust)`. The linear-regression assumptions were true, and we obtained nearly linear-regression results. The advantage of the robust estimate is that in neither case did we have to check assumptions.

◁

❑ Technical note

`regress` purposefully suppresses displaying the ANOVA table when `vce(robust)` is specified, as it is no longer appropriate in a statistical sense, even though, mechanically, the numbers would be unchanged. That is, sums of squares remain unchanged, but the meaning of those sums is no longer relevant. The F statistic, for instance, is no longer based on sums of squares; it becomes a Wald test based on the robustly estimated variance matrix. Nevertheless, `regress` continues to report the R^2

and the root MSE even though both numbers are based on sums of squares and are, strictly speaking, irrelevant. In this, the root MSE is more in violation of the spirit of the robust estimator than is R^2. As a goodness-of-fit statistic, R^2 is still fine; just do not use it in formulas to obtain F statistics because those formulas no longer apply. The root MSE is valid in a literal sense—it is the square root of the mean squared error, but it is no longer an estimate of σ because there is no single σ; the variance of the residual varies observation by observation.

❑

▷ Example 6: Alternative robust standard errors

The `vce(hc2)` and `vce(hc3)` options modify the robust variance calculation. In the context of linear regression without clustering, the idea behind the robust calculation is somehow to measure σ_j^2, the variance of the residual associated with the jth observation, and then to use that estimate to improve the estimated variance of $\widehat{\boldsymbol{\beta}}$. Because residuals have (theoretically and practically) mean 0, one estimate of σ_j^2 is the observation's squared residual itself—u_j^2. A finite-sample correction could improve that by multiplying u_j^2 by $n/(n-k)$, and, as a matter of fact, `vce(robust)` uses $\{n/(n-k)\}u_j^2$ as its estimate of the residual's variance.

`vce(hc2)` and `vce(hc3)` use alternative estimators of the observation-specific variances. For instance, if the residuals are homoskedastic, we can show that the expected value of u_j^2 is $\sigma^2(1-h_{jj})$, where h_{jj} is the jth diagonal element of the projection (hat) matrix. h_{jj} has average value k/n, so $1-h_{jj}$ has average value $1-k/n = (n-k)/n$. Thus the default robust estimator $\widehat{\sigma}_j = \{n/(n-k)\}u_j^2$ amounts to dividing u_j^2 by the average of the expectation.

`vce(hc2)` divides u_j^2 by $1-h_{jj}$ itself, so it should yield better estimates if the residuals really are homoskedastic. `vce(hc3)` divides u_j^2 by $(1-h_{jj})^2$ and has no such clean interpretation. Davidson and MacKinnon (1993) show that $u_j^2/(1-h_{jj})^2$ approximates a more complicated estimator that they obtain by jackknifing (MacKinnon and White 1985). Angrist and Pischke (2009) also illustrate the relative merits of these adjustments.

Here are the results of refitting our efficiency model using `vce(hc2)` and `vce(hc3)`:

```
. regress gpmw foreign, vce(hc2)
Linear regression                               Number of obs =      74
                                                F(  1,    72) =   12.93
                                                Prob > F      =  0.0006
                                                R-squared     =  0.2180
                                                Root MSE      =  .21605
```

Example 7: Standard errors for clustered data

The `vce(cluster` *clustvar*`)` option relaxes the assumption of independence. Below we have 28,534 observations on 4,711 women aged 14–46 years. Data were collected on these women between 1968 and 1988. We are going to fit a classic earnings model, and we begin by ignoring that each woman appears an average of 6.057 times in the data.

```
. use http://www.stata-press.com/data/r13/regsmpl, clear
(NLS Women 14-26 in 1968)
. regress ln_wage age c.age#c.age tenure
      Source |       SS       df       MS              Number of obs =   28101

The number of observations in our model is 28,101 because Stata drops observations that have a missing value for one or more of the variables in the model. We can be reasonably certain that the standard errors reported above are meaningless. Without a doubt, a woman with higher-than-average wages in one year typically has higher-than-average wages in other years, and so the residuals are not independent. One way to deal with this would be to fit a random-effects model—and we are going to do that—but first we fit the model using `regress` specifying `vce(cluster id)`, which treats only observations with different person `id`s as truly independent:

```
. regress ln_wage age c.age#c.age tenure, vce(cluster id)
Linear regression                               Number of obs =   28101
                                                F(  3,  4698) =  748.82
                                                Prob > F      =  0.0000
                                                R-squared     =  0.1644
                                                Root MSE      =  .43679

                                  (Std. Err. adjusted for 4699 clusters in idcode)
------------------------------------------------------------------------------
             |               Robust

       _cons |   .3339821   .0641918     5.20   0.000      .208136    .4598282
------------------------------------------------------------------------------
```

For comparison, we focus on the tenure coefficient, which in economics jargon can be interpreted as the rate of return for keeping your job. The 95% confidence interval we previously estimated—an interval we do not believe—is $[0.038, 0.041]$. The robust interval is twice as wide, being $[0.036, 0.042]$.

As we said, one correct way to fit this model is by random-effects regression. Here is the random-effects result:

```
. xtreg ln_wage age c.age#c.age tenure, re
Random-effects GLS regression                   Number of obs      =     28101

         rho |  .56095413   (fraction of variance due to u_i)
------------------------------------------------------------------------------
```

Robust regression estimated the 95% interval $[0.036, 0.042]$, and `xtreg` (see [XT] **xtreg**) estimates $[0.025, 0.027]$. Which is better? The random-effects regression estimator assumes a lot. We can check some of these assumptions by performing a Hausman test. Using `estimates` (see [R] **estimates store**), we store the random-effects estimation results, and then we run the required fixed-effects regression to perform the test.

```
. estimates store random
. xtreg ln_wage age c.age#c.age tenure, fe
Fixed-effects (within) regression               Number of obs      =     28101

```

The Hausman test casts grave suspicions on the random-effects model we just fit, so we should be careful in interpreting those results.

Meanwhile, our robust regression results still stand, as long as we are careful about the interpretation. The correct interpretation is that, if the data collection were repeated (on women sampled the same way as in the original sample), and if we were to refit the model, 95% of the time we would expect the estimated coefficient on tenure to be in the range $[0.036, 0.042]$.

Even with robust regression, we must be careful about going beyond that statement. Here the Hausman test is probably picking up something that differs within and between person, which would cast doubt on our robust regression model in terms of interpreting $[0.036, 0.042]$ to contain the rate of return for keeping a job, economywide, for all women, without exception.

◁

Weighted regression

regress can perform weighted and unweighted regression. We indicate the weight by specifying the [*weight*] qualifier. By default, regress assumes analytic weights; see the technical note below.

▷ Example 8: Using means as regression variables

We have census data recording the death rate (drate) and median age (medage) for each state. The data also record the region of the country in which each state is located and the overall population of the state:

```
. use http://www.stata-press.com/data/r13/census9
(1980 Census data by state)
. describe
Contains data from http://www.stata-press.com/data/r13/census9.dta
  obs:            50                          1980 Census data by state

state2          str2    %-2s                  Two-letter state abbreviation
drate           float   %9.0g                 Death Rate
pop             long    %12.0gc               Population
medage          float   %9.2f                 Median age
region          byte    %-8.0g     cenreg     Census region
-------------------------------------------------------------------------------
Sorted by:
```

We can use factor variables to include dummy variables for region. Because the variables in the regression reflect means rather than individual observations, the appropriate method of estimation is analytically weighted least squares (Davidson and MacKinnon 2004, 261–262), where the weight is total population:

```
. regress drate medage i.region [w=pop]
(analytic weights assumed)
(sum of wgt is   2.2591e+08)
      Source |       SS       df       MS              Number of obs =      50

```

To weight the regression by population, we added the qualifier [w=pop] to the end of the regress command. Our qualifier was vague (we did not say [aweight=pop]), but unless told otherwise, Stata

assumes analytic weights for `regress`. Stata informed us that the sum of the weight is 2.2591×10^8; there were approximately 226 million people residing in the United States according to our 1980 data. ◁

❑ Technical note

Once we fit a weighted regression, we can obtain the appropriately weighted variance–covariance matrix of the estimators using `estat vce` and perform appropriately weighted hypothesis tests using `test`.

In the weighted regression in example 8, we see that `4.region` is statistically significant but that `2.region` and `3.region` are not. We use `test` to test the joint significance of the region variables:

```
. test 2.region 3.region 4.region
 ( 1)  2.region = 0
 ( 2)  3.region = 0
 ( 3)  4.region = 0
       F(  3,    45) =    9.84
            Prob > F =    0.0000
```

The results indicate that the region variables are jointly significant.

❑

`regress` also accepts frequency weights (`fweight`s). Frequency weights are appropriate when the data do not reflect cell means, but instead represent replicated observations. Specifying `aweight`s or `fweight`s will not change the parameter estimates, but it will change the corresponding significance levels.

For instance, if we specified `[fweight=pop]` in the weighted regression example above—which would be statistically incorrect—Stata would treat the data as if the data represented 226 million independent observations on death rates and median age. The data most certainly do not represent that—they represent 50 observations on state averages.

With `aweight`s, Stata treats the number of observations on the process as the number of observations in the data. When we specify `fweight`s, Stata treats the number of observations as if it were equal to the sum of the weights; see *Methods and formulas* below.

❑ Technical note

A popular request on the help line is to describe the effect of specifying `[aweight=`*exp*`]` with `regress` in terms of transformation of the dependent and independent variables. The mechanical answer is that typing

```
. regress y x1 x2 [aweight=n]
```

is equivalent to fitting the model

$$y_j\sqrt{n_j} = \beta_0\sqrt{n_j} + \beta_1 x_{1j}\sqrt{n_j} + \beta_2 x_{2j}\sqrt{n_j} + u_j\sqrt{n_j}$$

This regression will reproduce the coefficients and covariance matrix produced by the `aweight`ed regression. The mean squared errors (estimates of the variance of the residuals) will, however, be different. The transformed regression reports s_t^2, an estimate of $\mathrm{Var}(u_j\sqrt{n_j})$. The `aweight`ed regression reports s_a^2, an estimate of $\mathrm{Var}(u_j\sqrt{n_j}\sqrt{N/\sum_k n_k})$, where N is the number of observations. Thus

$$s_a^2 = \frac{N}{\sum_k n_k} s_t^2 = \frac{s_t^2}{\overline{n}} \tag{1}$$

The logic for this adjustment is as follows: Consider the model

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + u$$

Assume that, were this model fit on individuals, $\mathrm{Var}(u) = \sigma_u^2$, a constant. Assume that individual data are not available; what is available are averages $(\overline{y}_j, \overline{x}_{1j}, \overline{x}_{2j})$ for $j = 1, \ldots, N$, and each average is calculated over n_j observations. Then it is still true that

$$\overline{y}_j = \beta_0 + \beta_1 \overline{x}_{1j} + \beta_2 \overline{x}_{2j} + \overline{u}_j$$

where $\overline{u}_j$ is the average of n_j mean 0, variance σ_u^2 deviates and has variance $\sigma_{\overline{u}}^2 = \sigma_u^2/n_j$. Thus multiplying through by $\sqrt{n_j}$ produces

$$\overline{y}_j\sqrt{n_j} = \beta_0\sqrt{n_j} + \beta_1 \overline{x}_{1j}\sqrt{n_j} + \beta_2 \overline{x}_{2j}\sqrt{n_j} + \overline{u}_j\sqrt{n_j}$$

and $\mathrm{Var}(\overline{u}_j\sqrt{n_j}) = \sigma_u^2$. The mean squared error, s_t^2, reported by fitting this transformed regression is an estimate of σ_u^2. The coefficients and covariance matrix could also be obtained by `aweighted regress`. The only difference would be in the reported mean squared error, which from (1) is $\sigma_u^2/\overline{n}$. On average, each observation in the data reflects the averages calculated over $\overline{n} = \sum_k n_k/N$ individuals, and thus this reported mean squared error is the average variance of an observation in the dataset. We can retrieve the estimate of σ_u^2 by multiplying the reported mean squared error by $\overline{n}$.

More generally, `aweights` are used to solve general heteroskedasticity problems. In these cases, we have the model

$$y_j = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + u_j$$

and the variance of u_j is thought to be proportional to a_j. If the variance is proportional to a_j, it is also proportional to αa_j, where α is any positive constant. Not quite arbitrarily, but with no loss of generality, we could choose $\alpha = \sum_k (1/a_k)/N$, the average value of the inverse of a_j. We can then write $\mathrm{Var}(u_j) = k\alpha a_j \sigma^2$, where k is the constant of proportionality that is no longer a function of the scale of the weights.

Dividing this regression through by the $\sqrt{a_j}$,

$$y_j/\sqrt{a_j} = \beta_0/\sqrt{a_j} + \beta_1 x_{1j}/\sqrt{a_j} + \beta_2 x_{2j}/\sqrt{a_j} + u_j/\sqrt{a_j}$$

produces a model with $\mathrm{Var}(u_j/\sqrt{a_j}) = k\alpha\sigma^2$, which is the constant part of $\mathrm{Var}(u_j)$. This variance is a function of α, the average of the reciprocal weights; if the weights are scaled arbitrarily, then so is this variance.

We can also fit this model by typing

```
. regress y x1 x2 [aweight=1/a]
```

This input will produce the same estimates of the coefficients and covariance matrix; the reported mean squared error is, from (1), $\{N/\sum_k (1/a_k)\} k\alpha\sigma^2 = k\sigma^2$. This variance is independent of the scale of a_j.

❑

Instrumental variables and two-stage least-squares regression

An alternate syntax for `regress` can be used to produce instrumental-variables (two-stage least squares) estimates.

`regress` *depvar* [*varlist*$_1$ [(*varlist*$_2$)]] [*if*] [*in*] [*weight*] [, *regress_options*]

This syntax is used mainly by programmers developing estimators using the instrumental-variables estimates as intermediate results. `ivregress` is normally used to directly fit these models; see [R] **ivregress**.

With this syntax, `regress` fits a structural equation of *depvar* on *varlist*$_1$ using instrumental variables regression; (*varlist*$_2$) indicates the list of instrumental variables. With the exception of `vce(hc2)` and `vce(hc3)`, all standard `regress` options are allowed.

Video example

Simple linear regression in Stata

Stored results

`regress` stores the following in `e()`:

Scalars

`e(N)`	number of observations
`e(mss)`	model sum of squares
`e(df_m)`	model degrees of freedom
`e(rss)`	residual sum of squares
`e(df_r)`	residual degrees of freedom
`e(r2)`	R-squared
`e(r2_a)`	adjusted R-squared
`e(F)`	F statistic
`e(rmse)`	root mean squared error
`e(ll)`	log likelihood under additional assumption of i.i.d. normal errors
`e(ll_0)`	log likelihood, constant-only model
`e(N_clust)`	number of clusters
`e(rank)`	rank of `e(V)`

Macros

`e(cmd)`	`regress`
`e(cmdline)`	command as typed
`e(depvar)`	name of dependent variable
`e(model)`	`ols` or `iv`
`e(wtype)`	weight type
`e(wexp)`	weight expression
`e(title)`	title in estimation output when `vce()` is not `ols`
`e(clustvar)`	name of cluster variable
`e(vce)`	*vcetype* specified in `vce()`
`e(vcetype)`	title used to label Std. Err.
`e(properties)`	`b V`
`e(estat_cmd)`	program used to implement `estat`
`e(predict)`	program used to implement `predict`
`e(marginsok)`	predictions allowed by `margins`
`e(asbalanced)`	factor variables `fvset` as `asbalanced`
`e(asobserved)`	factor variables `fvset` as `asobserved`

Matrices

`e(b)`	coefficient vector
`e(V)`	variance–covariance matrix of the estimators
`e(V_modelbased)`	model-based variance

Functions

`e(sample)`	marks estimation sample

Methods and formulas

Methods and formulas are presented under the following headings:

Coefficient estimation and ANOVA table
A general notation for the robust variance calculation
Robust calculation for regress

Coefficient estimation and ANOVA table

Variables printed in lowercase and not boldfaced (for example, x) are scalars. Variables printed in lowercase and boldfaced (for example, $\mathbf{x}$) are column vectors. Variables printed in uppercase and boldfaced (for example, $\mathbf{X}$) are matrices.

Let $\mathbf{v}$ be a column vector of weights specified by the user. If no weights are specified, $\mathbf{v} = \mathbf{1}$. Let $\mathbf{w}$ be a column vector of normalized weights. If no weights are specified or if the user specified `fweights` or `iweights`, $\mathbf{w} = \mathbf{v}$. Otherwise, $\mathbf{w} = \{\mathbf{v}/(\mathbf{1}'\mathbf{v})\}(\mathbf{1}'\mathbf{1})$.

The number of observations, n, is defined as $\mathbf{1}'\mathbf{w}$. For `iweights`, this is truncated to an integer. The sum of the weights is $\mathbf{1}'\mathbf{v}$. Define $c = 1$ if there is a constant in the regression and zero otherwise. Define k as the number of right-hand-side variables (including the constant).

Let $\mathbf{X}$ denote the matrix of observations on the right-hand-side variables, $\mathbf{y}$ the vector of observations on the left-hand-side variable, and $\mathbf{Z}$ the matrix of observations on the instruments. If the user specifies no instruments, then $\mathbf{Z} = \mathbf{X}$. In the following formulas, if the user specifies weights, then $\mathbf{X}'\mathbf{X}$, $\mathbf{X}'\mathbf{y}$, $\mathbf{y}'\mathbf{y}$, $\mathbf{Z}'\mathbf{Z}$, $\mathbf{Z}'\mathbf{X}$, and $\mathbf{Z}'\mathbf{y}$ are replaced by $\mathbf{X}'\mathbf{D}\mathbf{X}$, $\mathbf{X}'\mathbf{D}\mathbf{y}$, $\mathbf{y}'\mathbf{D}\mathbf{y}$, $\mathbf{Z}'\mathbf{D}\mathbf{Z}$, $\mathbf{Z}'\mathbf{D}\mathbf{X}$, and $\mathbf{Z}'\mathbf{D}\mathbf{y}$, respectively, where $\mathbf{D}$ is a diagonal matrix whose diagonal elements are the elements of $\mathbf{w}$. We suppress the $\mathbf{D}$ below to simplify the notation.

If no instruments are specified, define $\mathbf{A}$ as $\mathbf{X}'\mathbf{X}$ and $\mathbf{a}$ as $\mathbf{X}'\mathbf{y}$. Otherwise, define $\mathbf{A}$ as $\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}(\mathbf{X}'\mathbf{Z})'$ and $\mathbf{a}$ as $\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{y}$.

The coefficient vector $\mathbf{b}$ is defined as $\mathbf{A}^{-1}\mathbf{a}$. Although not shown in the notation, unless `hascons` is specified, $\mathbf{A}$ and $\mathbf{a}$ are accumulated in deviation form and the constant is calculated separately. This comment applies to all statistics listed below.

The total sum of squares, TSS, equals $\mathbf{y}'\mathbf{y}$ if there is no intercept and $\mathbf{y}'\mathbf{y} - \{(\mathbf{1}'\mathbf{y})^2/n\}$ otherwise. The degrees of freedom is $n - c$.

The error sum of squares, ESS, is defined as $\mathbf{y}'\mathbf{y} - 2\mathbf{b}\mathbf{X}'\mathbf{y} + \mathbf{b}'\mathbf{X}'\mathbf{X}\mathbf{b}$ if there are instruments and as $\mathbf{y}'\mathbf{y} - \mathbf{b}'\mathbf{X}'\mathbf{y}$ otherwise. The degrees of freedom is $n - k$.

The model sum of squares, MSS, equals TSS − ESS. The degrees of freedom is $k - c$.

The mean squared error, s^2, is defined as ESS$/(n - k)$. The root mean squared error is s, its square root.

The F statistic with $k - c$ and $n - k$ degrees of freedom is defined as

$$F = \frac{\text{MSS}}{(k-c)s^2}$$

if no instruments are specified. If instruments are specified and $c = 1$, then F is defined as

$$F = \frac{(\mathbf{b}-\mathbf{c})'\mathbf{A}(\mathbf{b}-\mathbf{c})}{(k-1)s^2}$$

where $\mathbf{c}$ is a vector of $k - 1$ zeros and kth element $\mathbf{1}'\mathbf{y}/n$. Otherwise, F is defined as "missing". (Here you may use the `test` command to construct any F test that you wish.)

The R-squared, R^2, is defined as $R^2 = 1 - \text{ESS}/\text{TSS}$.

The adjusted R-squared, R^2_a, is $1 - (1 - R^2)(n - c)/(n - k)$.

If `vce(robust)` is not specified, the conventional estimate of variance is $s^2\mathbf{A}^{-1}$. The handling of `vce(robust)` is described below.

A general notation for the robust variance calculation

Put aside all context of linear regression and the notation that goes with it—we will return to it. First, we are going to establish a notation for describing robust variance calculations.

The calculation formula for the robust variance calculation is

$$\widehat{\mathcal{V}} = q_c\widehat{\mathbf{V}}\Big(\sum_{k=1}^{M}\mathbf{u}_k^{(G)\prime}\mathbf{u}_k^{(G)}\Big)\widehat{\mathbf{V}}$$

where

$$\mathbf{u}_k^{(G)} = \sum_{j\in G_k} w_j\mathbf{u}_j$$

$G_1, G_2, \ldots, G_M$ are the clusters specified by `vce(cluster` *clustvar*`)`, and w_j are the user-specified weights, normalized if `aweights` or `pweights` are specified and equal to 1 if no weights are specified.

For `fweights` without clusters, the variance formula is

$$\widehat{\mathcal{V}} = q_c\widehat{\mathbf{V}}\Big(\sum_{j=1}^{N} w_j\mathbf{u}_j'\mathbf{u}_j\Big)\widehat{\mathbf{V}}$$

which is the same as expanding the dataset and making the calculation on the unweighted data.

If `vce(cluster` *clustvar*`)` is not specified, $M = N$, and each cluster contains 1 observation. The inputs into this calculation are

- $\widehat{\mathbf{V}}$, which is typically a conventionally calculated variance matrix;
- $\mathbf{u}_j$, $j = 1, \ldots, N$, a row vector of scores; and
- q_c, a constant finite-sample adjustment.

Thus we can now describe how estimators apply the robust calculation formula by defining $\widehat{\mathbf{V}}$, $\mathbf{u}_j$, and q_c.

Two definitions are popular enough for q_c to deserve a name. The regression-like formula for q_c (Fuller et al. 1986) is

$$q_c = \frac{N-1}{N-k}\,\frac{M}{M-1}$$

where M is the number of clusters and N is the number of observations. For weights, N refers to the sum of the weights if weights are frequency weights and the number of observations in the dataset (ignoring weights) in all other cases. Also note that, weighted or not, $M = N$ when `vce(cluster` *clustvar*`)` is not specified, and then $q_c = N/(N - k)$.

The asymptotic-like formula for q_c is

$$q_c = \frac{M}{M-1}$$

where $M = N$ if `vce(cluster` *clustvar*`)` is not specified.

See [U] **20.21 Obtaining robust variance estimates** and [P] **_robust** for a discussion of the robust variance estimator and a development of these formulas.

Robust calculation for regress

For `regress`, $\widehat{\mathbf{V}} = \mathbf{A}^{-1}$. The other terms are

No instruments, `vce(robust)`, but not `vce(hc2)` or `vce(hc3)`,

$$\mathbf{u}_j = (y_j - \mathbf{x}_j\mathbf{b})\mathbf{x}_j$$

and q_c is given by its regression-like definition.

No instruments, `vce(hc2)`,

$$\mathbf{u}_j = \frac{1}{\sqrt{1-h_{jj}}}(y_j - \mathbf{x}_j\mathbf{b})\mathbf{x}_j$$

where $q_c = 1$ and $h_{jj} = \mathbf{x}_j(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_j'$.

No instruments, `vce(hc3)`,

$$\mathbf{u}_j = \frac{1}{1-h_{jj}}(y_j - \mathbf{x}_j\mathbf{b})\mathbf{x}_j$$

where $q_c = 1$ and $h_{jj} = \mathbf{x}_j(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_j'$.

Instrumental variables,

$$\mathbf{u}_j = (y_j - \mathbf{x}_j\mathbf{b})\widehat{\mathbf{x}}_j$$

where q_c is given by its regression-like definition, and

$$\widehat{\mathbf{x}}_j' = \mathbf{P}\mathbf{z}_j'$$

where $\mathbf{P} = (\mathbf{X}'\mathbf{Z})(\mathbf{Z}'\mathbf{Z})^{-1}$.

Acknowledgments

The robust estimate of variance was first implemented in Stata by Mead Over of the Center for Global Development, Dean Jolliffe of the World Bank, and Andrew Foster of the Department of Economics at Brown University (Over, Jolliffe, and Foster 1996).

The history of regression is long and complicated: the books by Stigler (1986) and Hald (1998) are devoted largely to the story. Legendre published first on least squares in 1805. Gauss published later in 1809, but he had the idea earlier. Gauss, and especially Laplace, tied least squares to a normal errors assumption. The idea of the normal distribution can itself be traced back to De Moivre in 1733. Laplace discussed a variety of other estimation methods and error assumptions over his long career, while linear models long predate either innovation. Most of this work was linked to problems in astronomy and geodesy.

A second wave of ideas started when Galton used graphical and descriptive methods on data bearing on heredity to develop what he called regression. His term reflects the common phenomenon that characteristics of offspring are positively correlated with those of parents but with regression slope such that offspring "regress toward the mean". Galton's work was rather intuitive: contributions from Pearson, Edgeworth, Yule, and others introduced more formal machinery, developed related ideas on correlation, and extended application into the biological and social sciences. So most of the elements of regression as we know it were in place by 1900.

Pierre-Simon Laplace (1749–1827) was born in Normandy and was early recognized as a remarkable mathematician. He weathered a changing political climate well enough to rise to Minister of the Interior under Napoleon in 1799 (although only for 6 weeks) and to be made a Marquis by Louis XVIII in 1817. He made many contributions to mathematics and physics, his two main interests being theoretical astronomy and probability theory (including statistics). Laplace transforms are named for him.

Adrien-Marie Legendre (1752–1833) was born in Paris (or possibly in Toulouse) and educated in mathematics and physics. He worked in number theory, geometry, differential equations, calculus, function theory, applied mathematics, and geodesy. The Legendre polynomials are named for him. His main contribution to statistics is as one of the discoverers of least squares. He died in poverty, having refused to bow to political pressures.

Johann Carl Friedrich Gauss (1777–1855) was born in Braunschweig (Brunswick), now in Germany. He studied there and at Göttingen. His doctoral dissertation at the University of Helmstedt was a discussion of the fundamental theorem of algebra. He made many fundamental contributions to geometry, number theory, algebra, real analysis, differential equations, numerical analysis, statistics, astronomy, optics, geodesy, mechanics, and magnetism. An outstanding genius, Gauss worked mostly in isolation in Göttingen.

Francis Galton (1822–1911) was born in Birmingham, England, into a well-to-do family with many connections: he and Charles Darwin were first cousins. After an unsuccessful foray into medicine, he became independently wealthy at the death of his father. Galton traveled widely in Europe, the Middle East, and Africa, and became celebrated as an explorer and geographer. His pioneering work on weather maps helped in the identification of anticyclones, which he named. From about 1865, most of his work was centered on quantitative problems in biology, anthropology, and psychology. In a sense, Galton (re)invented regression, and he certainly named it. Galton also promoted the normal distribution, correlation approaches, and the use of median and selected quantiles as descriptive statistics. He was knighted in 1909.

Title

regress postestimation — Postestimation tools for regress

Description
Tests for violation of assumptions
Methods and formulas
Also see
Predictions
Variance inflation factors
Acknowledgments
DFBETA influence statistics
Measures of effect size
References

Description

The following postestimation commands are of special interest after `regress`:

Command	Description
`dfbeta`	DFBETA influence statistics
`estat hettest`	tests for heteroskedasticity
`estat imtest`	information matrix test
`estat ovtest`	Ramsey regression specification-error test for omitted variables
`estat szroeter`	Szroeter's rank test for heteroskedasticity
`estat vif`	variance inflation factors for the independent variables
`estat esize`	η^2 and ω^2 effect sizes

These commands are not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

Command	Description
contrast	contrasts and ANOVA-style joint tests of estimates
estat ic	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
estat summarize	summary statistics for the estimation sample
estat vce	variance–covariance matrix of the estimators (VCE)
estat (svy)	postestimation statistics for survey data
estimates	cataloging estimation results
forecast[1]	dynamic forecasts and simulations
hausman	Hausman's specification test
lincom	point estimates, standard errors, testing, and inference for linear combinations of coefficients
linktest	link test for model specification
lrtest[2]	likelihood-ratio test
margins	marginal means, predictive margins, marginal effects, and average marginal effects
marginsplot	graph the results from margins (profile plots, interaction plots, etc.)
nlcom	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
predict	predictions, residuals, influence statistics, and other diagnostic measures
predictnl	point estimates, standard errors, testing, and inference for generalized predictions
pwcompare	pairwise comparisons of estimates
suest	seemingly unrelated estimation
test	Wald tests of simple and composite linear hypotheses
testnl	Wald tests of nonlinear hypotheses

[1] forecast is not appropriate with mi or svy estimation results.

[2] lrtest is not appropriate with svy estimation results.

Predictions

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic]
```

statistic	Description
Main	
`xb`	linear prediction; the default
`residuals`	residuals
`score`	score; equivalent to `residuals`
`rstandard`	standardized residuals
`rstudent`	Studentized (jackknifed) residuals
`cooksd`	Cook's distance
`leverage` | `hat`	leverage (diagonal elements of hat matrix)
`pr(`*a*`,`*b*`)`	$\Pr(y_j \mid a < y_j < b)$
`e(`*a*`,`*b*`)`	$E(y_j \mid a < y_j < b)$
`ystar(`*a*`,`*b*`)`	$E(y_j^*)$, $y_j^* = \max\{a, \min(y_j, b)\}$
* `dfbeta(`*varname*`)`	DFBETA for *varname*
`stdp`	standard error of the linear prediction
`stdf`	standard error of the forecast
`stdr`	standard error of the residual
* `covratio`	COVRATIO
* `dfits`	DFITS
* `welsch`	Welsch distance

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

`rstandard`, `rstudent`, `cooksd`, `leverage`, `dfbeta()`, `stdf`, `stdr`, `covratio`, `dfits`, and `welsch` are not available if any `vce()` other than `vce(ols)` was specified with `regress`.

`xb`, `residuals`, `score`, and `stdp` are the only options allowed with `svy` estimation results.

where *a* and *b* may be numbers or variables; *a* missing ($a \geq .$) means $-\infty$, and *b* missing ($b \geq .$) means $+\infty$; see [U] 12.2.1 Missing values.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`xb`, the default, calculates the linear prediction.

`residuals` calculates the residuals.

`score` is equivalent to `residuals` in linear regression.

`rstandard` calculates the standardized residuals.

`rstudent` calculates the Studentized (jackknifed) residuals.

`cooksd` calculates the Cook's D influence statistic (Cook 1977).

`leverage` or `hat` calculates the diagonal elements of the projection ("hat") matrix.

`pr(`*a*`,`*b*`)` calculates $\Pr(a < \mathbf{x}_j\mathbf{b} + u_j < b)$, the probability that $y_j|\mathbf{x}_j$ would be observed in the interval (a, b).

a and *b* may be specified as numbers or variable names; *lb* and *ub* are variable names;
`pr(20,30)` calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < 30)$;
`pr(`*lb*`,`*ub*`)` calculates $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < ub)$; and
`pr(20,`*ub*`)` calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$.

a missing ($a \geq .$) means $-\infty$; `pr(.,30)` calculates $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$;
`pr(`*lb*`,30)` calculates $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$ in observations for which $lb \geq .$
and calculates $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < 30)$ elsewhere.

b missing ($b \geq .$) means $+\infty$; `pr(20,.)` calculates $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$;
`pr(20,`*ub*`)` calculates $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$ in observations for which $ub \geq .$
and calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$ elsewhere.

`e(`*a*`,`*b*`)` calculates $E(\mathbf{x}_j\mathbf{b} + u_j \mid a < \mathbf{x}_j\mathbf{b} + u_j < b)$, the expected value of $y_j|\mathbf{x}_j$ conditional on $y_j|\mathbf{x}_j$ being in the interval (a, b), meaning that $y_j|\mathbf{x}_j$ is truncated. *a* and *b* are specified as they are for `pr()`.

`ystar(`*a*`,`*b*`)` calculates $E(y_j^*)$, where $y_j^* = a$ if $\mathbf{x}_j\mathbf{b} + u_j \leq a$, $y_j^* = b$ if $\mathbf{x}_j\mathbf{b} + u_j \geq b$, and $y_j^* = \mathbf{x}_j\mathbf{b} + u_j$ otherwise, meaning that y_j^* is censored. *a* and *b* are specified as they are for `pr()`.

`dfbeta(`*varname*`)` calculates the DFBETA for *varname*, the difference between the regression coefficient when the jth observation is included and excluded, said difference being scaled by the estimated standard error of the coefficient. *varname* must have been included among the regressors in the previously fitted model. The calculation is automatically restricted to the estimation subsample.

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see *Methods and formulas*.

`stdr` calculates the standard error of the residuals.

`covratio` calculates COVRATIO (Belsley, Kuh, and Welsch 1980), a measure of the influence of the jth observation based on considering the effect on the variance–covariance matrix of the estimates. The calculation is automatically restricted to the estimation subsample.

`dfits` calculates DFITS (Welsch and Kuh 1977) and attempts to summarize the information in the leverage versus residual-squared plot into one statistic. The calculation is automatically restricted to the estimation subsample.

`welsch` calculates Welsch distance (Welsch 1982) and is a variation on `dfits`. The calculation is automatically restricted to the estimation subsample.

Remarks and examples for predict

Remarks are presented under the following headings:

Terminology
Fitted values and residuals
Prediction standard errors
Prediction with weighted data
Leverage statistics
Standardized and Studentized residuals
DFITS, Cook's Distance, and Welsch Distance
COVRATIO

Terminology

Many of these commands concern identifying influential data in linear regression. This is, unfortunately, a field that is dominated by jargon, codified and partially begun by Belsley, Kuh, and Welsch (1980). In the words of Chatterjee and Hadi (1986, 416), "Belsley, Kuh, and Welsch's book, *Regression Diagnostics*, was a very valuable contribution to the statistical literature, but it unleashed on an unsuspecting statistical community a computer speak (à la Orwell), the likes of which we have never seen." Things have only gotten worse since then. Chatterjee and Hadi's (1986, 1988) own attempts to clean up the jargon did not improve matters (see Hoaglin and Kempthorne [1986], Velleman [1986], and Welsch [1986]). We apologize for the jargon, and for our contribution to the jargon in the form of inelegant command names, we apologize most of all.

Model *sensitivity* refers to how estimates are affected by subsets of our data. Imagine data on y and x, and assume that the data are to be fit by the regression $y_i = \alpha + \beta x_i + \epsilon_i$. The regression estimates of α and β are a and b, respectively. Now imagine that the estimated a and b would be different if a small portion of the dataset, perhaps even one observation, were deleted. As a data analyst, you would like to think that you are summarizing tendencies that apply to all the data, but you have just been told that the model you fit is unduly influenced by one point or just a few points and that, as a matter of fact, there is another model that applies to the rest of the data—a model that you have ignored. The search for subsets of the data that, if deleted, would change the results markedly is a predominant theme of this entry.

There are three key issues in identifying model sensitivity to individual observations, which go by the names *residuals*, *leverage*, and *influence*. In our $y_i = a + bx_i + e_i$ regression, the residuals are, of course, e_i—they reveal how much our fitted value $\widehat{y}_i = a + bx_i$ differs from the observed y_i. A point (x_i, y_i) with a corresponding large residual is called an outlier. Say that you are interested in outliers because you somehow think that such points will exert undue influence on your estimates. Your feelings are generally right, but there are exceptions. A point might have a huge residual and yet not affect the estimated b at all. Nevertheless, studying observations with large residuals almost always pays off.

(x_i, y_i) can be an outlier in another way—just as y_i can be far from $\widehat{y}_i$, x_i can be far from the center of mass of the other x's. Such an "outlier" should interest you just as much as the more traditional outliers. Picture a scatterplot of y against x with thousands of points in some sort of mass at the lower left of the graph and one point at the upper right of the graph. Now run a regression line through the points—the regression line will come close to the point at the upper right of the graph and may in fact, go through it. That is, this isolated point will not appear as an outlier as measured by residuals because its residual will be small. Yet this point might have a dramatic effect on our resulting estimates in the sense that, were you to delete the point, the estimates would change markedly. Such a point is said to have high leverage. Just as with traditional outliers, a high leverage point does not necessarily have an undue effect on regression estimates, but if it does not, it is more the exception than the rule.

Now all this is a most unsatisfactory state of affairs. Points with large residuals may, but need not, have a large effect on our results, and points with small residuals may still have a large effect. Points with high leverage may, but need not, have a large effect on our results, and points with low leverage may still have a large effect. Can you not identify the influential points and simply have the computer list them for you? You can, but you will have to define what you mean by "influential".

"Influential" is defined with respect to some statistic. For instance, you might ask which points in your data have a large effect on your estimated a, which points have a large effect on your estimated b, which points have a large effect on your estimated standard error of b, and so on, but do not be surprised when the answers to these questions are different. In any case, obtaining such measures is not difficult—all you have to do is fit the regression excluding each observation one at a time and record the statistic of interest which, in the day of the modern computer, is not too onerous. Moreover, you can save considerable computer time by doing algebra ahead of time and working out formulas that will calculate the same answers as if you ran each of the regressions. (Ignore the question of pairs of observations that, together, exert undue influence, and triples, and so on, which remains largely unsolved and for which the brute force fit-every-possible-regression procedure is not a viable alternative.)

Fitted values and residuals

Typing `predict` *newvar* with no options creates *newvar* containing the fitted values. Typing `predict` *newvar*`, resid` creates *newvar* containing the residuals.

▷ Example 1

Continuing with example 1 from [R] **regress**, we wish to fit the following model:

$$\texttt{mpg} = \beta_0 + \beta_1\texttt{weight} + \beta_2\texttt{foreign} + \epsilon$$

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress mpg weight foreign
```

Source	SS	df	MS	Number of obs =	74
				F(2, 71) =	69.75
Model	1619.2877	2	809.643849	Prob > F =	0.0000
Residual	824.171761	71	11.608053	R-squared =	0.6627
				Adj R-squared =	0.6532
Total	2443.45946	73	33.4720474	Root MSE =	3.4071

mpg	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
weight	-.0065879	.0006371	-10.34	0.000	-.0078583	-.0053175
foreign	-1.650029	1.075994	-1.53	0.130	-3.7955	.4954422
_cons	41.6797	2.165547	19.25	0.000	37.36172	45.99768

That done, we can now obtain the predicted values from the regression. We will store them in a new variable called `pmpg` by typing `predict pmpg`. Because `predict` produces no output, we will follow that by summarizing our predicted and observed values.

```
. predict pmpg
(option xb assumed; fitted values)
. summarize pmpg mpg
```

Variable	Obs	Mean	Std. Dev.	Min	Max
pmpg	74	21.2973	4.709779	9.794333	29.82151
mpg	74	21.2973	5.785503	12	41

◁

▷ Example 2: Out-of-sample predictions

We can just as easily obtain predicted values from the model by using a wholly different dataset from the one on which the model was fit. The only requirement is that the data have the necessary variables, which here are `weight` and `foreign`.

Using the data on two new cars (the Pontiac Sunbird and the Volvo 260) from the `newautos.dta` dataset, we can obtain out-of-sample predictions (or forecasts) by typing

```
. use http://www.stata-press.com/data/r13/newautos, clear
(New Automobile Models)
. predict pmpg
(option xb assumed; fitted values)
. list, divider
```

	make	weight	foreign	pmpg
1.	Pont. Sunbird	2690	Domestic	23.95829
2.	Volvo 260	3170	Foreign	19.14607

The Pontiac Sunbird has a predicted mileage rating of 23.96 mpg, whereas the Volvo 260 has a predicted rating of 19.15 mpg. In comparison, the actual mileage ratings are 24 for the Pontiac and 17 for the Volvo.

◁

Prediction standard errors

`predict` can calculate the standard error of the forecast (`stdf` option), the standard error of the prediction (`stdp` option), and the standard error of the residual (`stdr` option). It is easy to confuse `stdf` and `stdp` because both are often called the prediction error. Consider the prediction $\widehat{y}_j = \mathbf{x}_j\mathbf{b}$, where $\mathbf{b}$ is the estimated coefficient (column) vector and $\mathbf{x}_j$ is a (row) vector of independent variables for which you want the prediction. First, $\widehat{y}_j$ has a variance due to the variance of the estimated coefficient vector $\mathbf{b}$,

$$\mathrm{Var}(\widehat{y}_j) = \mathrm{Var}(\mathbf{x}_j\mathbf{b}) = s^2 h_j$$

where $h_j = \mathbf{x}_j(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_j'$ and s^2 is the mean squared error of the regression. Do not panic over the algebra—just remember that $\mathrm{Var}(\widehat{y}_j) = s^2 h_j$, whatever s^2 and h_j are. `stdp` calculates this quantity. This is the error in the prediction due to the uncertainty about $\mathbf{b}$.

If you are about to hand this number out as your forecast, however, there is another error. According to your model, the true value of y_j is given by

$$y_j = \mathbf{x}_j\mathbf{b} + \epsilon_j = \widehat{y}_j + \epsilon_j$$

and thus the $\mathrm{Var}(y_j) = \mathrm{Var}(\widehat{y}_j) + \mathrm{Var}(\epsilon_j) = s^2 h_j + s^2$, which is the square of `stdf`. `stdf`, then, is the sum of the error in the prediction plus the residual error.

`stdr` has to do with an analysis-of-variance decomposition of s^2, the estimated variance of y. The standard error of the prediction is $s^2 h_j$, and therefore $s^2 h_j + s^2(1 - h_j) = s^2$ decomposes s^2 into the prediction and residual variances.

▷ Example 3: standard error of the forecast

Returning to our model of `mpg` on `weight` and `foreign`, we previously predicted the mileage rating for the Pontiac Sunbird and Volvo 260 as 23.96 and 19.15 mpg, respectively. We now want to put a standard error around our forecast. Remember, the data for these two cars were in `newautos.dta`:

```
. use http://www.stata-press.com/data/r13/newautos, clear
(New Automobile Models)
. predict pmpg
(option xb assumed; fitted values)
. predict se_pmpg, stdf
. list, divider
```

	make	weight	foreign	pmpg	se_pmpg
1.	Pont. Sunbird	2690	Domestic	23.95829	3.462791
2.	Volvo 260	3170	Foreign	19.14607	3.525875

Thus an approximate 95% confidence interval for the mileage rating of the Volvo 260 is $19.15 \pm 2 \cdot 3.53 = [\,12.09, 26.21\,]$.

◁

Prediction with weighted data

`predict` can be used after frequency-weighted (`fweight`) estimation, just as it is used after unweighted estimation. The technical note below concerns the use of `predict` after analytically weighted (`aweight`) estimation.

❑ Technical note

After analytically weighted estimation, `predict` is willing to calculate only the prediction (no options), residual (`residual` option), standard error of the prediction (`stdp` option), and diagonal elements of the projection matrix (`hat` option). Moreover, the results produced by `hat` need to be adjusted, as will be described. For analytically weighted estimation, the standard error of the forecast and residuals, the standardized and Studentized residuals, and Cook's D are not statistically well-defined concepts.

❑

Leverage statistics

In addition to providing fitted values and the associated standard errors, the `predict` command can also be used to generate various statistics used to detect the influence of individual observations. This section provides a brief introduction to leverage (hat) statistics, and some of the following subsections discuss other influence statistics produced by `predict`.

▷ Example 4: diagonal elements of projection matrix

The diagonal elements of the projection matrix, obtained by the `hat` option, are a measure of distance in explanatory variable space. `leverage` is a synonym for `hat`.

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. regress mpg weight foreign
  (output omitted)
. predict xdist, hat
. summarize xdist, detail
```

Leverage

Percentiles		Smallest		
1%	.0192325	.0192325		
5%	.0192686	.0192366		
10%	.0193448	.019241	Obs	74
25%	.0220291	.0192686	Sum of Wgt.	74
50%	.0383797		Mean	.0405405
		Largest	Std. Dev.	.0207624
75%	.0494002	.0880814		
90%	.0693432	.099715	Variance	.0004311
95%	.0880814	.099715	Skewness	1.159745
99%	.1003283	.1003283	Kurtosis	4.083313

Some 5% of our sample has an `xdist` measure in excess of 0.08. Let's force them to reveal their identities:

```
. list foreign make mpg if xdist>.08, divider
```

	foreign	make	mpg
24.	Domestic	Ford Fiesta	28
26.	Domestic	Linc. Continental	12
27.	Domestic	Linc. Mark V	12
43.	Domestic	Plym. Champ	34
64.	Foreign	Peugeot 604	14

To understand why these cars are on this list, we must remember that the explanatory variables in our model are `weight` and `foreign` and that `xdist` measures distance in this metric. The Ford Fiesta and the Plymouth Champ are the two lightest domestic cars in our data. The Lincolns are the two heaviest domestic cars, and the Peugeot is the heaviest foreign car. ◁

See `lvr2plot` in [R] **regress postestimation diagnostic plots** for information on a leverage-versus-squared-residual plot.

Standardized and Studentized residuals

The terms standardized and Studentized residuals have meant different things to different authors. In Stata, `predict` defines the standardized residual as $\widehat{e}_i = e_i/(s\sqrt{1-h_i})$ and the Studentized residual as $r_i = e_i/(s_{(i)}\sqrt{1-h_i})$, where $s_{(i)}$ is the root mean squared error of a regression with the ith observation removed. Stata's definition of the Studentized residual is the same as the one given in Bollen and Jackman (1990, 264) and is what Chatterjee and Hadi (1988, 74) call the "externally Studentized" residual. Stata's "standardized" residual is the same as what Chatterjee and Hadi (1988, 74) call the "internally Studentized" residual.

Standardized and Studentized residuals are attempts to adjust residuals for their standard errors. Although the ϵ_i theoretical residuals are homoskedastic by assumption (that is, they all have the same variance), the calculated e_i are not. In fact,

$$\mathrm{Var}(e_i) = \sigma^2(1-h_i)$$

where h_i are the leverage measures obtained from the diagonal elements of hat matrix. Thus observations with the greatest leverage have corresponding residuals with the smallest variance.

Standardized residuals use the root mean squared error of the regression for σ. Studentized residuals use the root mean squared error of a regression omitting the observation in question for σ. In general, Studentized residuals are preferable to standardized residuals for purposes of outlier identification. Studentized residuals can be interpreted as the t statistic for testing the significance of a dummy variable equal to 1 in the observation in question and 0 elsewhere (Belsley, Kuh, and Welsch 1980). Such a dummy variable would effectively absorb the observation and so remove its influence in determining the other coefficients in the model. Caution must be exercised here, however, because of the simultaneous testing problem. You cannot simply list the residuals that would be individually significant at the 5% level—their joint significance would be far less (their joint significance *level* would be far greater).

▷ Example 5: standardized and Studentized residuals

In the *Terminology* section of *Remarks and examples for predict*, we distinguished residuals from leverage and speculated on the impact of an observation with a small residual but large leverage. If we adjust the residuals for their standard errors, however, the adjusted residual would be (relatively) larger and perhaps large enough so that we could simply examine the adjusted residuals. Taking our `price` on `weight` and `foreign##c.mpg` model from example 1 of [R] **regress postestimation diagnostic plots**, we can obtain the in-sample standardized and Studentized residuals by typing

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
. predict esta if e(sample), rstandard
. predict estu if e(sample), rstudent
```

In the *lvr2plot* section of [R] **regress postestimation diagnostic plots**, we discovered that the VW Diesel has the highest leverage in our data, but a corresponding small residual. The standardized and Studentized residuals for the VW Diesel are

```
. list make price esta estu if make=="VW Diesel"
```

	make	price	esta	estu
71.	VW Diesel	5,397	.6142691	.6114758

The Studentized residual of 0.611 can be interpreted as the t statistic for including a dummy variable for VW Diesel in our regression. Such a variable would not be significant.

◁

DFITS, Cook's Distance, and Welsch Distance

DFITS (Welsch and Kuh 1977), Cook's Distance (Cook 1977), and Welsch Distance (Welsch 1982) are three attempts to summarize the information in the leverage versus residual-squared plot into one statistic. That is, the goal is to create an index that is affected by the size of the residuals—outliers—and the size of h_i—leverage. Viewed mechanically, one way to write DFITS (Bollen and Jackman 1990, 265) is

$$\text{DFITS}_i = r_i\sqrt{\frac{h_i}{1-h_i}}$$

where r_i are the Studentized residuals. Thus large residuals increase the value of DFITS, as do large values of h_i. Viewed more traditionally, DFITS is a scaled difference between predicted values for the ith case when the regression is fit with and without the ith observation, hence the name.

The mechanical relationship between DFITS and Cook's Distance, D_i (Bollen and Jackman 1990, 266), is

$$D_i = \frac{1}{k}\frac{s_{(i)}^2}{s^2}\text{DFITS}_i^2$$

where k is the number of variables (including the constant) in the regression, s is the root mean squared error of the regression, and $s_{(i)}$ is the root mean squared error when the ith observation is omitted. Viewed more traditionally, D_i is a scaled measure of the distance between the coefficient vectors when the ith observation is omitted.

The mechanical relationship between DFITS and Welsch's Distance, W_i (Chatterjee and Hadi 1988, 123), is

$$W_i = \text{DFITS}_i\sqrt{\frac{n-1}{1-h_i}}$$

The interpretation of W_i is more difficult, as it is based on the empirical influence curve. Although DFITS and Cook's distance are similar, the Welsch distance measure includes another normalization by leverage.

Belsley, Kuh, and Welsch (1980, 28) suggest that DFITS values greater than $2\sqrt{k/n}$ deserve more investigation, and so values of Cook's distance greater than $4/n$ should also be examined (Bollen and Jackman 1990, 265–266). Through similar logic, the cutoff for Welsch distance is approximately $3\sqrt{k}$ (Chatterjee and Hadi 1988, 124).

Example 6: DFITS influence measure

Continuing with our model of `price` on `weight` and `foreign##c.mpg`, we can obtain the DFITS influence measure:

```
. predict e if e(sample), resid
. predict dfits, dfits
```

We did not specify `if e(sample)` in computing the DFITS statistic. DFITS is available only over the estimation sample, so specifying `if e(sample)` would have been redundant. It would have done no harm, but it would not have changed the results.

Our model has $k = 5$ independent variables (k includes the constant) and $n = 74$ observations; following the $2\sqrt{k/n}$ cutoff advice, we type

```
. list make price e dfits if abs(dfits) > 2*sqrt(5/74), divider
```

	make	price	e	dfits
12.	Cad. Eldorado	14,500	7271.96	.9564455
13.	Cad. Seville	15,906	5036.348	1.356619
24.	Ford Fiesta	4,389	3164.872	.5724172
27.	Linc. Mark V	13,594	3109.193	.5200413
28.	Linc. Versailles	13,466	6560.912	.8760136
42.	Plym. Arrow	4,647	-3312.968	-.9384231

We calculate Cook's distance and list the observations greater than the suggested $4/n$ cutoff:

```
. predict cooksd if e(sample), cooksd
. list make price e cooksd if cooksd > 4/74, divider
```

	make	price	e	cooksd
12.	Cad. Eldorado	14,500	7271.96	.1492676
13.	Cad. Seville	15,906	5036.348	.3328515
24.	Ford Fiesta	4,389	3164.872	.0638815
28.	Linc. Versailles	13,466	6560.912	.1308004
42.	Plym. Arrow	4,647	-3312.968	.1700736

Here we used `if e(sample)` because Cook's distance is not restricted to the estimation sample by default. It is worth comparing this list with the preceding one.

Finally, we use Welsch distance and the suggested $3\sqrt{k}$ cutoff:

```
. predict wd, welsch
. list make price e wd if abs(wd) > 3*sqrt(5), divider
```

	make	price	e	wd
12.	Cad. Eldorado	14,500	7271.96	8.394372
13.	Cad. Seville	15,906	5036.348	12.81125
28.	Linc. Versailles	13,466	6560.912	7.703005
42.	Plym. Arrow	4,647	-3312.968	-8.981481

Here we did not need to specify `if e(sample)` because `welsch` automatically restricts the prediction to the estimation sample.

◁

COVRATIO

COVRATIO (Belsley, Kuh, and Welsch 1980) measures the influence of the ith observation by considering the effect on the variance–covariance matrix of the estimates. The measure is the ratio of the determinants of the covariances matrix, with and without the ith observation. The resulting formula is

$$\text{COVRATIO}_i = \frac{1}{1-h_i}\left(\frac{n-k-\widehat{e}_i^2}{n-k-1}\right)^k$$

where $\widehat{e}_i$ is the standardized residual.

For noninfluential observations, the value of COVRATIO is approximately 1. Large values of the residuals or large values of leverage will cause deviations from 1, although if both are large, COVRATIO may tend back toward 1 and therefore not identify such observations (Chatterjee and Hadi 1988, 139).

Belsley, Kuh, and Welsch (1980) suggest that observations for which

$$|\text{COVRATIO}_i - 1| \geq \frac{3k}{n}$$

are worthy of further examination.

▷ Example 7: COVRATIO influence measure

Using our model of `price` on `weight` and `foreign##c.mpg`, we can obtain the COVRATIO measure and list the observations outside the suggested cutoff by typing

```
. predict covr, covratio
. list make price e covr if abs(covr-1) >= 3*5/74, divider
```

	make	price	e	covr
12.	Cad. Eldorado	14,500	7271.96	.3814242
13.	Cad. Seville	15,906	5036.348	.7386969
28.	Linc. Versailles	13,466	6560.912	.4761695
43.	Plym. Champ	4,425	1621.747	1.27782
53.	Audi 5000	9,690	591.2883	1.206842
57.	Datsun 210	4,589	19.81829	1.284801
64.	Peugeot 604	12,990	1037.184	1.348219
66.	Subaru	3,798	-909.5894	1.264677
71.	VW Diesel	5,397	999.7209	1.630653
74.	Volvo 260	11,995	1327.668	1.211888

The `covratio` option automatically restricts the prediction to the estimation sample.

◁

DFBETA influence statistics

Syntax for dfbeta

```
dfbeta [ indepvar [ indepvar [...] ] ] [ , stub(name) ]
```

Menu for dfbeta

Statistics > Linear models and related > Regression diagnostics > DFBETAs

Description for dfbeta

`dfbeta` will calculate one, more than one, or all the DFBETAs after `regress`. Although `predict` will also calculate DFBETAs, `predict` can do this for only one variable at a time. `dfbeta` is a convenience tool for those who want to calculate DFBETAs for multiple variables. The names for the new variables created are chosen automatically and begin with the letters `_dfbeta_`.

Option for dfbeta

`stub(`*name*`)` specifies the leading characters `dfbeta` uses to name the new variables to be generated. The default is `stub(_dfbeta_)`.

Remarks and examples for dfbeta

DFBETAs are perhaps the most direct influence measure of interest to model builders. DFBETAs focus on one coefficient and measure the difference between the regression coefficient when the ith observation is included and excluded, the difference being scaled by the estimated standard error of the coefficient. Belsley, Kuh, and Welsch (1980, 28) suggest observations with $|\text{DFBETA}_i| > 2/\sqrt{n}$ as deserving special attention, but it is also common practice to use 1 (Bollen and Jackman 1990, 267), meaning that the observation shifted the estimate at least one standard error.

▷ Example 8: DFBETAs influence measure; the dfbeta() option

Using our model of `price` on `weight` and `foreign##c.mpg`, let's first ask which observations have the greatest impact on the determination of the coefficient on `1.foreign`. We will use the suggested $2/\sqrt{n}$ cutoff:

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
```

```
. sort foreign make
. predict dfor, dfbeta(1.foreign)
. list make price foreign dfor if abs(dfor) > 2/sqrt(74), divider
```

	make	price	foreign	dfor
12.	Cad. Eldorado	14,500	Domestic	-.5290519
13.	Cad. Seville	15,906	Domestic	.8243419
28.	Linc. Versailles	13,466	Domestic	-.5283729
42.	Plym. Arrow	4,647	Domestic	-.6622424
43.	Plym. Champ	4,425	Domestic	.2371104
64.	Peugeot 604	12,990	Foreign	.2552032
69.	Toyota Corona	5,719	Foreign	-.256431

The Cadillac Seville shifted the coefficient on `1.foreign` 0.82 standard deviations!

Now let us ask which observations have the greatest effect on the `mpg` coefficient:

```
. predict dmpg, dfbeta(mpg)
. list make price mpg dmpg if abs(dmpg) > 2/sqrt(74), divider
```

	make	price	mpg	dmpg
12.	Cad. Eldorado	14,500	14	-.5970351
13.	Cad. Seville	15,906	21	1.134269
28.	Linc. Versailles	13,466	14	-.6069287
42.	Plym. Arrow	4,647	28	-.8925859
43.	Plym. Champ	4,425	34	.3186909

Once again we see the Cadillac Seville heading the list, indicating that our regression results may be dominated by this one car.

◁

▷ Example 9: DFBETAs influence measure; the dfbeta command

We can use `predict, dfbeta()` or the `dfbeta` command to generate the DFBETAs. `dfbeta` makes up names for the new variables automatically and, without arguments, generates the DFBETAs for all the variables in the regression:

```
. dfbeta
                        _dfbeta_1: dfbeta(weight)
                        _dfbeta_2: dfbeta(1.foreign)
                        _dfbeta_3: dfbeta(mpg)
                        _dfbeta_4: dfbeta(1.foreign#c.mpg)
```

`dfbeta` created four new variables in our dataset: `_dfbeta_1`, containing the DFBETAs for `weight`; `_dfbeta_2`, containing the DFBETAs for `mpg`; and so on. Had we wanted only the DFBETAs for `mpg` and `weight`, we might have typed

```
. dfbeta mpg weight
                        _dfbeta_5: dfbeta(weight)
                        _dfbeta_6: dfbeta(mpg)
```

In the example above, we typed `dfbeta mpg weight` instead of `dfbeta`; if we had typed `dfbeta` followed by `dfbeta mpg weight`, here is what would have happened:

```
. dfbeta
                          _dfbeta_7: dfbeta(weight)
                          _dfbeta_8: dfbeta(1.foreign)
                          _dfbeta_9: dfbeta(mpg)
                         _dfbeta_10: dfbeta(1.foreign#c.mpg)
. dfbeta mpg weight
                         _dfbeta_11: dfbeta(weight)
                         _dfbeta_12: dfbeta(mpg)
```

`dfbeta` would have made up different names for the new variables. `dfbeta` never replaces existing variables—it instead makes up a different name, so we need to pay attention to `dfbeta`'s output. ◁

Tests for violation of assumptions

Syntax for estat hettest

`estat hettest` [*varlist*] [`, rhs` [`normal`|`iid`|`fstat`] `mtest`[`(`*spec*`)`]]

Menu for estat

Statistics > Postestimation > Reports and statistics

Description for estat hettest

`estat hettest` performs three versions of the Breusch–Pagan (1979) and Cook–Weisberg (1983) test for heteroskedasticity. All three versions of this test present evidence against the null hypothesis that $\mathbf{t} = \mathbf{0}$ in $\mathrm{Var}(e) = \sigma^2\exp(\mathbf{zt})$. In the `normal` version, performed by default, the null hypothesis also includes the assumption that the regression disturbances are independent-normal draws with variance σ^2. The normality assumption is dropped from the null hypothesis in the `iid` and `fstat` versions, which respectively produce the score and F tests discussed in *Methods and formulas*. If *varlist* is not specified, the fitted values are used for $\mathbf{z}$. If *varlist* or the `rhs` option is specified, the variables specified are used for $\mathbf{z}$.

Options for estat hettest

`rhs` specifies that tests for heteroskedasticity be performed for the right-hand-side (explanatory) variables of the fitted regression model. The `rhs` option may be combined with a *varlist*.

`normal`, the default, causes `estat hettest` to compute the original Breusch–Pagan/Cook–Weisberg test, which assumes that the regression disturbances are normally distributed.

`iid` causes `estat hettest` to compute the $N * R^2$ version of the score test that drops the normality assumption.

`fstat` causes `estat hettest` to compute the F-statistic version that drops the normality assumption.

`mtest`[`(`*spec*`)`] specifies that multiple testing be performed. The argument specifies how p-values are adjusted. The following specifications, *spec*, are supported:

`bonferroni`	Bonferroni's multiple testing adjustment
`holm`	Holm's multiple testing adjustment
`sidak`	Šidák's multiple testing adjustment
`noadjust`	no adjustment is made for multiple testing

`mtest` may be specified without an argument. This is equivalent to specifying `mtest(noadjust)`; that is, tests for the individual variables should be performed with unadjusted p-values. By default, `estat hettest` does not perform multiple testing. `mtest` may not be specified with `iid` or `fstat`.

Syntax for estat imtest

```
estat imtest [, preserve white]
```

Menu for estat

Statistics > Postestimation > Reports and statistics

Description for estat imtest

`estat imtest` performs an information matrix test for the regression model and an orthogonal decomposition into tests for heteroskedasticity, skewness, and kurtosis due to Cameron and Trivedi (1990); White's test for homoskedasticity against unrestricted forms of heteroskedasticity (1980) is available as an option. White's test is usually similar to the first term of the Cameron–Trivedi decomposition.

Options for estat imtest

`preserve` specifies that the data in memory be preserved, all variables and cases that are not needed in the calculations be dropped, and at the conclusion the original data be restored. This option is costly for large datasets. However, because `estat imtest` has to perform an auxiliary regression on $k(k+1)/2$ temporary variables, where k is the number of regressors, it may not be able to perform the test otherwise.

`white` specifies that White's original heteroskedasticity test also be performed.

Syntax for estat ovtest

```
estat ovtest [, rhs]
```

Menu for estat

Statistics > Postestimation > Reports and statistics

Description for estat ovtest

`estat ovtest` performs two versions of the Ramsey (1969) regression specification-error test (RESET) for omitted variables. This test amounts to fitting $y = \mathbf{xb} + \mathbf{zt} + u$ and then testing $\mathbf{t} = \mathbf{0}$. If the `rhs` option is not specified, powers of the fitted values are used for $\mathbf{z}$. If `rhs` is specified, powers of the individual elements of $\mathbf{x}$ are used.

Option for estat ovtest

`rhs` specifies that powers of the right-hand-side (explanatory) variables be used in the test rather than powers of the fitted values.

Syntax for estat szroeter

`estat szroeter` [*varlist*] [`, rhs mtest(`*spec*`)`]

Either *varlist* or `rhs` must be specified.

Menu for estat

Statistics > Postestimation > Reports and statistics

Description for estat szroeter

`estat szroeter` performs Szroeter's rank test for heteroskedasticity for each of the variables in *varlist* or for the explanatory variables of the regression if `rhs` is specified.

Options for estat szroeter

`rhs` specifies that tests for heteroskedasticity be performed for the right-hand-side (explanatory) variables of the fitted regression model. Option `rhs` may be combined with a *varlist*.

`mtest(`*spec*`)` specifies that multiple testing be performed. The argument specifies how p-values are adjusted. The following specifications, *spec*, are supported:

`bonferroni`	Bonferroni's multiple testing adjustment
`holm`	Holm's multiple testing adjustment
`sidak`	Šidák's multiple testing adjustment
`noadjust`	no adjustment is made for multiple testing

`estat szroeter` always performs multiple testing. By default, it does not adjust the p-values.

Remarks and examples for estat hettest, estat imtest, estat ovtest, and estat szroeter

We introduce some regression diagnostic commands that are designed to test for certain violations that `rvfplot` (see [R] **regress postestimation diagnostic plots**) less formally attempts to detect. `estat ovtest` provides Ramsey's test for omitted variables—a pattern in the residuals. `estat hettest` provides a test for heteroskedasticity—the increasing or decreasing variation in the residuals with fitted values, with respect to the explanatory variables, or with respect to yet other variables. The score test implemented in `estat hettest` (Breusch and Pagan 1979; Cook and Weisberg 1983) performs a score test of the null hypothesis that $b = 0$ against the alternative hypothesis of multiplicative heteroskedasticity. `estat szroeter` provides a rank test for heteroskedasticity, which is an alternative to the score test computed by `estat hettest`. Finally, `estat imtest` computes an information matrix test, including an orthogonal decomposition into tests for heteroskedasticity, skewness, and kurtosis (Cameron and Trivedi 1990). The heteroskedasticity test computed by `estat imtest` is similar to the general test for heteroskedasticity that was proposed by White (1980). Cameron and Trivedi (2010, chap. 3) discuss most of these tests and provides more examples.

▷ Example 10: estat ovtest, estat hettest, estat szroeter, and estat imtest

We use our model of `price` on `weight` and `foreign##c.mpg`.

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
. estat ovtest
Ramsey RESET test using powers of the fitted values of price
       Ho:  model has no omitted variables
                  F(3, 66) =      7.77
                  Prob > F =      0.0002
. estat hettest
Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
         Ho: Constant variance
         Variables: fitted values of price
         chi2(1)      =     6.50
         Prob > chi2  =   0.0108
```

Testing for heteroskedasticity in the right-hand-side variables is requested by specifying the `rhs` option. By specifying the `mtest(bonferroni)` option, we request that tests be conducted for each of the variables, with a Bonferroni adjustment for the p-values to accommodate our testing multiple hypotheses.

```
. estat hettest, rhs mtest(bonf)

Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
         Ho: Constant variance

------------------------------------------------------------
    Variable |       chi2   df       p
-------------+----------------------------------------------
      weight |      15.24    1   0.0004 #
     foreign |
    Foreign |       6.15    1   0.0525 #
         mpg |       9.04    1   0.0106 #
     foreign#|
       c.mpg |
    Foreign |       6.02    1   0.0566 #
-------------+----------------------------------------------
simultaneous |      15.60    4   0.0036
------------------------------------------------------------
          # Bonferroni-adjusted p-values

. estat szroeter, rhs mtest(holm)

Szroeter's test for homoskedasticity
    Ho: variance constant
    Ha: variance monotonic in variable

------------------------------------------------------------
    Variable |       chi2   df       p
-------------+----------------------------------------------
      weight |      17.07    1   0.0001 #
     foreign |
    Foreign |       6.15    1   0.0131 #
         mpg |      11.45    1   0.0021 #
     foreign#|
       c.mpg |
    Foreign |       6.17    1   0.0260 #
------------------------------------------------------------
                # Holm-adjusted p-values
```

Finally, we request the information matrix test, which is a conditional moments test with second-, third-, and fourth-order moment conditions.

```
. estat imtest

Cameron & Trivedi's decomposition of IM-test

---------------------------------------------------
              Source |       chi2     df       p
---------------------+-----------------------------
  Heteroskedasticity |      18.86     10    0.0420
            Skewness |      11.69      4    0.0198
            Kurtosis |       2.33      1    0.1273
---------------------+-----------------------------
               Total |      32.87     15    0.0049
---------------------------------------------------
```

We find evidence for omitted variables, heteroskedasticity, and nonnormal skewness.

So, why bother with the various graphical commands when the tests seem so much easier to interpret? In part, it is a matter of taste: both are designed to uncover the same problem, and both are, in fact, going about it in similar ways. One is based on a formal calculation, whereas the other is based on personal judgment in evaluating a graph. On the other hand, the tests are seeking evidence of specific problems, whereas judgment is more general. The careful analyst will use both.

We performed the omitted-variable test first. Omitted variables are a more serious problem than heteroskedasticity or the violations of higher moment conditions tested by `estat imtest`. If this

were not a manual, having found evidence of omitted variables, we would never have run the `estat hettest`, `estat szroeter`, and `estat imtest` commands, at least not until we solved the omitted-variable problem.

◁

❑ Technical note

`estat ovtest` and `estat hettest` both perform two flavors of their respective tests. By default, `estat ovtest` looks for evidence of omitted variables by fitting the original model augmented by $\widehat{y}^2$, $\widehat{y}^3$, and $\widehat{y}^4$, which are the fitted values from the original model. Under the assumption of no misspecification, the coefficients on the powers of the fitted values will be zero. With the `rhs` option, `estat ovtest` instead augments the original model with powers (second through fourth) of the explanatory variables (except for dummy variables).

`estat hettest`, by default, looks for heteroskedasticity by modeling the variance as a function of the fitted values. If, however, we specify a variable or variables, the variance will be modeled as a function of the specified variables. In our example, if we had, a priori, some reason to suspect heteroskedasticity and that the heteroskedasticity is a function of a car's weight, then using a test that focuses on weight would be more powerful than the more general tests such as White's test or the first term in the Cameron–Trivedi decomposition test.

`estat hettest`, by default, computes the original Breusch–Pagan/Cook–Weisberg test, which includes the assumption of normally distributed errors. Koenker (1981) derived an $N * R^2$ version of this test that drops the normality assumption. Wooldridge (2013) gives an F-statistic version that does not require the normality assumption.

❑

Stored results for estat hettest, estat imtest, and estat ovtest

`estat hettest` stores the following results for the (multivariate) score test in `r()`:

Scalars

`r(chi2)`	χ^2 test statistic
`r(df)`	#df for the asymptotic χ^2 distribution under H_0
`r(p)`	p-value

`estat hettest, fstat` stores results for the (multivariate) score test in `r()`:

Scalars

`r(F)`	test statistic
`r(df_m)`	#df of the test for the F distribution under H_0
`r(df_r)`	#df of the residuals for the F distribution under H_0
`r(p)`	p-value

`estat hettest` (if `mtest` is specified) and `estat szroeter` store the following in `r()`:

Matrices

`r(mtest)`	a matrix of test results, with rows corresponding to the univariate tests
	`mtest[.,1]` χ^2 test statistic
	`mtest[.,2]` #df
	`mtest[.,3]` unadjusted p-value
	`mtest[.,4]` adjusted p-value (if an `mtest()` adjustment method is specified)

Macros

`r(mtmethod)`	adjustment method for p-values

`estat imtest` stores the following in `r()`:

Scalars

`r(chi2_t)`	IM-test statistic $\left(=$ `r(chi2_h)` $+$ `r(chi2_s)` $+$ `r(chi2_k)`$\right)$
`r(df_t)`	df for limiting χ^2 distribution under H_0 $\left(=$ `r(df_h)` $+$ `r(df_s)` $+$ `r(df_k)`$\right)$
`r(chi2_h)`	heteroskedasticity test statistic
`r(df_h)`	df for limiting χ^2 distribution under H_0
`r(chi2_s)`	skewness test statistic
`r(df_s)`	df for limiting χ^2 distribution under H_0
`r(chi2_k)`	kurtosis test statistic
`r(df_k)`	df for limiting χ^2 distribution under H_0
`r(chi2_w)`	White's heteroskedasticity test (if `white` specified)
`r(df_w)`	df for limiting χ^2 distribution under H_0

`estat ovtest` stores the following in `r()`:

Scalars

`r(p)`	two-sided p-value
`r(F)`	F statistic
`r(df)`	degrees of freedom
`r(df_r)`	residual degrees of freedom

Variance inflation factors

Syntax for estat vif

```
estat vif [ , uncentered ]
```

Menu for estat

Statistics > Postestimation > Reports and statistics

Description for estat vif

`estat vif` calculates the centered or uncentered variance inflation factors (VIFs) for the independent variables specified in a linear regression model.

Option for estat vif

`uncentered` requests that the computation of the uncentered variance inflation factors. This option is often used to detect the collinearity of the regressors with the constant. `estat vif, uncentered` may be used after regression models fit without the constant term.

Remarks and examples for estat vif

Problems arise in regression when the predictors are highly correlated. In this situation, there may be a significant change in the regression coefficients if you add or delete an independent variable. The estimated standard errors of the fitted coefficients are inflated, or the estimated coefficients may not be statistically significant even though a statistical relation exists between the dependent and independent variables.

Data analysts rely on these facts to check informally for the presence of multicollinearity. `estat vif`, another command for use after `regress`, calculates the variance inflation factors and tolerances for each of the independent variables.

The output shows the variance inflation factors together with their reciprocals. Some analysts compare the reciprocals with a predetermined tolerance. In the comparison, if the reciprocal of the VIF is smaller than the tolerance, the associated predictor variable is removed from the regression model. However, most analysts rely on informal rules of thumb applied to the VIF; see Chatterjee and Hadi (2012). According to these rules, there is evidence of multicollinearity if

1. The largest VIF is greater than 10 (some choose a more conservative threshold value of 30).
2. The mean of all the VIFs is considerably larger than 1.

▷ Example 11: estat vif

We examine a regression model fit using the ubiquitous automobile dataset:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price mpg rep78 trunk headroom length turn displ gear_ratio
```

Source	SS	df	MS	Number of obs =	69
				F(8, 60) =	6.33
Model	264102049	8	33012756.2	Prob > F =	0.0000
Residual	312694909	60	5211581.82	R-squared =	0.4579
				Adj R-squared =	0.3856
Total	576796959	68	8482308.22	Root MSE =	2282.9

price	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
mpg	-144.84	82.12751	-1.76	0.083	-309.1195	19.43948
rep78	727.5783	337.6107	2.16	0.035	52.25638	1402.9
trunk	44.02061	108.141	0.41	0.685	-172.2935	260.3347
headroom	-807.0996	435.5802	-1.85	0.069	-1678.39	64.19062
length	-8.688914	34.89848	-0.25	0.804	-78.49626	61.11843
turn	-177.9064	137.3455	-1.30	0.200	-452.6383	96.82551
displacement	30.73146	7.576952	4.06	0.000	15.5753	45.88762
gear_ratio	1500.119	1110.959	1.35	0.182	-722.1303	3722.368
_cons	6691.976	7457.906	0.90	0.373	-8226.058	21610.01

```
. estat vif
```

Variable	VIF	1/VIF
length	8.22	0.121614
displacement	6.50	0.153860
turn	4.85	0.205997
gear_ratio	3.45	0.290068
mpg	3.03	0.330171
trunk	2.88	0.347444
headroom	1.80	0.554917
rep78	1.46	0.686147
Mean VIF	4.02	

The results are mixed. Although we have no VIFs greater than 10, the mean VIF is greater than 1, though not considerably so. We could continue the investigation of collinearity, but given that other authors advise that collinearity is a problem only when VIFs exist that are greater than 30 (contradicting our rule above), we will not do so here.

◁

Example 12: estat vif, with strong evidence of multicollinearity

This example comes from a dataset described in Kutner, Nachtsheim, and Neter (2004, 257) that examines body fat as modeled by caliper measurements on the triceps, midarm, and thigh.

```
. use http://www.stata-press.com/data/r13/bodyfat
(Body Fat)
. regress bodyfat tricep thigh midarm
```

Source	SS	df	MS		
Model	396.984607	3	132.328202	Number of obs	= 20
Residual	98.4049068	16	6.15030667	F(3, 16)	= 21.52
				Prob > F	= 0.0000
				R-squared	= 0.8014
				Adj R-squared	= 0.7641
Total	495.389513	19	26.0731323	Root MSE	= 2.48

bodyfat	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
triceps	4.334085	3.015511	1.44	0.170	-2.058512	10.72668
thigh	-2.856842	2.582015	-1.11	0.285	-8.330468	2.616785
midarm	-2.186056	1.595499	-1.37	0.190	-5.568362	1.19625
_cons	117.0844	99.78238	1.17	0.258	-94.44474	328.6136

```
. estat vif
```

Variable	VIF	1/VIF
triceps	708.84	0.001411
thigh	564.34	0.001772
midarm	104.61	0.009560
Mean VIF	459.26	

Here we see strong evidence of multicollinearity in our model. More investigation reveals that the measurements on the thigh and the triceps are highly correlated:

```
. correlate triceps thigh midarm
(obs=20)
```

	triceps	thigh	midarm
triceps	1.0000		
thigh	0.9238	1.0000	
midarm	0.4578	0.0847	1.0000

If we remove the predictor `tricep` from the model (because it had the highest VIF), we get

```
. regress bodyfat thigh midarm
```

Source	SS	df	MS		
Model	384.279748	2	192.139874	Number of obs	= 20
Residual	111.109765	17	6.53586854	F(2, 17)	= 29.40
				Prob > F	= 0.0000
				R-squared	= 0.7757
				Adj R-squared	= 0.7493
Total	495.389513	19	26.0731323	Root MSE	= 2.5565

_cons	-25.99696	6.99732	-3.72	0.002	-40.76001	-11.2339

```
. estat vif
    Variable |       VIF       1/VIF
-------------+----------------------
      midarm |      1.01    0.992831
       thigh |      1.01    0.992831
-------------+----------------------
    Mean VIF |      1.01
```

Note how the coefficients change and how the estimated standard errors for each of the regression coefficients become much smaller. The calculated value of R^2 for the overall regression for the subset model does not appreciably decline when we remove the correlated predictor. Removing an independent variable from the model is one way to deal with multicollinearity. Other methods include ridge regression, weighted least squares, and restricting the use of the fitted model to data that follow the same pattern of multicollinearity. In economic studies, it is sometimes possible to estimate the regression coefficients from different subsets of the data by using cross-section and time series.

◁

All examples above demonstrated the use of centered VIFs. As pointed out by Belsley (1991), the centered VIFs may fail to discover collinearity involving the constant term. One solution is to use the uncentered VIFs instead. According to the definition of the uncentered VIFs, the constant is viewed as a legitimate explanatory variable in a regression model, which allows one to obtain the VIF value for the constant term.

▷ Example 13: estat vif, with strong evidence of collinearity with the constant term

Consider the extreme example in which one of the regressors is highly correlated with the constant. We simulate the data and examine both centered and uncentered VIF diagnostics after fitted regression model as follows.

```
. use http://www.stata-press.com/data/r13/extreme_collin
. regress y one x z

```

```
. estat vif, uncentered
    Variable |       VIF       1/VIF
-------------+----------------------
         one |    402.94    0.002482
   intercept |    401.26    0.002492
           z |      2.93    0.341609
           x |      1.13    0.888705
-------------+----------------------
    Mean VIF |    202.06
```

According to the values of the centered VIFs (1.03, 1.03, 1.00), no harmful collinearity is detected in the model. However, by the construction of these simulated data, we know that `one` is highly collinear with the constant term. As such, the large values of uncentered VIFs for `one` (402.94) and `intercept` (401.26) reveal high collinearity of the variable `one` with the constant term.

◁

Measures of effect size

Syntax for estat esize

```
estat esize [ , omega level(#) ]
```

Menu for estat

Statistics > Postestimation > Reports and statistics

Description for estat esize

`estat esize` calculates effect sizes for linear models after `regress` or `anova`. By default, `estat esize` reports η^2 (eta-squared) estimates (Kerlinger 1964), which are equivalent to R^2 estimates. If the option `omega` is specified, `estat esize` reports ω^2 estimates (Hays 1963), which are equivalent to adjusted R^2 estimates. Confidence intervals for η^2 and ω^2 estimates are estimated by using the noncentral F distribution (Smithson 2001). See Kline (2013) or Thompson (2006) for further information.

Options for estat esize

`omega` specifies that the ω^2 estimates of effect size be reported. The default is η^2 estimates.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see **[U] 20.7 Specifying the width of confidence intervals**.

Remarks and examples for estat esize

Whereas p-values are used to assess the statistical significance of a result, measures of effect size are used to assess the practical significance of a result. Effect sizes can be broadly categorized as "measures of group differences" (the d family) and "measures of association" (the r family); see Ellis (2010, table 1.1). The d family includes estimators such as Cohen's D, Hedges's G, and Glass's Δ (also see [R] **esize**). The r family includes estimators such as the point-biserial correlation coefficient, ω^2, and η^2. For an introduction to the concepts and calculation of effect sizes, see Kline (2013) or Thompson (2006). For a more detailed discussion, see Kirk (1996), Ellis (2010), Cumming (2012), Grissom and Kim (2012), and Kelley and Preacher (2012).

▷ Example 14: Calculating effect sizes for a linear regression model

Suppose we fit a linear regression model for low-birthweight infants.

```
. use http://www.stata-press.com/data/r13/lbw
(Hosmer & Lemeshow data)
. regress bwt smoke i.race
```

Source	SS	df	MS	Number of obs	=	189
				F(3, 185)	=	8.69
Model	12346897.6	3	4115632.54	Prob > F	=	0.0000
Residual	87568400.9	185	473342.708	R-squared	=	0.1236
				Adj R-squared	=	0.1094
Total	99915298.6	188	531464.354	Root MSE	=	688

bwt	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]

❑ Technical note

η^2 and ω^2 were developed in the context of analysis of variance. Thus, the published research on the calculation of their confidence intervals focuses on cases where the numerator degrees of freedom are relatively small (for example, df < 20).

Some combinations of the F statistic, numerator degrees of freedom, and denominator degrees of freedom yield confidence limits that do not contain the corresponding estimated value for an η^2 or ω^2. This problem is most commonly observed for larger numerator degrees of freedom.

Nothing in the literature suggests alternative methods for constructing confidence intervals in such cases; therefore, we recommend cautious interpretation of confidence intervals for η^2 and ω^2 when the numerator degrees of freedom are greater than 20.

❑

Stored results for estat esize

`estat esize` stores the following results in `r()`:

Scalars
- `r(level)` confidence level

Matrices
- `r(esize)` a matrix of effect sizes, confidence intervals, degrees of freedom, and F statistics with rows corresponding to each term in the model
  - `esize[.,1]` η^2
  - `esize[.,2]` lower confidence bound for η^2
  - `esize[.,3]` upper confidence bound for η^2
  - `esize[.,4]` ω^2
  - `esize[.,5]` lower confidence bound for ω^2
  - `esize[.,6]` upper confidence bound for ω^2
  - `esize[.,7]` numerator degrees of freedom
  - `esize[.,8]` denominator degrees of freedom
  - `esize[.,9]` F statistic

Methods and formulas

See Hamilton (2013, chap. 7), Kohler and Kreuter (2012, sec. 9.3), or Baum (2006, chap. 5) for an overview of using Stata to perform regression diagnostics. See Peracchi (2001, chap. 8) for a mathematically rigorous discussion of diagnostics.

Methods and formulas are presented under the following headings:

predict
Special-interest postestimation commands

predict

Assume that you have already fit the regression model

$$\mathbf{y} = \mathbf{X}\mathbf{b} + \mathbf{e}$$

where $\mathbf{X}$ is $n \times k$.

Denote the previously estimated coefficient vector by $\mathbf{b}$ and its estimated variance matrix by $\mathbf{V}$. `predict` works by recalling various aspects of the model, such as $\mathbf{b}$, and combining that information with the data currently in memory. Let $\mathbf{x}_j$ be the jth observation currently in memory, and let s^2 be the mean squared error of the regression.

If the user specified weights in `regress`, then $\mathbf{X}'\mathbf{X}$ in the following formulas is replaced by $\mathbf{X}'\mathbf{D}\mathbf{X}$, where $\mathbf{D}$ is defined in *Coefficient estimation and ANOVA table* under *Methods and formulas* in [R] **regress**.

Let $\mathbf{V} = s^2(\mathbf{X}'\mathbf{X})^{-1}$. Let k be the number of independent variables including the intercept, if any, and let y_j be the observed value of the dependent variable.

The *predicted value* (`xb` option) is defined as $\widehat{y}_j = \mathbf{x}_j\mathbf{b}$.

Let ℓ_j represent a lower bound for an observation j and u_j represent an upper bound. The probability that $y_j|\mathbf{x}_j$ would be observed in the interval (ℓ_j, u_j)—the `pr(`ℓ`, `u`)` option—is

$$P(\ell_j, u_j) = \Pr(\ell_j < \mathbf{x}_j\mathbf{b} + e_j < u_j) = \Phi\left(\frac{u_j - \widehat{y}_j}{s}\right) - \Phi\left(\frac{\ell_j - \widehat{y}_j}{s}\right)$$

where for the `pr(`ℓ`, `u`)`, `e(`ℓ`, `u`)`, and `ystar(`ℓ`, `u`)` options, ℓ_j and u_j can be anywhere in the range $(-\infty, +\infty)$.

The option `e(`ℓ`, `u`)` computes the expected value of $y_j|\mathbf{x}_j$ conditional on $y_j|\mathbf{x}_j$ being in the interval (ℓ_j, u_j), that is, when $y_j|\mathbf{x}_j$ is truncated. It can be expressed as

$$E(\ell_j, u_j) = E(\mathbf{x}_j\mathbf{b} + e_j \mid \ell_j < \mathbf{x}_j\mathbf{b} + e_j < u_j) = \widehat{y}_j - s\frac{\phi\left(\frac{u_j - \widehat{y}_j}{s}\right) - \phi\left(\frac{\ell_j - \widehat{y}_j}{s}\right)}{\Phi\left(\frac{u_j - \widehat{y}_j}{s}\right) - \Phi\left(\frac{\ell_j - \widehat{y}_j}{s}\right)}$$

where ϕ is the normal density and Φ is the cumulative normal.

You can also compute `ystar(`ℓ, u`)`—the expected value of $y_j|\mathbf{x}_j$, where y_j is assumed censored at ℓ_j and u_j:

$$y_j^* = \begin{cases} \ell_j & \text{if } \mathbf{x}_j\mathbf{b} + e_j \le \ell_j \\ \mathbf{x}_j\mathbf{b} + u & \text{if } \ell_j < \mathbf{x}_j\mathbf{b} + e_j < u_j \\ u_j & \text{if } \mathbf{x}_j\mathbf{b} + e_j \ge u_j \end{cases}$$

This computation can be expressed in several ways, but the most intuitive formulation involves a combination of the two statistics just defined:

$$y_j^* = P(-\infty, \ell_j)\ell_j + P(\ell_j, u_j)E(\ell_j, u_j) + P(u_j, +\infty)u_j$$

A diagonal element of the projection matrix (`hat`) or (`leverage`) is given by

$$h_j = \mathbf{x}_j(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_j'$$

The *standard error of the prediction* (the `stdp` option) is defined as $s_{p_j} = \sqrt{\mathbf{x}_j\mathbf{V}\mathbf{x}_j'}$

and can also be written as $s_{p_j} = s\sqrt{h_j}$.

The *standard error of the forecast* (`stdf`) is defined as $s_{f_j} = s\sqrt{1 + h_j}$.

The *standard error of the residual* (`stdr`) is defined as $s_{r_j} = s\sqrt{1-h_j}$.

The *residuals* (`residuals`) are defined as $\widehat{e}_j = y_j - \widehat{y}_j$.

The *standardized residuals* (`rstandard`) are defined as $\widehat{e}_{s_j} = \widehat{e}_j / s_{r_j}$.

The *Studentized residuals* (`rstudent`) are defined as

$$r_j = \frac{\widehat{e}_j}{s_{(j)}\sqrt{1-h_j}}$$

where $s_{(j)}$ represents the root mean squared error with the jth observation removed, which is given by

$$s^2_{(j)} = \frac{s^2(T-k)}{T-k-1} - \frac{\widehat{e}_j^2}{(T-k-1)(1-h_j)}$$

Cook's D (`cooksd`) is given by

$$D_j = \frac{\widehat{e}^2_{s_j}(s_{p_j}/s_{r_j})^2}{k} = \frac{h_j \widehat{e}_j^2}{k s^2 (1-h_j)^2}$$

DFITS (`dfits`) is given by

$$\text{DFITS}_j = r_j\sqrt{\frac{h_j}{1-h_j}}$$

Welsch distance (`welsch`) is given by

$$W_j = \frac{r_j\sqrt{h_j(n-1)}}{1-h_j}$$

COVRATIO (`covratio`) is given by

$$\text{COVRATIO}_j = \frac{1}{1-h_j}\left(\frac{n-k-\widehat{e}_j^2}{n-k-1}\right)^k$$

The DFBETAs (`dfbeta`) for a particular regressor x_i are given by

$$\text{DFBETA}_j = \frac{r_j u_j}{\sqrt{U^2(1-h_j)}}$$

where u_j are the residuals obtained from a regression of x_i on the remaining x's and $U^2 = \sum_j u_j^2$.

Special-interest postestimation commands

The omitted-variable test (Ramsey 1969) reported by `estat ovtest` fits the regression $y_i = \mathbf{x}_i\mathbf{b} + \mathbf{z}_i\mathbf{t} + u_i$ and then performs a standard F test of $\mathbf{t} = \mathbf{0}$. The default test uses $\mathbf{z}_i = (\widehat{y}_i^2, \widehat{y}_i^3, \widehat{y}_i^4)$. If `rhs` is specified, $\mathbf{z}_i = (x_{1i}^2, x_{1i}^3, x_{1i}^4, x_{2i}^2, \ldots, x_{mi}^4)$. In either case, the variables are normalized to have minimum 0 and maximum 1 before powers are calculated.

The test for heteroskedasticity (Breusch and Pagan 1979; Cook and Weisberg 1983) models $\mathrm{Var}(e_i) = \sigma^2 \exp(\mathbf{zt})$, where $\mathbf{z}$ is a variable list specified by the user, the list of right-hand-side variables, or the fitted values $\mathbf{x}\widehat{\boldsymbol{\beta}}$. The test is of $\mathbf{t} = \mathbf{0}$. Mechanically, `estat hettest` fits the augmented regression $\widehat{e}_i^2/\widehat{\sigma}^2 = a + \mathbf{z}_i\mathbf{t} + v_i$.

The original Breusch–Pagan/Cook–Weisberg version of the test assumes that the e_i are normally distributed under the null hypothesis which implies that the score test statistic S is equal to the model sum of squares from the augmented regression divided by 2. Under the null hypothesis, S has the χ^2 distribution with m degrees of freedom, where m is the number of columns of $\mathbf{z}$.

Koenker (1981) derived a score test of the null hypothesis that $\mathbf{t} = \mathbf{0}$ under the assumption that the e_i are independent and identically distributed (i.i.d.). Koenker showed that $S = N * R^2$ has a large-sample χ^2 distribution with m degrees of freedom, where N is the number of observations and R^2 is the R-squared in the augmented regression and m is the number of columns of $\mathbf{z}$. `estat hettest, iid` produces this version of the test.

Wooldridge (2013) showed that an F test of $\mathbf{t} = \mathbf{0}$ in the augmented regression can also be used under the assumption that the e_i are i.i.d. `estat hettest, fstat` produces this version of the test.

Szroeter's class of tests for homoskedasticity against the alternative that the residual variance increases in some variable x is defined in terms of

$$H = \frac{\sum_{i=1}^{n} h(x_i)e_i^2}{\sum_{i=1}^{n} e_i^2}$$

where $h(x)$ is some weight function that increases in x (Szroeter 1978). H is a weighted average of the $h(x)$, with the squared residuals serving as weights. Under homoskedasticity, H should be approximately equal to the unweighted average of $h(x)$. Large values of H suggest that e_i^2 tends to be large where $h(x)$ is large; that is, the variance indeed increases in x, whereas small values of H suggest that the variance actually decreases in x. `estat szroeter` uses $h(x_i) = \mathrm{rank}(x_i \text{ in } x_1 \ldots x_n)$; see Judge et al. [1985, 452] for details. `estat szroeter` displays a normalized version of H,

$$Q = \sqrt{\frac{6n}{n^2 - 1}}H$$

which is approximately $N(0, 1)$ distributed under the null (homoskedasticity).

`estat hettest` and `estat szroeter` provide adjustments of p-values for multiple testing. The supported methods are described in [R] **test**.

`estat imtest` performs the information matrix test for the regression model, as well as an orthogonal decomposition into tests for heteroskedasticity δ_1, nonnormal skewness δ_2, and nonnormal kurtosis δ_3 (Cameron and Trivedi 1990; Long and Trivedi 1993). The decomposition is obtained via three auxiliary regressions. Let e be the regression residuals, $\widehat{\sigma}^2$ be the maximum likelihood estimate of σ^2 in the regression, n be the number of observations, X be the set of k variables specified with `estat imtest`, and R^2_{un} be the uncentered R^2 from a regression. δ_1 is obtained as nR^2_{un} from a regression of $e^2 - \widehat{\sigma}^2$ on the cross products of the variables in X. δ_2 is computed as nR^2_{un} from a regression of $e^3 - 3\widehat{\sigma}^2 e$ on X. Finally, δ_3 is obtained as nR^2_{un} from a regression of $e^4 - 6\widehat{\sigma}^2 e^2 - 3\widehat{\sigma}^4$

on X. δ_1, δ_2, and δ_3 are asymptotically χ^2 distributed with $1/2k(k+1)$, K, and 1 degree of freedom. The information test statistic $\delta = \delta_1 + \delta_2 + \delta_3$ is asymptotically χ^2 distributed with $1/2k(k+3)$ degrees of freedom. White's test for heteroskedasticity is computed as nR^2 from a regression of $\widehat{u}^2$ on X and the cross products of the variables in X. This test statistic is usually close to δ_1.

`estat vif` calculates the centered variance inflation factor (VIF_c) (Chatterjee and Hadi 2012, 248–251) for x_j, given by

$$\text{VIF}_c(x_j) = \frac{1}{1 - \widehat{R}_j^2}$$

where $\widehat{R}_j^2$ is the square of the centered multiple correlation coefficient that results when x_j is regressed with intercept against all the other explanatory variables.

The uncentered variance inflation factor (VIF_{uc}) (Belsley 1991, 28–29) for x_j is given by

$$\text{VIF}_{uc}(x_j) = \frac{1}{1 - \widetilde{R}_j^2}$$

where $\widetilde{R}_j^2$ is the square of the uncentered multiple correlation coefficient that results when x_j is regressed without intercept against all the other explanatory variables including the constant term.

The methods and formulas for `estat esize` are described in *Methods and formulas* of [R] **esize**.

Acknowledgments

`estat ovtest` and `estat hettest` are based on programs originally written by Richard Goldstein (1991, 1992). `estat imtest`, `estat szroeter`, and the current version of `estat hettest` were written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands. `estat imtest` is based in part on code written by J. Scott Long of the Department of Sociology at Indiana University, coauthor of the Stata Press book *Regression Models for Categorical and Limited Dependent Variables*, and author of the Stata Press book *The Workflow of Data Analysis Using Stata*.

Title

regress postestimation diagnostic plots — Postestimation plots for regress

Description rvfplot avplot avplots cprplot acprplot
rvpplot lvr2plot Methods and formulas References Also see

Description

The following postestimation commands are of special interest after `regress`:

Command	Description
`rvfplot`	residual-versus-fitted plot
`avplot`	added-variable plot
`avplots`	all added-variables plots in one image
`cprplot`	component-plus-residual plot
`acprplot`	augmented component-plus-residual plot
`rvpplot`	residual-versus-predictor plot
`lvr2plot`	leverage-versus-squared-residual plot

These commands are not appropriate after the `svy` prefix.

For a discussion of the terminology used in this entry, see the *Terminology* section of *Remarks and examples for predict* in [R] **regress postestimation**.

rvfplot

Syntax for rvfplot

`rvfplot` [, *rvfplot_options*]

rvfplot_options	Description
Plot	
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
Add plots	
`addplot(`*plot*`)`	add plots to the generated graph
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu for rvfplot

Statistics > Linear models and related > Regression diagnostics > Residual-versus-fitted plot

Description for rvfplot

`rvfplot` graphs a residual-versus-fitted plot, a graph of the residuals against the fitted values.

Options for rvfplot

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

Add plots

`addplot(`*plot*`)` provides a way to add plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples for rvfplot

`rvfplot` graphs the residuals against the fitted values.

▷ Example 1

Using `auto.dta` described in **[U] 1.2.2 Example datasets**, we will use `regress` to fit a model of `price` on `weight`, `mpg`, `foreign`, and the interaction of `foreign` with `mpg`. We specify `foreign##c.mpg` to obtain the interaction of `foreign` with `mpg`; see **[U] 11.4.3 Factor variables**.

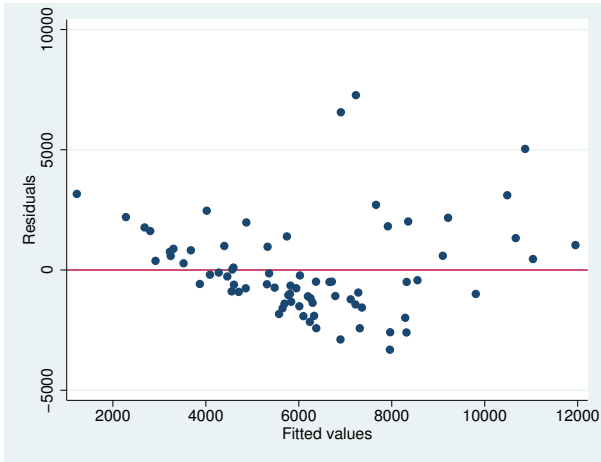
```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price weight foreign##c.mpg
```

Source	SS	df	MS		
Model	350319665	4	87579916.3	Number of obs	= 74
Residual	284745731	69	4126749.72	F(4, 69)	= 21.22
				Prob > F	= 0.0000
				R-squared	= 0.5516
				Adj R-squared	= 0.5256
Total	635065396	73	8699525.97	Root MSE	= 2031.4

price	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
weight	4.613589	.7254961	6.36	0.000	3.166263	6.060914
foreign						
Foreign	11240.33	2751.681	4.08	0.000	5750.878	16729.78
mpg	263.1875	110.7961	2.38	0.020	42.15527	484.2197
foreign#c.mpg						
Foreign	-307.2166	108.5307	-2.83	0.006	-523.7294	-90.70368
_cons	-14449.58	4425.72	-3.26	0.002	-23278.65	-5620.51

Once we have fit a model, we may use any of the regression diagnostics commands. `rvfplot` (read residual-versus-fitted plot) graphs the residuals against the fitted values:

```
. rvfplot, yline(0)
```



All the diagnostic plot commands allow the `graph twoway` and `graph twoway scatter` options; we specified a `yline(0)` to draw a line across the graph at $y = 0$; see [G-2] **graph twoway scatter**.

In a well-fitted model, there should be no pattern to the residuals plotted against the fitted values—something not true of our model. Ignoring the two outliers at the top center of the graph, we see curvature in the pattern of the residuals, suggesting a violation of the assumption that `price` is linear in our independent variables. We might also have seen increasing or decreasing variation in the residuals—heteroskedasticity. Any pattern whatsoever indicates a violation of the least-squares assumptions.

◁

avplot

Syntax for avplot

```
avplot indepvar [ , avplot_options ]
```

avplot_options	Description
Plot	
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
Reference line	
`rlopts(`*cline_options*`)`	affect rendition of the reference line
Add plots	
`addplot(`*plot*`)`	add other plots to the generated graph
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu for avplot

Statistics > Linear models and related > Regression diagnostics > Added-variable plot

Description for avplot

`avplot` graphs an added-variable plot (a.k.a. partial-regression leverage plot, partial regression plot, or adjusted partial residual plot) after `regress`. *indepvar* may be an independent variable (a.k.a. predictor, carrier, or covariate) that is currently in the model or not.

Options for avplot

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

Reference line

`rlopts(`*cline_options*`)` affects the rendition of the reference line. See [G-3] ***cline_options***.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples for avplot

`avplot` graphs an added-variable plot, also known as the partial-regression leverage plot.

One of the wonderful features of one-regressor regressions (regressions of y on one x) is that we can graph the data and the regression line. There is no easier way to understand the regression than to examine such a graph. Unfortunately, we cannot do this when we have more than one regressor. With two regressors, it is still theoretically possible—the graph must be drawn in three dimensions, but with three or more regressors no graph is possible.

The added-variable plot is an attempt to project multidimensional data back to the two-dimensional world for each of the original regressors. This is, of course, impossible without making some concessions. Call the coordinates on an added-variable plot y and x. The added-variable plot has the following properties:

- There is a one-to-one correspondence between (x_i, y_i) and the ith observation used in the original regression.
- A regression of y on x has the same coefficient and standard error (up to a degree-of-freedom adjustment) as the estimated coefficient and standard error for the regressor in the original regression.
- The "outlierness" of each observation in determining the slope is in some sense preserved.

It is equally important to note the properties that are not listed. The y and x coordinates of the added-variable plot cannot be used to identify functional form, or, at least, not well (see Mallows [1986]). In the construction of the added-variable plot, the relationship between y and x is forced to be linear.

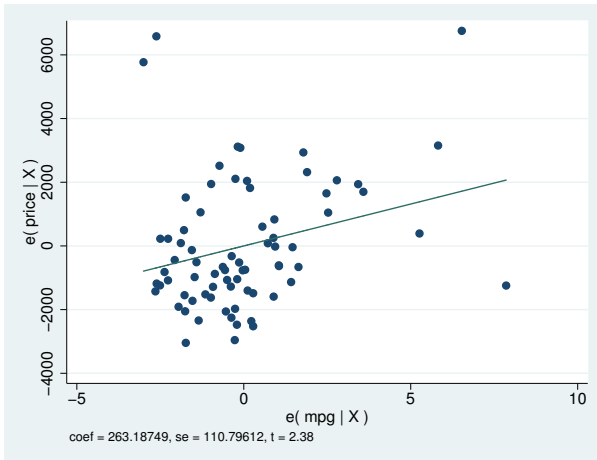
▷ Example 2

Let's use the same model as we used in example 1.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
```

We can now examine the added-variable plot for `mpg`.

```
. avplot mpg
```



This graph suggests a problem in determining the coefficient on `mpg`. Were this a one-regressor regression, the two points at the top-left corner and the one at the top right would cause us concern, and so it does in our more complicated multiple-regressor case. To identify the problem points, we retyped our command, modifying it to read `avplot mpg, mlabel(make)`, and discovered that the two cars at the top left are the Cadillac Eldorado and the Lincoln Versailles; the point at the top right is the Cadillac Seville. These three cars account for 100% of the luxury cars in our data, suggesting that our model is misspecified. By the way, the point at the lower right of the graph, also cause for concern, is the Plymouth Arrow, our data entry error.

◁

❑ Technical note

Stata's `avplot` command can be used with regressors already in the model, as we just did, or with potential regressors not yet in the model. In either case, `avplot` will produce the correct graph. The name "added-variable plot" is unfortunate in the case when the variable is already among the list of regressors but is, we think, still preferable to the name "partial-regression leverage plot" assigned by Belsley, Kuh, and Welsch (1980, 30) and more in the spirit of the original use of such plots by Mosteller and Tukey (1977, 271–279). Welsch (1986, 403), however, disagrees: "I am sorry to see that Chatterjee and Hadi [1986] endorse the term 'added-variable plot' when X_j is part of the original model" and goes on to suggest the name "adjusted partial residual plot".

❑

avplots

Syntax for avplots

`avplots` [, *avplots_options*]

avplots_options	Description
Plot	
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
combine_options	any of the options documented in [G-2] **graph combine**
Reference line	
`rlopts(`*cline_options*`)`	affect rendition of the reference line
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu for avplots

Statistics > Linear models and related > Regression diagnostics > Added-variable plot

Description for avplots

`avplots` graphs all the added-variable plots in one image.

Options for avplots

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

combine_options are any of the options documented in [G-2] **graph combine**. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Reference line

`rlopts(`*cline_options*`)` affects the rendition of the reference line. See [G-3] ***cline_options***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples for avplots

▷ Example 3

In example 2, we used `avplot` to examine the added-variable plot for `mpg` in our regression of `price` on `weight` and `foreign##c.mpg`. Now let's use `avplots` to graph an added-variable plot for every regressor in the data.

```
. avplots

twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu for cprplot

Statistics > Linear models and related > Regression diagnostics > Component-plus-residual plot

Description for cprplot

`cprplot` graphs a component-plus-residual plot (a.k.a. partial residual plot) after `regress`. *indepvar* must be an independent variable that is currently in the model.

Options for cprplot

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

Reference line

`rlopts(`*cline_options*`)` affects the rendition of the reference line. See [G-3] ***cline_options***.

Options

`lowess` adds a lowess smooth of the plotted points to assist in detecting nonlinearities.

`lsopts(`*lowess_options*`)` affects the rendition of the lowess smooth. For an explanation of these options, especially the `bwidth()` option, see [R] **lowess**. Specifying `lsopts()` implies the `lowess` option.

`mspline` adds a median spline of the plotted points to assist in detecting nonlinearities.

`msopts(`*mspline_options*`)` affects the rendition of the spline. For an explanation of these options, especially the `bands()` option, see [G-2] **graph twoway mspline**. Specifying `msopts()` implies the `mspline` option.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples for cprplot

Added-variable plots are successful at identifying outliers, but they cannot be used to identify functional form. The component-plus-residual plot (Ezekiel 1924; Larsen and McCleary 1972) is another attempt at projecting multidimensional data into a two-dimensional form, but with different properties. Although the added-variable plot can identify outliers, the component-plus-residual plot cannot. It can, however, be used to examine the functional form assumptions of the model. Both plots have the property that a regression line through the coordinates has a slope equal to the estimated coefficient in the regression model.

▷ Example 4

We illustrate component-plus-residual plots using a variation of `auto.dta`.

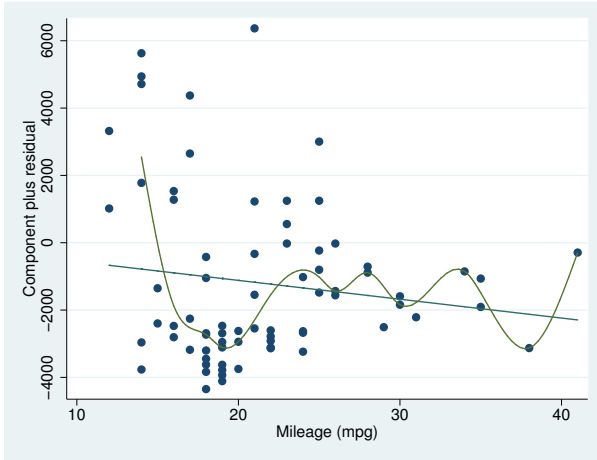
```
. use http://www.stata-press.com/data/r13/auto1
(Automobile Models)
. regress price mpg weight
      Source |       SS       df       MS              Number of obs =      74
-------------+------------------------------           F(  2,    71) =   14.90
       Model |  187716578      2  93858289              Prob > F      =  0.0000
    Residual |  447348818     71  6300687.58            R-squared     =  0.2956
-------------+------------------------------           Adj R-squared =  0.2757
       Total |  635065396     73  8699525.97            Root MSE      =  2510.1

------------------------------------------------------------------------------
       price |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
         mpg |   -55.9393   75.24136    -0.74   0.460    -205.9663    94.08771
      weight |   1.710992   .5861682     2.92   0.005     .5422063    2.879779
       _cons |    2197.9   3190.768     0.69   0.493    -4164.311     8560.11
------------------------------------------------------------------------------
```

In fact, we know that the effects of mpg in this model are nonlinear—if we added mpg squared to the model, its coefficient would have a t statistic of 2.38, the t statistic on mpg would become −2.48, and weight's effect would become about one-third of its current value and become statistically insignificant. Pretend that we do not know this.

The component-plus-residual plot for mpg is

```
. cprplot mpg, mspline msopts(bands(13))
```



We are supposed to examine the above graph for nonlinearities or, equivalently, ask if the regression line, which has slope equal to the estimated effect of mpg in the original model, fits the data adequately. To assist our eyes, we added a median spline. Perhaps some people may detect nonlinearity from this graph, but we assert that if we had not previously revealed the nonlinearity of mpg and if we had not added the median spline, the graph would not overly bother us.

◁

acprplot

Syntax for acprplot

```
acprplot indepvar [ , acprplot_options ]
```

acprplot_options	Description
Plot	
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
Reference line	
rlopts(*cline_options*)	affect rendition of the reference line
Options

Menu for acprplot

Statistics > Linear models and related > Regression diagnostics > Augmented component-plus-residual plot

Description for acprplot

acprplot graphs an augmented component-plus-residual plot (a.k.a. augmented partial residual plot) as described by Mallows (1986). This seems to work better than the component-plus-residual plot for identifying nonlinearities in the data.

Options for acprplot

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

Reference line

rlopts(*cline_options*) affects the rendition of the reference line. See [G-3] ***cline_options***.

Options

`lowess` adds a lowess smooth of the plotted points to assist in detecting nonlinearities.

`lsopts(`*lowess_options*`)` affects the rendition of the lowess smooth. For an explanation of these options, especially the `bwidth()` option, see [R] **lowess**. Specifying `lsopts()` implies the `lowess` option.

`mspline` adds a median spline of the plotted points to assist in detecting nonlinearities.

`msopts(`*mspline_options*`)` affects the rendition of the spline. For an explanation of these options, especially the `bands()` option, see [G-2] **graph twoway mspline**. Specifying `msopts()` implies the `mspline` option.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples for acprplot

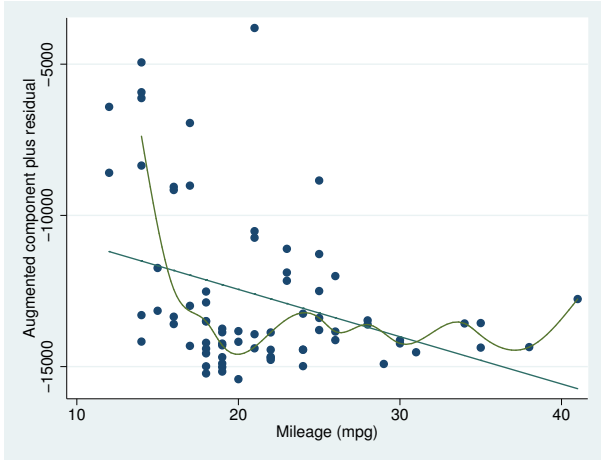
In the *cprplot* section above, we discussed the component-plus-residual plot. Mallows (1986) proposed an augmented component-plus-residual plot that is often more sensitive to detecting nonlinearity.

▷ Example 5

Let's compare the augmented component-plus-residual plot with the component-plus-residual plot of example 4.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
```

```
. acprplot mpg, mspline msopts(bands(13))
```



It does do somewhat better.

◁

rvpplot

Syntax for rvpplot

`rvpplot` *indepvar* [`,` *rvpplot_options*]

rvpplot_options	Description
Plot	
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
Add plots	
`addplot(`*plot*`)`	add other plots to the generated graph
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu for rvpplot

Statistics > Linear models and related > Regression diagnostics > Residual-versus-predictor plot

Description for rvpplot

`rvpplot` graphs a residual-versus-predictor plot (a.k.a. independent variable plot or carrier plot), a graph of the residuals against the specified predictor.

Options for rvpplot

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph; see [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

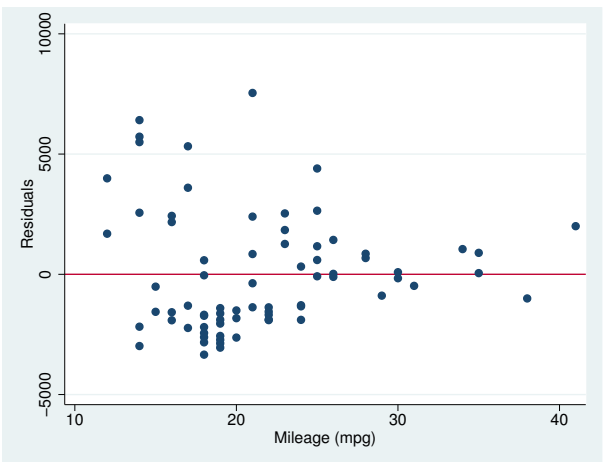
Remarks and examples for rvpplot

The residual-versus-predictor plot is a simple way to look for violations of the regression assumptions. If the assumptions are correct, there should be no pattern on the graph.

▷ Example 6

Let's use our model of `price` on `mpg` and `weight`.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
. rvpplot mpg, yline(0)
```



Remember, any pattern counts as a problem, and in this graph, we see that the variation in the residuals decreases as mpg increases.

◁

lvr2plot

Syntax for lvr2plot

```
lvr2plot [ , lvr2plot_options ]
```

lvr2plot_options	Description
Plot	
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
Add plots	
`addplot(`*plot*`)`	add other plots to the generated graph
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu for lvr2plot

Statistics > Linear models and related > Regression diagnostics > Leverage-versus-squared-residual plot

Description for lvr2plot

`lvr2plot` graphs a leverage-versus-squared-residual plot (a.k.a. L-R plot).

Options for lvr2plot

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

marker_label_options specify if and how the markers are to be labeled; see [G-3] ***marker_label_options***.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

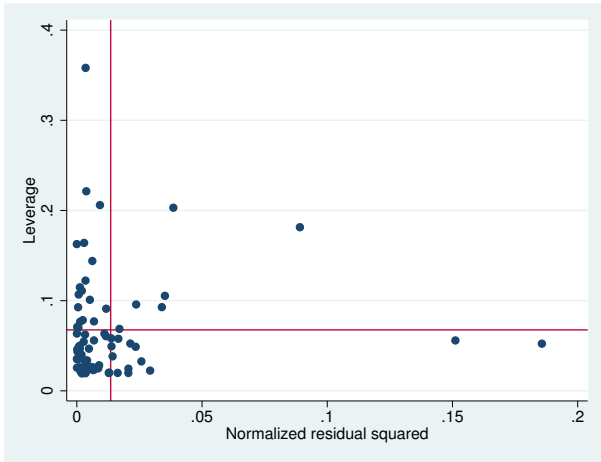
Remarks and examples for lvr2plot

One of the most useful diagnostic graphs is provided by `lvr2plot` (leverage-versus-residual-squared plot), a graph of leverage against the (normalized) residuals squared.

▷ Example 7

We illustrate `lvr2plot` using our model in example 1.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
. lvr2plot
```

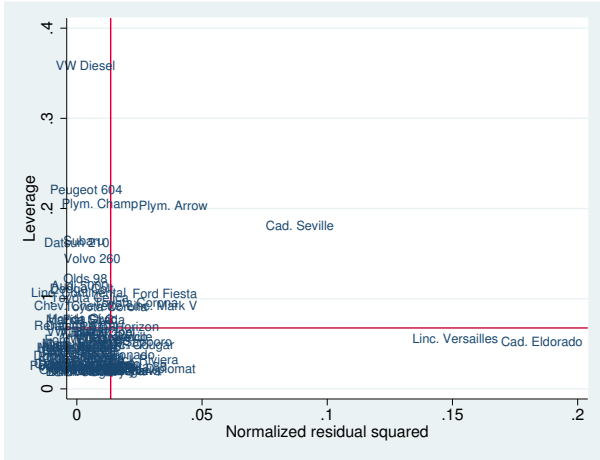


The lines on the chart show the average values of leverage and the (normalized) residuals squared. Points above the horizontal line have higher-than-average leverage; points to the right of the vertical line have larger-than-average residuals.

One point immediately catches our eye, and four more make us pause. The point at the top of the graph has high leverage and a smaller-than-average residual. The other points that bother us all have higher-than-average leverage, two with smaller-than-average residuals and two with larger-than-average residuals.

A less pretty but more useful version of the above graph specifies that `make` be used as the symbol (see [G-3] ***marker_label_options***):

```
. lvr2plot, mlabel(make) mlabp(0) m(none) mlabsize(small)
```



The VW Diesel, Plymouth Champ, Plymouth Arrow, and Peugeot 604 are the points that cause us the most concern. When we further examine our data, we discover that the VW Diesel is the only diesel in our data and that the data for the Plymouth Arrow were entered incorrectly into the computer. No such simple explanations were found for the Plymouth Champ and Peugeot 604.

◁

Methods and formulas

See Hamilton (2013, 209–214) and Kohler and Kreuter (2012, sec. 9.3) for a discussion of these diagnostic graphs.

The `lvr2plot` command plots leverage against the squares of the normalized residuals. The normalized residuals are defined as $\widehat{e}_{n_j} = \widehat{e}_j/(\sum_i \widehat{e}_i^2)^{1/2}$.

Description

The following postestimation commands for time series are available for `regress`:

Command	Description
`estat archlm`	test for ARCH effects in the residuals
`estat bgodfrey`	Breusch–Godfrey test for higher-order serial correlation
`estat durbinalt`	Durbin's alternative test for serial correlation
`estat dwatson`	Durbin–Watson d statistic to test for first-order serial correlation

These commands provide regression diagnostic tools specific to time series. You must `tsset` your data before using these commands; see [TS] **tsset**.

`estat archlm` tests for time-dependent volatility. `estat bgodfrey`, `estat durbinalt`, and `estat dwatson` test for serial correlation in the residuals of a linear regression. For non-time-series regression diagnostic tools, see [R] **regress postestimation**.

`estat archlm` performs Engle's Lagrange multiplier (LM) test for the presence of autoregressive conditional heteroskedasticity.

`estat bgodfrey` performs the Breusch–Godfrey test for higher-order serial correlation in the disturbance. This test does not require that all the regressors be strictly exogenous.

`estat durbinalt` performs Durbin's alternative test for serial correlation in the disturbance. This test does not require that all the regressors be strictly exogenous.

`estat dwatson` computes the Durbin–Watson d statistic (Durbin and Watson 1950) to test for first-order serial correlation in the disturbance when all the regressors are strictly exogenous.

Syntax for estat archlm

`estat archlm` [`,` *archlm_options*]

archlm_options	Description
`lags(`*numlist*`)`	test *numlist* lag orders
`force`	allow test after `regress, vce(robust)`

Options for estat archlm

`lags(`*numlist*`)` specifies a list of numbers, indicating the lag orders to be tested. The test will be performed separately for each order. The default is order one.

`force` allows the test to be run after `regress, vce(robust)`. The command will not work if the `vce(cluster` *clustvar*`)` option is specified with `regress`; see [R] **regress**.

Syntax for estat bgodfrey

`estat bgodfrey` [`,` *bgodfrey_options*]

bgodfrey_options	Description
`lags(`*numlist*`)`	test *numlist* lag orders
`nomiss0`	do not use Davidson and MacKinnon's approach
`small`	obtain p-values using the F or t distribution

Options for estat bgodfrey

`lags(`*numlist*`)` specifies a list of numbers, indicating the lag orders to be tested. The test will be performed separately for each order. The default is order one.

`nomiss0` specifies that Davidson and MacKinnon's approach (1993, 358), which replaces the missing values in the initial observations on the lagged residuals in the auxiliary regression with zeros, not be used.

`small` specifies that the p-values of the test statistics be obtained using the F or t distribution instead of the default chi-squared or normal distribution.

Syntax for estat durbinalt

`estat durbinalt` [`,` *durbinalt_options*]

durbinalt_options	Description
`lags(`*numlist*`)`	test *numlist* lag orders
`nomiss0`	do not use Davidson and MacKinnon's approach
`robust`	compute standard errors using the robust/sandwich estimator
`small`	obtain p-values using the F or t distribution
`force`	allow test after `regress, vce(robust)` or after `newey`

Options for estat durbinalt

`lags(`*numlist*`)` specifies a list of numbers, indicating the lag orders to be tested. The test will be performed separately for each order. The default is order one.

`nomiss0` specifies that Davidson and MacKinnon's approach (1993, 358), which replaces the missing values in the initial observations on the lagged residuals in the auxiliary regression with zeros, not be used.

`robust` specifies that the Huber/White/sandwich robust estimator of the variance–covariance matrix be used in Durbin's alternative test.

`small` specifies that the p-values of the test statistics be obtained using the F or t distribution instead of the default chi-squared or normal distribution. This option may not be specified with `robust`, which always uses an F or t distribution.

`force` allows the test to be run after `regress, vce(robust)` and after `newey` (see [R] **regress** and [TS] **newey**). The command will not work if the `vce(cluster` *clustvar*`)` option is specified with `regress`.

Syntax for estat dwatson

```
estat dwatson
```

Statistics > Postestimation > Reports and statistics

Remarks and examples

The Durbin–Watson test is used to determine whether the error term in a linear regression model follows an AR(1) process. For the linear model

$$y_t = \mathbf{x}_t\boldsymbol{\beta} + u_t$$

the AR(1) process can be written as

$$u_t = \rho u_{t-1} + \epsilon_t$$

In general, an AR(1) process requires only that ϵ_t be independent and identically distributed (i.i.d.). The Durbin–Watson test, however, requires ϵ_t to be distributed $N(0, \sigma^2)$ for the statistic to have an exact distribution. Also, the Durbin–Watson test can be applied only when the regressors are strictly exogenous. A regressor x is strictly exogenous if $\text{Corr}(x_s, u_t) = 0$ for all s and t, which precludes the use of the Durbin–Watson statistic with models where lagged values of the dependent variable are included as regressors.

The null hypothesis of the test is that there is no first-order autocorrelation. The Durbin–Watson d statistic can take on values between 0 and 4 and under the null d is equal to 2. Values of d less than 2 suggest positive autocorrelation ($\rho > 0$), whereas values of d greater than 2 suggest negative autocorrelation ($\rho < 0$). Calculating the exact distribution of the d statistic is difficult, but empirical upper and lower bounds have been established based on the sample size and the number of regressors. Extended tables for the d statistic have been published by Savin and White (1977). For example, suppose you have a model with 30 observations and three regressors (including the constant term). For a test of the null hypothesis of no autocorrelation versus the alternative of positive autocorrelation, the lower bound of the d statistic is 1.284, and the upper bound is 1.567 at the 5% significance level. You would reject the null if $d < 1.284$, and you would fail to reject if $d > 1.567$. A value falling within the range (1.284, 1.567) leads to no conclusion about whether or not to reject the null hypothesis.

When lagged dependent variables are included among the regressors, the past values of the error term are correlated with those lagged variables at time t, implying that they are not strictly exogenous regressors. The inclusion of covariates that are not strictly exogenous causes the d statistic to be biased toward the acceptance of the null hypothesis. Durbin (1970) suggested an alternative test for models with lagged dependent variables and extended that test to the more general AR(p) serial correlation process

$$u_t = \rho_1 u_{t-1} + \cdots + \rho_p u_{t-p} + \epsilon_t$$

where ϵ_t is i.i.d. with variance σ^2 but is not assumed or required to be normal for the test.

The null hypothesis of Durbin's alternative test is

$$H_0 : \rho_1 = 0, \ldots, \rho_p = 0$$

and the alternative is that at least one of the ρ's is nonzero. Although the null hypothesis was originally derived for an AR(p) process, this test turns out to have power against MA(p) processes as well. Hence, the actual null of this test is that there is no serial correlation up to order p because the MA(p) and the AR(p) models are locally equivalent alternatives under the null. See Godfrey (1988, 113–115) for a discussion of this result.

Durbin's alternative test is in fact a LM test, but it is most easily computed with a Wald test on the coefficients of the lagged residuals in an auxiliary OLS regression of the residuals on their lags and all the covariates in the original regression. Consider the linear regression model

$$y_t = \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + u_t \tag{1}$$

in which the covariates x_1 through x_k are not assumed to be strictly exogenous and u_t is assumed to be i.i.d. and to have finite variance. The process is also assumed to be stationary. (See Wooldridge [2013] for a discussion of stationarity.) Estimating the parameters in (1) by OLS obtains the residuals $\widehat{u}_t$. Next another OLS regression is performed of $\widehat{u}_t$ on $\widehat{u}_{t-1}, \ldots, \widehat{u}_{t-p}$ and the other regressors,

$$\widehat{u}_t = \gamma_1 \widehat{u}_{t-1} + \cdots + \gamma_p \widehat{u}_{t-p} + \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + \epsilon_t \tag{2}$$

where ϵ_t stands for the random-error term in this auxiliary OLS regression. Durbin's alternative test is then obtained by performing a Wald test that $\gamma_1, \ldots, \gamma_p$ are jointly zero. The test can be made robust to an unknown form of heteroskedasticity by using a robust VCE estimator when estimating the regression in (2). When there are only strictly exogenous regressors and $p = 1$, this test is asymptotically equivalent to the Durbin–Watson test.

The Breusch–Godfrey test is also an LM test of the null hypothesis of no autocorrelation versus the alternative that u_t follows an AR(p) or MA(p) process. Like Durbin's alternative test, it is based on the auxiliary regression (2), and it is computed as NR^2, where N is the number of observations and R^2 is the simple R^2 from the regression. This test and Durbin's alternative test are asymptotically equivalent. The test statistic NR^2 has an asymptotic χ^2 distribution with p degrees of freedom. It is valid with or without the strict exogeneity assumption but is not robust to conditional heteroskedasticity, even if a robust VCE is used when fitting (2).

In fitting (2), the values of the lagged residuals will be missing in the initial periods. As noted by Davidson and MacKinnon (1993), the residuals will not be orthogonal to the other covariates in the model in this restricted sample, which implies that the R^2 from the auxiliary regression will not be zero when the lagged residuals are left out. Hence, Breusch and Godfrey's NR^2 version of the test may overreject in small samples. To correct this problem, Davidson and MacKinnon (1993) recommend setting the missing values of the lagged residuals to zero and running the auxiliary regression in (2) over the full sample used in (1). This small-sample correction has become conventional for both the Breusch–Godfrey and Durbin's alternative test, and it is the default for both commands. Specifying the `nomiss0` option overrides this default behavior and treats the initial missing values generated by regressing on the lagged residuals as missing. Hence, `nomiss0` causes these initial observations to be dropped from the sample of the auxiliary regression.

Durbin's alternative test and the Breusch–Godfrey test were originally derived for the case covered by `regress` without the `vce(robust)` option. However, after `regress, vce(robust)` and `newey`, Durbin's alternative test is still valid and can be invoked if the `robust` and `force` options are specified.

▷ Example 1: tests for serial correlation

Using data from Klein (1950), we first fit an OLS regression of consumption on the government wage bill:

```
. use http://www.stata-press.com/data/r13/klein
. tsset yr
        time variable:  yr, 1920 to 1941
                delta:  1 unit
. regress consump wagegovt
```

Source	SS	df	MS	Number of obs =	22
				F(1, 20) =	17.72
Model	532.567711	1	532.567711	Prob > F =	0.0004
Residual	601.207167	20	30.0603584	R-squared =	0.4697
				Adj R-squared =	0.4432
Total	1133.77488	21	53.9892799	Root MSE =	5.4827

consump	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
wagegovt	2.50744	.5957173	4.21	0.000	1.264796	3.750085
_cons	40.84699	3.192183	12.80	0.000	34.18821	47.50577

If we assume that `wagegov` is a strictly exogenous variable, we can use the Durbin–Watson test to check for first-order serial correlation in the errors.

```
. estat dwatson
Durbin-Watson d-statistic(  2,    22) =  .3217998
```

The Durbin–Watson d statistic, 0.32, is far from the center of its distribution ($d = 2.0$). Given 22 observations and two regressors (including the constant term) in the model, the lower 5% bound is about 0.997, much greater than the computed d statistic. Assuming that `wagegov` is strictly exogenous, we can reject the null of no first-order serial correlation. Rejecting the null hypothesis does not necessarily mean an AR process; other forms of misspecification may also lead to a significant test statistic. If we are willing to assume that the errors follow an AR(1) process and that `wagegov` is strictly exogenous, we could refit the model using `arima` or `prais` and model the error process explicitly; see [TS] **arima** and [TS] **prais**.

If we are not willing to assume that `wagegov` is strictly exogenous, we could instead use Durbin's alternative test or the Breusch–Godfrey to test for first-order serial correlation. Because we have only 22 observations, we will use the `small` option.

```
. estat durbinalt, small
Durbin's alternative test for autocorrelation
```

lags(*p*)	F	df	Prob > F
1	35.035	(1, 19)	0.0000

H0: no serial correlation

```
. estat bgodfrey, small
Breusch-Godfrey LM test for autocorrelation
```

lags(*p*)	F	df	Prob > F
1	14.264	(1, 19)	0.0013

H0: no serial correlation

Both tests strongly reject the null of no first-order serial correlation, so we decide to refit the model with two lags of `consump` included as regressors and then rerun `estat durbinalt` and `estat bgodfrey`. Because the revised model includes lagged values of the dependent variable, the Durbin–Watson test is not applicable.

```
. regress consump wagegovt L.consump L2.consump
```

Source	SS	df	MS		
Model	702.660311	3	234.220104	Number of obs	= 20
Residual	85.1596011	16	5.32247507	F(3, 16)	= 44.01
				Prob > F	= 0.0000
Total	787.819912	19	41.4642059	R-squared	= 0.8919
				Adj R-squared	= 0.8716
				Root MSE	= 2.307

consump	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
wagegovt	.6904282	.3295485	2.10	0.052	-.0081835	1.38904
consump						
L1.	1.420536	.197024	7.21	0.000	1.002864	1.838208
L2.	-.650888	.1933351	-3.37	0.004	-1.06074	-.241036
_cons	9.209073	5.006701	1.84	0.084	-1.404659	19.82281

```
. estat durbinalt, small lags(1/2)
Durbin's alternative test for autocorrelation
```

lags(*p*)	F	df	Prob > F
1	0.080	(1, 15)	0.7805
2	0.260	(2, 14)	0.7750

H0: no serial correlation

```
. estat bgodfrey, small lags(1/2)
Breusch-Godfrey LM test for autocorrelation
```

lags(*p*)	F	df	Prob > F
1	0.107	(1, 15)	0.7484
2	0.358	(2, 14)	0.7056

H0: no serial correlation

Although `wagegov` and the constant term are no longer statistically different from zero at the 5% level, the output from `estat durbinalt` and `estat bgodfrey` indicates that including the two lags of `consump` has removed any serial correlation from the errors.

◁

Engle (1982) suggests an LM test for checking for autoregressive conditional heteroskedasticity (ARCH) in the errors. The pth-order ARCH model can be written as

$$\begin{aligned}\sigma_t^2 &= E(u_t^2|u_{t-1},\ldots,u_{t-p}) \\ &= \gamma_0 + \gamma_1 u_{t-1}^2 + \cdots + \gamma_p u_{t-p}^2\end{aligned}$$

To test the null hypothesis of no autoregressive conditional heteroskedasticity (that is, $\gamma_1 = \cdots = \gamma_p = 0$), we first fit the OLS model (1), obtain the residuals $\widehat{u}_t$, and run another OLS regression on the lagged residuals:

$$\widehat{u}_t^2 = \gamma_0 + \gamma_1 \widehat{u}_{t-1}^2 + \cdots + \gamma_p \widehat{u}_{t-p}^2 + \epsilon \tag{3}$$

The test statistic is NR^2, where N is the number of observations in the sample and R^2 is the R^2 from the regression in (3). Under the null hypothesis, the test statistic follows a χ_p^2 distribution.

▷ Example 2: estat archlm

We refit the original model that does not include the two lags of `consump` and then use `estat archlm` to see if there is any evidence that the errors are autoregressive conditional heteroskedastic.

```
. regress consump wagegovt
```

Source	SS	df	MS		
Model	532.567711	1	532.567711	Number of obs	= 22
Residual	601.207167	20	30.0603584	F(1, 20)	= 17.72
				Prob > F	= 0.0004
Total	1133.77488	21	53.9892799	R-squared	= 0.4697
				Adj R-squared	= 0.4432
				Root MSE	= 5.4827

consump	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
wagegovt	2.50744	.5957173	4.21	0.000	1.264796	3.750085
_cons	40.84699	3.192183	12.80	0.000	34.18821	47.50577

```
. estat archlm, lags(1 2 3)
LM test for autoregressive conditional heteroskedasticity (ARCH)
```

lags(p)	chi2	df	Prob > chi2
1	5.543	1	0.0186
2	9.431	2	0.0090
3	9.039	3	0.0288

H0: no ARCH effects *vs.* H1: ARCH(*p*) disturbance

`estat archlm` shows the results for tests of ARCH(1), ARCH(2), and ARCH(3) effects, respectively. At the 5% significance level, all three tests reject the null hypothesis that the errors are not autoregressive conditional heteroskedastic. See [TS] **arch** for information on fitting ARCH models.

◁

Stored results

`estat archlm` stores the following in `r()`:

Scalars

`r(N)`	number of observations	`r(N_gaps)`	number of gaps
`r(k)`	number of regressors		

Macros

`r(lags)`	lag order

Matrices

`r(arch)`	test statistic for each lag order	`r(p)`	two-sided *p*-values
`r(df)`	degrees of freedom		

`estat bgodfrey` stores the following in `r()`:

Scalars

`r(N)`	number of observations	`r(N_gaps)`	number of gaps
`r(k)`	number of regressors		

Macros

`r(lags)`	lag order

Matrices

`r(chi2)`	χ^2 statistic for each lag order	`r(p)`	two-sided p-values
`r(F)`	F statistic for each lag order (`small` only)	`r(df)`	degrees of freedom
`r(df_r)`	residual degrees of freedom (`small` only)		

`estat durbinalt` stores the following in `r()`:

Scalars

`r(N)`	number of observations	`r(N_gaps)`	number of gaps
`r(k)`	number of regressors		

Macros

`r(lags)`	lag order

Matrices

`r(chi2)`	χ^2 statistic for each lag order	`r(p)`	two-sided p-values
`r(F)`	F statistic for each lag order (`small` only)	`r(df)`	degrees of freedom
`r(df_r)`	residual degrees of freedom (`small` only)		

`estat dwatson` stores the following in `r()`:

Scalars

`r(N)`	number of observations	`r(N_gaps)`	number of gaps
`r(k)`	number of regressors	`r(dw)`	Durbin–Watson statistic

Methods and formulas

Consider the regression

$$y_t = \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + u_t \tag{4}$$

in which some of the covariates are not strictly exogenous. In particular, some of the x_{it} may be lags of the dependent variable. We are interested in whether the u_t are serially correlated.

The Durbin–Watson d statistic reported by `estat dwatson` is

$$d = \frac{\sum_{t=1}^{n-1} (\widehat{u}_{t+1} - \widehat{u}_t)^2}{\sum_{t=1}^{n} \widehat{u}_t^2}$$

where $\widehat{u}_t$ represents the residual of the tth observation.

To compute Durbin's alternative test and the Breusch–Godfrey test against the null hypothesis that there is no pth order serial correlation, we fit the regression in (4), compute the residuals, and then fit the following auxiliary regression of the residuals $\widehat{u}_t$ on p lags of $\widehat{u}_t$ and on all the covariates in the original regression in (4):

$$\widehat{u}_t = \gamma_1 \widehat{u}_{t-1} + \cdots + \gamma_p \widehat{u}_{t-p} + \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + \epsilon \tag{5}$$

Durbin's alternative test is computed by performing a Wald test to determine whether the coefficients of $\widehat{u}_{t-1}, \ldots, \widehat{u}_{t-p}$ are jointly different from zero. By default, the statistic is assumed to be distributed $\chi^2(\mathrm{p})$. When `small` is specified, the statistic is assumed to follow an $F(p, N-p-k)$ distribution. The reported p-value is a two-sided p-value. When `robust` is specified, the Wald test is performed using the Huber/White/sandwich estimator of the variance–covariance matrix, and the test is robust to an unspecified form of heteroskedasticity.

The Breusch–Godfrey test is computed as NR^2, where N is the number of observations in the auxiliary regression (5) and R^2 is the R^2 from the same regression (5). Like Durbin's alternative test, the Breusch–Godfrey test is asymptotically distributed $\chi^2(p)$, but specifying `small` causes the p-value to be computed using an $F(p, N-p-k)$.

By default, the initial missing values of the lagged residuals are replaced with zeros, and the auxiliary regression is run over the full sample used in the original regression of (4). Specifying the `nomiss0` option causes these missing values to be treated as missing values, and the observations are dropped from the sample.

Engle's LM test for ARCH(p) effects fits an OLS regression of $\widehat{u}_t^2$ on $\widehat{u}_{t-1}^2, \ldots, \widehat{u}_{t-p}^2$:

$$\widehat{u}_t^2 = \gamma_0 + \gamma_1 \widehat{u}_{t-1}^2 + \cdots + \gamma_p \widehat{u}_{t-p}^2 + \epsilon$$

The test statistic is nR^2 and is asymptotically distributed $\chi^2(p)$.

Acknowledgment

The original versions of `estat archlm`, `estat bgodfrey`, and `estat durbinalt` were written by Christopher F. Baum of the Department of Economics at Boston College and author of the Stata Press books *An Introduction to Modern Econometrics Using Stata* and *An Introduction to Stata Programming*.

James Durbin (1923–2012) was a British statistician who was born in Wigan, near Manchester. He studied mathematics at Cambridge and after military service and various research posts joined the London School of Economics in 1950. Later in life, he was also affiliated with University College London. His many contributions to statistics centered on serial correlation, time series (including major contributions to structural or unobserved components models), sample survey methodology, goodness-of-fit tests, and sample distribution functions, with emphasis on applications in the social sciences. He served terms as president of the Royal Statistical Society and the International Statistical Institute.

Geoffrey Stuart Watson (1921–1998) was born in Victoria, Australia, and earned degrees at Melbourne University and North Carolina State University. After a visit to the University of Cambridge, he returned to Australia, working at Melbourne and then the Australian National University. Following periods at Toronto and Johns Hopkins, he settled at Princeton. Throughout his wide-ranging career, he made many notable accomplishments and important contributions, including the Durbin–Watson test for serial correlation, the Nadaraya–Watson estimator in nonparametric regression, and methods for analyzing directional data.

Leslie G. Godfrey (1946–) was born in London and earned degrees at the Universities of Exeter and London. He is now a professor of econometrics at the University of York. His interests center on implementation and interpretation of tests of econometric models, including nonnested models.

Trevor Stanley Breusch (1949–) was born in Queensland and earned degrees at the University of Queensland and Australian National University (ANU). After a post at the University of Southampton, he returned to work at ANU. His background is in econometric methods and his recent interests include political values and social attitudes, earnings and income, and measurement of underground economic activity.

Title

#review — Review previous commands

Syntax Description Remarks and examples

Syntax

```
#review [ #1 [ #2 ] ]
```

Description

The `#review` command displays the last few lines typed at the terminal.

Remarks and examples

`#review` (pronounced *pound-review*) is a Stata preprocessor command. `#`*command*s do not generate a return code or generate ordinary Stata errors. The only error message associated with `#`*command*s is "unrecognized #command".

The `#review` command displays the last few lines typed at the terminal. If no arguments follow `#review`, the last five lines typed at the terminal are displayed. The first argument specifies the number of lines to be reviewed, so `#review 10` displays the last 10 lines typed. The second argument specifies the number of lines to be displayed, so `#review 10 5` displays five lines, starting at the 10th previous line.

Stata reserves a buffer for `#review` lines and stores as many previous lines in the buffer as will fit, rolling out the oldest line to make room for the newest. Requests to `#review` lines no longer stored will be ignored. Only lines typed at the terminal are placed in the `#review` buffer. See **[U] 10.5 Editing previous lines in Stata**.

▷ Example 1

Typing `#review` by itself will show the last five lines you typed at the terminal:

```
. #review
5 use mydata
4 * comments go into the #review buffer, too
3 describe
2 tabulate marriage educ [freq=number]
1 tabulate marriage educ [freq=number], chi2
. _
```

Typing `#review 15 2` shows the 15th and 14th previous lines:

```
. #review 15 2
15 replace x=. if x<200
14 summarize x
. _
```

◁

Title

roc — Receiver operating characteristic (ROC) analysis

Description Reference

Description

ROC analysis quantifies the accuracy of diagnostic tests or other evaluation modalities used to discriminate between two states or conditions, which are here referred to as normal and abnormal or control and case. The discriminatory accuracy of a diagnostic test is measured by its ability to correctly classify known normal and abnormal subjects. For this reason, we often refer to the diagnostic test as a classifier. The analysis uses the ROC curve, a graph of the sensitivity versus 1 − specificity of the diagnostic test. The sensitivity is the fraction of positive cases that are correctly classified by the diagnostic test, whereas the specificity is the fraction of negative cases that are correctly classified. Thus the sensitivity is the true-positive rate, and the specificity is the true-negative rate.

There are six ROC commands:

Command	Entry	Description
`roccomp`	[R] **roccomp**	Tests of equality of ROC areas
`rocgold`	[R] **roccomp**	Tests of equality of ROC areas against a standard ROC curve
`rocfit`	[R] **rocfit**	Parametric ROC models
`rocreg`	[R] **rocreg**	Nonparametric and parametric ROC regression models
`rocregplot`	[R] **rocregplot**	Plot marginal and covariate-specific ROC curves
`roctab`	[R] **roctab**	Nonparametric ROC analysis

Postestimation commands are available after `rocfit` and `rocreg`; see [R] **rocfit postestimation** and [R] **rocreg postestimation**.

Both nonparametric and parametric (semiparametric) methods have been suggested for generating the ROC curve. The `roctab` command performs nonparametric ROC analysis for a single classifier. `roccomp` extends the nonparametric ROC analysis function of `roctab` to situations where we have multiple diagnostic tests of interest to be compared and tested. The `rocgold` command also provides ROC analysis for multiple classifiers. `rocgold` compares each classifier's ROC curve to a "gold standard" ROC curve and makes adjustments for multiple comparisons in the analysis. Both `rocgold` and `roccomp` also allow parametric estimation of the ROC curve through a binormal fit. In a binormal fit, both the control and the case populations are normal.

The `rocfit` command also estimates the ROC curve of a classifier through a binormal fit. Unlike `roctab`, `roccomp`, and `rocgold`, `rocfit` is an estimation command. In postestimation, graphs of the ROC curve and confidence bands can be produced. Additional tests on the parameters can also be conducted.

ROC analysis can be interpreted as a two-stage process. First, the control distribution of the classifier is estimated, assuming a normal model or using a distribution-free estimation technique. The classifier is standardized using the control distribution to 1 − percentile value, the false-positive rate. Second, the ROC curve is estimated as the case distribution of the standardized classifier values.

Covariates may affect both stages of ROC analysis. The first stage may be affected, yielding a covariate-adjusted ROC curve. The second stage may also be affected, producing multiple covariate-specific ROC curves.

The rocreg command performs ROC analysis under both types of covariate effects. Both parametric (semiparametric) and nonparametric methods may be used by rocreg. Like rocfit, rocreg is an estimation command and provides many postestimation capabilities.

The global performance of a diagnostic test is commonly summarized by the area under the ROC curve (AUC). This area can be interpreted as the probability that the result of a diagnostic test of a randomly selected abnormal subject will be greater than the result of the same diagnostic test from a randomly selected normal subject. The greater the AUC, the better the global performance of the diagnostic test. Each of the ROC commands provides computation of the AUC.

Citing a lack of clinical relevance for the AUC, other ROC summary measures have been suggested. These include the partial area under the ROC curve for a given false-positive rate t [pAUC(t)]. This is the area under the ROC curve from the false-positive rate of 0 to t. The ROC value at a particular false-positive rate and the false-positive rate for a particular ROC value are also useful summary measures for the ROC curve. These three measures are directly estimated by rocreg during the model fit or postestimation stages. Point estimates of ROC value are computed by the other ROC commands, but no standard errors are reported.

See Pepe (2003) for a discussion of ROC analysis. Pepe has posted Stata datasets and programs used to reproduce results presented in the book (http://www.stata.com/bookstore/pepe.html).

Syntax

Test equality of ROC areas

`roccomp` *refvar classvar* [*classvars*] [*if*] [*in*] [*weight*] [`,` *roccomp_options*]

Test equality of ROC area against a standard ROC curve

`rocgold` *refvar goldvar classvar* [*classvars*] [*if*] [*in*] [*weight*] [`,` *rocgold_options*]

roccomp_options	Description
Main	
`by(`*varname*`)`	split into groups by variable
`test(`*matname*`)`	use contrast matrix for comparing ROC areas
`graph`	graph the ROC curve
`norefline`	suppress plotting the 45-degree reference line
`separate`	place each ROC curve on its own graph
`summary`	report the area under the ROC curve
`binormal`	estimate areas by using binormal distribution assumption
`line#opts(`*cline_options*`)`	affect rendition of the #th binormal fit line
`level(#)`	set confidence level; default is `level(95)`
Plot	
`plot#opts(`*plot_options*`)`	affect rendition of the #th ROC curve
Reference line	
`rlopts(`*cline_options*`)`	affect rendition of the reference line
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

rocgold_options	Description
Main	
sidak	adjust the significance probability by using Šidák's method
test(*matname*)	use contrast matrix for comparing ROC areas
graph	graph the ROC curve
norefline	suppress plotting the 45-degree reference line
separate	place each ROC curve on its own graph
summary	report the area under the ROC curve
binormal	estimate areas by using binormal distribution assumption
line#opts(*cline_options*)	affect rendition of the #th binormal fit line
level(#)	set confidence level; default is level(95)
Plot	
plot#opts(*plot_options*)	affect rendition of the #th ROC curve; plot 1 is the "gold standard"
Reference line	
rlopts(*cline_options*)	affect rendition of the reference line
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than by() documented in [G-3] ***twoway_options***

plot_options	Description
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
cline_options	change the look of the line

fweights are allowed; see [U] **11.1.6 weight**.

roccomp

Statistics > Epidemiology and related > ROC analysis > Test equality of two or more ROC areas

rocgold

Statistics > Epidemiology and related > ROC analysis > Test equality of ROC area against gold standard

Description

The above commands are used to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data.

The two variables *refvar* and *classvar* must be numeric. The reference variable indicates the true state of the observation, such as diseased and nondiseased or normal and abnormal, and must be coded as 0 and 1. The rating or outcome of the diagnostic test or test modality is recorded in *classvar*, which must be at least ordinal, with higher values indicating higher risk.

roccomp tests the equality of two or more ROC areas obtained from applying two or more test modalities to the same sample or to independent samples. roccomp expects the data to be in wide form when comparing areas estimated from the same sample and in long form for areas estimated from independent samples.

rocgold independently tests the equality of the ROC area of each of several test modalities, specified by *classvar*, against a "gold standard" ROC curve, *goldvar*. For each comparison, rocgold reports the raw and the Bonferroni-adjusted significance probability. Optionally, Šidák's adjustment for multiple comparisons can be obtained.

See [R] **rocfit** and [R] **rocreg** for commands that fit maximum-likelihood ROC models.

Options

Main

by(*varname*) (roccomp only) is required when comparing independent ROC areas. The by() variable identifies the groups to be compared.

sidak (rocgold only) requests that the significance probability be adjusted for the effect of multiple comparisons by using Šidák's method. Bonferroni's adjustment is reported by default.

test(*matname*) specifies the contrast matrix to be used when comparing ROC areas. By default, the null hypothesis that all areas are equal is tested.

graph produces graphical output of the ROC curve.

norefline suppresses plotting the 45-degree reference line from the graphical output of the ROC curve.

separate is meaningful only with roccomp and specifies that each ROC curve be placed on its own graph rather than one curve on top of the other.

summary reports the area under the ROC curve, its standard error, and its confidence interval. This option is needed only when also specifying graph.

binormal specifies that the areas under the ROC curves to be compared should be estimated using the binormal distribution assumption. By default, areas to be compared are computed using the trapezoidal rule.

line#opts(*cline_options*) affects the rendition of the line representing the #th ROC curve drawn using the binormal distribution assumption; see [G-3] ***cline_options***. These lines are drawn only if the binormal option is specified.

level(#) specifies the confidence level, as a percentage, for the confidence intervals. The default is level(95) or as set by set level; see [R] **level**.

Plot

plot#opts(*plot_options*) affects the rendition of the #th ROC curve—the curve's plotted points connected by lines. The *plot_options* can affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] ***marker_options***, [G-3] ***marker_label_options***, and [G-3] ***cline_options***.

For rocgold, plot1opts() are applied to the ROC for the gold standard.

Reference line

rlopts(*cline_options*) affects the rendition of the reference line; see [G-3] ***cline_options***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***. These include options for titling the graph (see [G-3] ***title_options***), options for saving the graph to disk (see [G-3] ***saving_option***), and the `by()` option (see [G-3] ***by_option***).

Remarks and examples

Remarks are presented under the following headings:

Introduction
Comparing areas under the ROC curve
Correlated data
Independent data
Comparing areas with a gold standard

Introduction

`roccomp` provides comparison of the ROC curves of multiple classifiers. `rocgold` compares the ROC curves of multiple classifiers with a single "gold standard" classifier. Adjustment of inference for multiple comparisons is also provided by `rocgold`.

See Pepe (2003) for a discussion of ROC analysis. Pepe has posted Stata datasets and programs used to reproduce results presented in the book (http://www.stata.com/bookstore/pepe.html).

Comparing areas under the ROC curve

The area under multiple ROC curves can be compared by using `roccomp`. The command syntax is slightly different if the ROC curves are correlated (that is, different diagnostic tests are applied to the same sample) or independent (that is, diagnostic tests are applied to different samples).

Correlated data

▷ Example 1

Hanley and McNeil (1983) presented data from an evaluation of two computer algorithms designed to reconstruct CT images from phantoms. We will call these two algorithms' modalities 1 and 2. A sample of 112 phantoms was selected; 58 phantoms were considered normal, and the remaining 54 were abnormal. Each of the two modalities was applied to each phantom, and the resulting images were rated by a reviewer using a six-point scale: 1 = definitely normal, 2 = probably normal, 3 = possibly normal, 4 = possibly abnormal, 5 = probably abnormal, and 6 = definitely abnormal. Because each modality was applied to the same sample of phantoms, the two sets of outcomes are correlated.

We list the first 7 observations:

```
. use http://www.stata-press.com/data/r13/ct
. list in 1/7, sep(0)
```

	mod1	mod2	status
1.	2	1	0
2.	5	5	1
3.	2	1	0
4.	2	3	0
5.	5	6	1
6.	2	2	0
7.	3	2	0

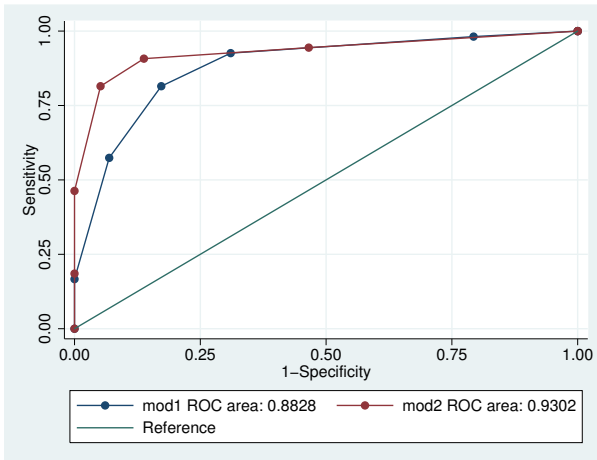
The data are in wide form, which is required when dealing with correlated data. Each observation corresponds to one phantom. The variable `mod1` identifies the rating assigned for the first modality, and `mod2` identifies the rating assigned for the second modality. The true status of the phantoms is given by `status=0` if they are normal and `status=1` if they are abnormal. The observations with at least one missing rating were dropped from the analysis.

We plot the two ROC curves and compare their areas.

```
. roccomp status mod1 mod2, graph summary
```

	Obs	ROC Area	Std. Err.	−Asymptotic Normal− [95% Conf.	Interval]
mod1	112	0.8828	0.0317	0.82067	0.94498
mod2	112	0.9302	0.0256	0.88005	0.98042

```
Ho: area(mod1) = area(mod2)
    chi2(1) =     2.31       Prob>chi2 =   0.1282
```



By default, `roccomp`, with the `graph` option specified, plots the ROC curves on the same graph. Optionally the curves can be plotted side by side, each on its own graph, by also specifying `separate`.

For each curve, `roccomp` reports summary statistics and provides a test for the equality of the area under the curves, using an algorithm suggested by DeLong, DeLong, and Clarke-Pearson (1988).

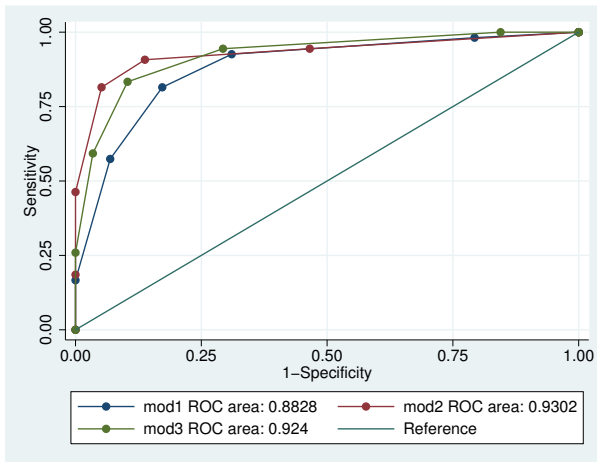
Although the area under the ROC curve for modality 2 is larger than that of modality 1, the chi-squared test yielded a significance probability of 0.1282, suggesting that there is no significant difference between these two areas.

The `roccomp` command can also be used to compare more than two ROC areas. To illustrate this, we modified the previous dataset by including a fictitious third modality.

```
. use http://www.stata-press.com/data/r13/ct2
. roccomp status mod1 mod2 mod3, graph summary
```

	Obs	ROC Area	Std. Err.	−Asymptotic Normal− [95% Conf.	Interval]
mod1	112	0.8828	0.0317	0.82067	0.94498
mod2	112	0.9302	0.0256	0.88005	0.98042
mod3	112	0.9240	0.0241	0.87670	0.97132

```
Ho: area(mod1) = area(mod2) = area(mod3)
    chi2(2) =     6.54       Prob>chi2 =   0.0381
```



By default, `roccomp` tests whether the areas under the ROC curves are all equal. Other comparisons can be tested by creating a contrast matrix and specifying `test(`*matname*`)`, where *matname* is the name of the contrast matrix.

For example, assume that we are interested in testing whether the area under the ROC for `mod1` is equal to that of `mod3`. To do this, we can first create an appropriate contrast matrix and then specify its name with the `test()` option.

Of course, this is a trivial example because we could have just specified

```
. roccomp status mod1 mod3
```

without including `mod2` to obtain the same test results. However, for illustration, we will continue with this example.

The contrast matrix must have its number of columns equal to the number of *classvars* (that is, the total number of ROC curves) and a number of rows less than or equal to the number of *classvars*, and the elements of each row must add to zero.

```
. matrix C=(1,0,-1)
. roccomp status mod1 mod2 mod3, test(C)
                              ROC                    -Asymptotic Normal--
                    Obs       Area     Std. Err.      [95% Conf. Interval]
---------------------------------------------------------------------------
mod1                112     0.8828       0.0317        0.82067     0.94498
mod2                112     0.9302       0.0256        0.88005     0.98042
mod3                112     0.9240       0.0241        0.87670     0.97132
---------------------------------------------------------------------------
Ho: Comparison as defined by contrast matrix: C
    chi2(1) =     5.25       Prob>chi2 =    0.0220
```

Although all three areas are reported, the comparison is made using the specified contrast matrix.

Perhaps more interesting would be a comparison of the area from `mod1` and the average area of `mod2` and `mod3`.

```
. matrix C=(1,-.5,-.5)
. roccomp status mod1 mod2 mod3, test(C)
                              ROC                    -Asymptotic Normal--
                    Obs       Area     Std. Err.      [95% Conf. Interval]
---------------------------------------------------------------------------
mod1                112     0.8828       0.0317        0.82067     0.94498
mod2                112     0.9302       0.0256        0.88005     0.98042
mod3                112     0.9240       0.0241        0.87670     0.97132
---------------------------------------------------------------------------
Ho: Comparison as defined by contrast matrix: C
    chi2(1) =     3.43       Prob>chi2 =    0.0642
```

Other contrasts could be made. For example, we could test if `mod3` is different from at least one of the other two by first creating the following contrast matrix:

```
. matrix C=(-1,0,1 \ 0,-1,1)
. mat list C
C[2,3]
    c1  c2  c3
r1  -1   0   1
r2   0  -1   1
```

◁

Independent data

▷ Example 2

In example 1, we noted that because each test modality was applied to the same sample of phantoms, the classification outcomes were correlated. Now assume that we have collected the same data presented by Hanley and McNeil (1983), except that we applied the first test modality to one sample of phantoms and the second test modality to a different sample of phantoms. The resulting measurements are now considered independent.

Here are a few of the observations.

```
. use http://www.stata-press.com/data/r13/ct3
. list in 1/7, sep(0)
```

	pop	status	rating	mod
1.	12	0	1	1
2.	31	0	1	2
3.	1	1	1	1
4.	3	1	1	2
5.	28	0	2	1
6.	19	0	2	2
7.	3	1	2	1

The data are in long form, which is required when dealing with independent data. The data consist of 24 observations: 6 observations corresponding to abnormal phantoms and 6 to normal phantoms evaluated using the first modality, and similarly 6 observations corresponding to abnormal phantoms and 6 to normal phantoms evaluated using the second modality. The number of phantoms corresponding to each observation is given by the `pop` variable. Once again we have frequency-weighted data. The variable `mod` identifies the modality, and `rating` is the assigned classification.

We can better view our data by using the `table` command.

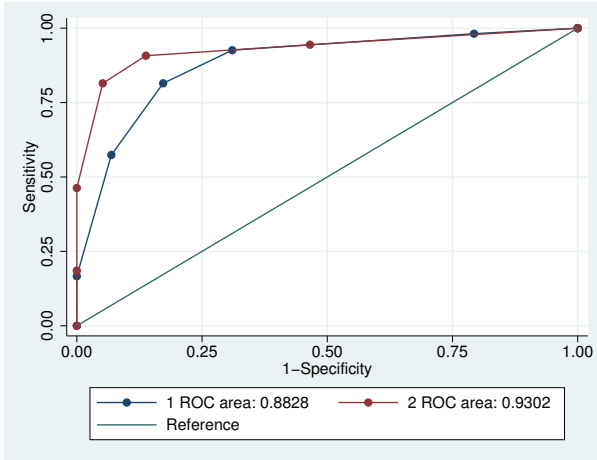
```
. table status rating [fw=pop], by(mod) row col
```

mod and status	rating 1	2	3	4	5	6	Total
1							
0	12	28	8	6	4		58
1	1	3	6	13	22	9	54
Total	13	31	14	19	26	9	112
2							
0	31	19	5	3			58
1	3	2	5	19	15	10	54
Total	34	21	10	22	15	10	112

The `status` variable indicates the true status of the phantoms: `status` $= 0$ if they are normal and `status` $= 1$ if they are abnormal.

We now compare the areas under the two ROC curves.

```
. roccomp status rating [fw=pop], by(mod) graph summary
                                 ROC                    -Asymptotic Normal--
mod                 Obs       Area     Std. Err.      [95% Conf. Interval]
-------------------------------------------------------------------------------
1                   112     0.8828       0.0317        0.82067     0.94498
2                   112     0.9302       0.0256        0.88005     0.98042
-------------------------------------------------------------------------------
Ho: area(1) = area(2)
    chi2(1) =     1.35       Prob>chi2 =    0.2447
```



Comparing areas with a gold standard

The area under multiple ROC curves can be compared with a gold standard using `rocgold`. The command syntax is similar to that of `roccomp`. The tests are corrected for the effect of multiple comparisons.

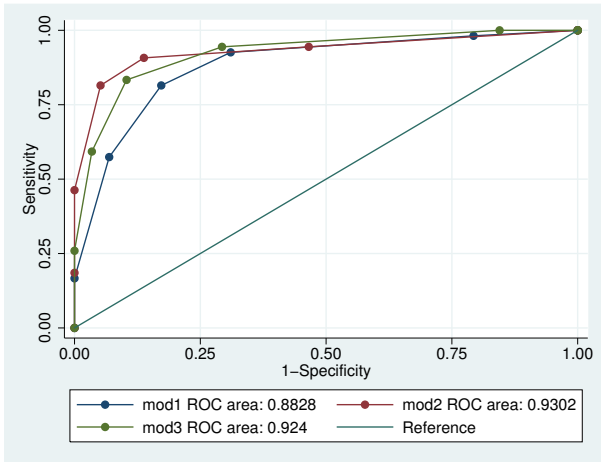
▷ Example 3

We will use the same data (presented by Hanley and McNeil [1983]) as in the `roccomp` examples. Let's assume that the first modality is considered to be the standard against which both the second and third modalities are compared.

We want to plot and compare both the areas of the ROC curves of `mod2` and `mod3` with `mod1`. Because we consider `mod1` to be the gold standard, it is listed first after the reference variable in the `rocgold` command line.

```
. use http://www.stata-press.com/data/r13/ct2
. rocgold status mod1 mod2 mod3, graph summary
```

	ROC Area	Std. Err.	chi2	df	Pr>chi2	Bonferroni Pr>chi2
mod1 (standard)	0.8828	0.0317				
mod2	0.9302	0.0256	2.3146	1	0.1282	0.2563
mod3	0.9240	0.0241	5.2480	1	0.0220	0.0439



Equivalently, we could have done this in two steps by using the `roccomp` command.

```
. roccomp status mod1 mod2, graph summary
. roccomp status mod1 mod3, graph summary
```

Stored results

`roccomp` stores the following in `r()`:

Scalars

`r(N_g)`	number of groups	`r(df)`	χ^2 degrees of freedom
`r(p)`	significance probability	`r(chi2)`	χ^2

Matrices

`r(V)`	variance–covariance matrix

`rocgold` stores the following in `r()`:

Scalars

`r(N_g)`	number of groups

Matrices

`r(V)`	variance–covariance matrix	`r(p)`	significance-probability vector
`r(chi2)`	χ^2 vector	`r(p_adj)`	adjusted significance-probability vector
`r(df)`	χ^2 degrees-of-freedom vector		

Methods and formulas

Assume that we applied a diagnostic test to each of N_n normal and N_a abnormal subjects. Further assume that the higher the outcome value of the diagnostic test, the higher the risk of the subject being abnormal. Let $\widehat{\theta}$ be the estimated area under the curve, and let $X_i, i = 1, 2, \ldots, N_a$ and $Y_j, j = 1, 2, \ldots, N_n$ be the values of the diagnostic test for the abnormal and normal subjects, respectively.

Areas under ROC curves are compared using an algorithm suggested by DeLong, DeLong, and Clarke-Pearson (1988). Let $\widehat{\boldsymbol{\theta}} = (\widehat{\theta^1}, \widehat{\theta^2}, \ldots, \widehat{\theta^k})$ be a vector representing the areas under k ROC curves. See *Methods and formulas* in [R] **roctab** for the definition of these area estimates.

For the rth area, define

$$V_{10}^r(X_i) = \frac{1}{N_n} \sum_{j=1}^{N_n} \psi(X_i^r, Y_j^r)$$

and for each normal subject, j, define

$$V_{01}^r(Y_j) = \frac{1}{N_a} \sum_{i=1}^{N_a} \psi(X_i^r, Y_j^r)$$

where

$$\psi(X^r, Y^r) = \begin{cases} 1 & Y^r < X^r \\ \frac{1}{2} & Y^r = X^r \\ 0 & Y^r > X^r \end{cases}$$

Define the $k \times k$ matrix $\mathbf{S_{10}}$ such that the (r, s)th element is

$$S_{10}^{r,s} = \frac{1}{N_a - 1} \sum_{i=1}^{N_a} \{V_{10}^r(X_i) - \widehat{\theta^r}\}\{V_{10}^s(X_i) - \widehat{\theta^s}\}$$

and $\mathbf{S_{01}}$ such that the (r, s)th element is

$$S_{01}^{r,s} = \frac{1}{N_n - 1} \sum_{j=1}^{N_n} \{V_{01}^r(Y_i) - \widehat{\theta^r}\}\{V_{01}^s(Y_i) - \widehat{\theta^s}\}$$

Then the covariance matrix is

$$S = \frac{1}{N_a} S_{10} + \frac{1}{N_n} S_{01}$$

Let $\mathbf{L}$ be a contrast matrix defining the comparison, so that

$$(\widehat{\theta} - \theta)' \mathbf{L}' \left(\mathbf{L} \mathbf{S} \mathbf{L}'\right)^{-1} \mathbf{L} (\widehat{\theta} - \theta)$$

has a chi-squared distribution with degrees of freedom equal to the rank of $\mathbf{LSL}'$.

maximize_options	control the maximization process; seldom used

`fp`, is allowed; see **[U] 11.1.10 Prefix commands**.

`fweight`s are allowed; see **[U] 11.1.6 weight**.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Epidemiology and related > ROC analysis > Parametric ROC analysis without covariates

Description

`rocfit` fits maximum-likelihood ROC models assuming a binormal distribution of the latent variable.

The two variables *refvar* and *classvar* must be numeric. The reference variable indicates the true state of the observation, such as diseased and nondiseased or normal and abnormal, and must be coded as 0 and 1. The rating or outcome of the diagnostic test or test modality is recorded in *classvar*, which must be at least ordinal, with higher values indicating higher risk.

See [R] **roc** for other commands designed to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data.

Options

Model

`continuous(#)` specifies that the continuous *classvar* be divided into # groups of approximately equal length. This option is required when *classvar* takes on more than 20 distinct values.

`continuous(.)` may be specified to indicate that *classvar* be used as it is, even though it could have more than 20 distinct values.

`generate(`*newvar*`)` specifies the new variable that is to contain the values indicating the groups produced by `continuous(#)`. `generate()` may be specified only with `continuous()`.

SE

`vce(`*vcetype*`)` specifies the type of standard error reported. *vcetype* may be either `oim` or `opg`; see [R] ***vce_option***.

Reporting

`level(#)`; see [R] **estimation options**.

Maximization

maximize_options: `difficult`, `technique(`*algorithm_spec*`)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(`*init_specs*`)`; see [R] **maximize**. These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default *vcetype* to `vce(opg)`.

Remarks and examples

Dorfman and Alf (1969) developed a generalized approach for obtaining maximum likelihood estimates of the parameters for a smooth fitting ROC curve. The most commonly used method for ordinal data, and the one implemented here, is based upon the binormal model; see Pepe (2003), Pepe, Longton, and Janes (2009), and Janes, Longton, and Pepe (2009) for methods of ROC analysis for continuous data, including methods for adjusting for covariates.

The model assumes the existence of an unobserved, continuous, latent variable that is normally distributed (perhaps after a monotonic transformation) in both the normal and abnormal populations with means μ_n and μ_a and variances σ_n^2 and σ_a^2, respectively. The model further assumes that the K categories of the rating variable result from partitioning the unobserved latent variable by $K-1$ fixed boundaries. The method fits a straight line to the empirical ROC points plotted using normal probability scales on both axes. Maximum likelihood estimates of the line's slope and intercept and the $K-1$ boundaries are obtained simultaneously. See *Methods and formulas* for details.

The intercept from the fitted line is a measurement of $(\mu_a - \mu_n)/\sigma_a$, and the slope measures σ_n/σ_a.

Thus the intercept is the standardized difference between the two latent population means, and the slope is the ratio of the two standard deviations. The null hypothesis that there is no difference between the two population means is evaluated by testing that the intercept $= 0$, and the null hypothesis that the variances in the two populations are equal is evaluated by testing that the slope $= 1$.

▷ Example 1

We use Hanley and McNeil's (1982) dataset, described in example 1 of [R] **roctab**, to fit a smooth ROC curve assuming a binormal model.

```
. use http://www.stata-press.com/data/r13/hanley
. rocfit disease rating
Fitting binormal model:
Iteration 0:   log likelihood = -123.68069
Iteration 1:   log likelihood = -123.64867
Iteration 2:   log likelihood = -123.64855
Iteration 3:   log likelihood = -123.64855
Binormal model of disease on rating              Number of obs   =        109
Goodness-of-fit chi2(2) =        0.21
Prob > chi2             =      0.9006
Log likelihood          =  -123.64855
```

d(a)	1.907771	0.259822	1.398530	2.417012

(*) z test for slope==1

`rocfit` outputs the MLE for the intercept and slope of the fitted regression line along with, here, four boundaries (because there are five ratings) labeled `/cut1` through `/cut4`. Also `rocfit` computes and reports four indices based on the fitted ROC curve: the area under the curve (labeled `ROC area`), $\delta(m)$ (labeled `delta(m)`), d_e (labeled `d(e)`), and d_a (labeled `d(a)`). More information about these indices can be found in *Methods and formulas* and in Erdreich and Lee (1981).

◁

Stored results

rocfit stores the following in e():

Scalars

e(N)	number of observations
e(k)	number of parameters
e(k_eq)	number of equations in e(b)
e(k_eq_model)	number of equations in overall model test
e(k_dv)	number of dependent variables
e(df_m)	model degrees of freedom
e(ll)	log likelihood
e(chi2_gf)	goodness-of-fit χ^2
e(df_gf)	goodness-of-fit degrees of freedom
e(p_gf)	χ^2 goodness-of-fit significance probability
e(area)	area under the ROC curve
e(se_area)	standard error for the area under the ROC curve
e(deltam)	delta(m)
e(se_delm)	standard area for delta(m)
e(de)	d(e) index
e(se_de)	standard error for d(e) index
e(da)	d(a) index
e(se_da)	standard error for d(a) index
e(rank)	rank of e(V)
e(ic)	number of iterations
e(rc)	return code
e(converged)	1 if converged, 0 otherwise

Macros

e(cmd)	rocfit
e(cmdline)	command as typed
e(depvar)	*refvar* and *classvar*
e(wtype)	weight type
e(wexp)	weight expression
e(title)	title in estimation output
e(chi2type)	GOF; type of model χ^2 test
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(opt)	type of optimization
e(which)	max or min; whether optimizer is to perform maximization or minimization
e(ml_method)	type of ml method
e(user)	name of likelihood-evaluator program
e(technique)	maximization technique
e(properties)	b V

Matrices

e(b)	coefficient vector
e(ilog)	iteration log (up to 20 iterations)
e(gradient)	gradient vector
e(V)	variance–covariance matrix of the estimators

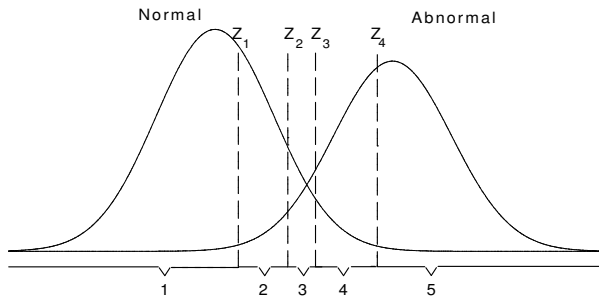
Functions

e(sample)	marks estimation sample

Methods and formulas

Dorfman and Alf (1969) developed a general procedure for obtaining maximum likelihood estimates of the parameters of a smooth-fitting ROC curve. The most common method, and the one implemented in Stata, is based upon the binormal model.

The model assumes that there is an unobserved continuous latent variable that is normally distributed in both the normal and abnormal populations. The idea is better explained with the following illustration:



The latent variable is assumed to be normally distributed for both the normal and abnormal subjects, perhaps after a monotonic transformation, with means μ_n and μ_a and variances σ_n^2 and σ_a^2, respectively.

This latent variable is assumed to be partitioned into the k categories of the rating variable by $k-1$ fixed boundaries. In the above figure, the $k=5$ categories of the rating variable identified on the bottom result from the partition of the four boundaries Z_1 through Z_4.

Let R_j for $j=1,2,\ldots,k$ indicate the categories of the rating variable, let $i=1$ if the subject belongs to the normal group, and let $i=2$ if the subject belongs to the abnormal group.

Then

$$p(R_j|i=1) = F(Z_j) - F(Z_{j-1})$$

where $Z_k = (x_k - \mu_n)/\sigma_n$, F is the cumulative normal distribution, $F(Z_0)=0$, and $F(Z_k)=1$. Also,

$$p(R_j|i=2) = F(bZ_j - a) - F(bZ_{j-1} - a)$$

where $b = \sigma_n/\sigma_a$ and $a = (\mu_a - \mu_n)/\sigma_a$.

The parameters a, b and the $k-1$ fixed boundaries Z_j are simultaneously estimated by maximizing the log-likelihood function

$$\log L = \sum_{i=1}^{2}\sum_{j=1}^{k} r_{ij}\log\{p(R_j|i)\}$$

where r_{ij} is the number of R_js in group i.

The area under the fitted ROC curve is computed as

$$\Phi\left(\frac{a}{\sqrt{1+b^2}}\right)$$

where Φ is the standard normal cumulative distribution function.

Point estimates for the ROC curve indices are as follows:

$$\delta(m) = \frac{a}{b} \qquad d_e = \frac{2a}{b+1} \qquad d_a = \frac{a\sqrt{2}}{\sqrt{1+b^2}}$$

Variances for these indices are computed using the delta method.

The $\delta(m)$ estimates $(\mu_a - \mu_n)/\sigma_n$, d_e estimates $2(\mu_a - \mu_n)/(\sigma_a - \sigma_n)$, and d_a estimates $\sqrt{2}(\mu_a - \mu_n)/(\sigma_a^2 - \sigma_n^2)^2$.

Simultaneous confidence bands for the entire curve are obtained, as suggested by Ma and Hall (1993), by first obtaining Working–Hotelling (1929) confidence bands for the fitted straight line in normal probability coordinates and then transforming them back to ROC coordinates.

Title

rocfit postestimation — Postestimation tools for rocfit

Description Syntax for rocplot Menu Options for rocplot
Remarks and examples Also see

Description

The following command is of special interest after `rocfit`:

Command	Description
`rocplot`	plot the fitted ROC curve and simultaneous confidence bands

The following standard postestimation commands are also available:

Command	Description
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estimates`	cataloging estimation results
* `lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
* `test`	Wald tests of simple and composite linear hypotheses

*See *Using lincom and test* below.

Special-interest postestimation command

`rocplot` plots the fitted ROC curve and simultaneous confidence bands.

Syntax for rocplot

```
rocplot [ , rocplot_options ]
```

rocplot_options	Description
Main	
`confband`	display confidence bands
`norefline`	suppress plotting the reference line
`level(#)`	set confidence level; default is `level(95)`
Plot	
`plotopts(`*plot_options*`)`	affect rendition of the ROC points
Fit line	
`lineopts(`*cline_options*`)`	affect rendition of the fitted ROC line
CI plot	
`ciopts(`*area_options*`)`	affect rendition of the confidence bands
Reference line	
`rlopts(`*cline_options*`)`	affect rendition of the reference line
Add plots	
`addplot(`*plot*`)`	add other plots to the generated graph
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

plot_options	Description
marker_options	change look of markers (color, size, etc.)
marker_label_options	add marker labels; change look or position
cline_options	change the look of the line

Menu

Statistics > Epidemiology and related > ROC analysis > ROC curves after rocfit

Options for rocplot

Main

`confband` specifies that simultaneous confidence bands be plotted around the ROC curve.

`norefline` suppresses plotting the 45-degree reference line from the graphical output of the ROC curve.

`level(#)` specifies the confidence level, as a percentage, for the confidence bands. The default is `level(95)` or as set by `set level`; see [R] **level**.

Plot

`plotopts(`*plot_options*`)` affects the rendition of the plotted ROC points, including the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected. For the full list of available *plot_options*, see [G-3] ***marker_options***, [G-3] ***marker_label_options***, and [G-3] ***cline_options***.

Fit line

`lineopts(`*cline_options*`)` affects the rendition of the fitted ROC line; see [G-3] ***cline_options***.

CI plot

`ciopts(`*area_options*`)` affects the rendition of the confidence bands; see [G-3] ***area_options***.

Reference line

`rlopts(`*cline_options*`)` affects the rendition of the reference line; see [G-3] ***cline_options***.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples

Remarks are presented under the following headings:

Using lincom and test
Using rocplot

Using lincom and test

`intercept`, `slope`, and `cut#`, shown in example 1 of [R] **rocfit**, are equation names and not variable names, so they need to be referenced as described in *Special syntaxes after multiple-equation estimation* of [R] **test**. For example, instead of typing

```
. test intercept
intercept not found
r(111);
```

you should type

```
. test [intercept]_cons
 ( 1)  [intercept]_cons = 0

           chi2(  1) =   28.48
         Prob > chi2 =    0.0000
```

Using rocplot

▷ Example 1

In example 1 of [R] **rocfit**, we fit a ROC curve by typing `rocfit disease rating`.

In the output table for our model, we are testing whether the variances of the two latent populations are equal by testing that the slope = 1.

We plot the fitted ROC curve.

```
. rocplot, confband
```

np_options	Description
Model	
`auc`	estimate total area under the ROC curve; the default
`roc(`*numlist*`)`	estimate ROC for given false-positive rates
`invroc(`*numlist*`)`	estimate false-positive rates for given ROC values
`pauc(`*numlist*`)`	estimate partial area under the ROC curve (pAUC) up to each false-positive rate
`cluster(`*varname*`)`	variable identifying resampling clusters
`ctrlcov(`*varlist*`)`	adjust control distribution for covariates in *varlist*
`ctrlmodel(strata|linear)`	stratify or regress on covariates; default is `ctrlmodel(strata)`
`pvc(empirical|normal)`	use empirical or normal distribution percentile value estimates; default is `pvc(empirical)`
`tiecorrected`	adjust for tied observations; not allowed with `pvc(normal)`
Bootstrap	
`nobootstrap`	do not perform bootstrap, just output point estimates
`bseed(#)`	random-number seed for bootstrap
`breps(#)`	number of bootstrap replications; default is `breps(1000)`
`bootcc`	perform case–control (stratified on *refvar*) sampling rather than cohort sampling in bootstrap
`nobstrata`	ignore covariate stratification in bootstrap sampling
`nodots`	suppress bootstrap replication dots
Reporting	
`level(#)`	set confidence level; default is `level(95)`

probit_options	Description
Model	
* `probit`	fit the probit model
`roccov(`*varlist*`)`	covariates affecting ROC curve
`fprpts(#)`	number of false-positive rate points to use in fitting ROC curve; default is `fprpts(10)`
`ctrlfprall`	fit ROC curve at each false-positive rate in control population
`cluster(`*varname*`)`	variable identifying resampling clusters
`ctrlcov(`*varlist*`)`	adjust control distribution for covariates in *varlist*
`ctrlmodel(strata | linear)`	stratify or regress on covariates; default is `ctrlmodel(strata)`
`pvc(empirical | normal)`	use empirical or normal distribution percentile value estimates; default is `pvc(empirical)`
`tiecorrected`	adjust for tied observations; not allowed with `pvc(normal)`
Bootstrap	
`nobootstrap`	do not perform bootstrap, just output point estimates
`bseed(#)`	random-number seed for bootstrap
`breps(#)`	number of bootstrap replications; default is `breps(1000)`
`bootcc`	perform case–control (stratified on *refvar*) sampling rather than cohort sampling in bootstrap
`nobstrata`	ignore covariate stratification in bootstrap sampling
`nodots`	suppress bootstrap replication dots
`bsave(`*filename*`, ...)`	save bootstrap replicates from parametric estimation
`bfile(`*filename*`)`	use bootstrap replicates dataset for estimation replay
Reporting	
`level(#)`	set confidence level; default is `level(95)`

* `probit` is required.

probit_ml_options	Description
Model	
* probit	fit the probit model
* ml	fit the probit model by maximum likelihood estimation
roccov(*varlist*)	covariates affecting ROC curve
cluster(*varname*)	variable identifying clusters
ctrlcov(*varlist*)	adjust control distribution for covariates in *varlist*
Reporting	
level(#)	set confidence level; default is level(95)
display_options	control column formats, line width, and display of omitted variables
Maximization	
maximize_options	control the maximization process; seldom used

*probit and ml are required.

fweights, iweights, and pweights are allowed with maximum likelihood estimation; see [U] **11.1.6 weight**.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Epidemiology and related > ROC analysis > ROC regression models

Description

The rocreg command is used to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data under the presence of covariates.

The two variables *refvar* and *classvar* must be numeric. The reference variable indicates the true state of the observation—such as diseased and nondiseased or normal and abnormal—and must be coded as 0 and 1. The *refvar* coded as 0 can also be called the control population, while the *refvar* coded as 1 comprises the case population. The rating or outcome of the diagnostic test or test modality is recorded in *classvar*, which must be ordinal, with higher values indicating higher risk.

rocreg can fit three models: a nonparametric model, a parametric probit model that uses the bootstrap for inference, and a parametric probit model fit using maximum likelihood.

Options

Options are presented under the following headings:

Options for nonparametric ROC estimation, using bootstrap
Options for parametric ROC estimation, using bootstrap
Options for parametric ROC estimation, using maximum likelihood

Options for nonparametric ROC estimation, using bootstrap

Model

`auc` estimates the total area under the ROC curve. This is the default summary statistic.

`roc(`*numlist*`)` estimates the ROC corresponding to each of the false-positive rates in *numlist*. The values of *numlist* must be in the range (0,1).

`invroc(`*numlist*`)` estimates the false-positive rates corresponding to each of the ROC values in *numlist*. The values of *numlist* must be in the range (0,1).

`pauc(`*numlist*`)` estimates the partial area under the ROC curve up to each false-positive rate in *numlist*. The values of *numlist* must in the range (0,1].

`cluster(`*varname*`)` specifies the variable identifying resampling clusters.

`ctrlcov(`*varlist*`)` specifies the covariates to be used to adjust the control population.

`ctrlmodel(strata|linear)` specifies how to model the control population of classifiers on `ctrlcov()`. When `ctrlmodel(linear)` is specified, linear regression is used. The default is `ctrlmodel(strata)`; that is, the control population of classifiers is stratified on the control variables.

`pvc(empirical|normal)` determines how the percentile values of the control population will be calculated. When `pvc(normal)` is specified, the standard normal cumulative distribution function (CDF) is used for calculation. Specifying `pvc(empirical)` will use the empirical CDFs of the control population classifiers for calculation. The default is `pvc(empirical)`.

`tiecorrected` adjusts the percentile values for ties. For each value of the classifier, one half the probability that the classifier equals that value under the control population is added to the percentile value. `tiecorrected` is not allowed with `pvc(normal)`.

Bootstrap

`nobootstrap` specifies that bootstrap standard errors not be calculated.

`bseed(#)` specifies the random-number seed to be used in the bootstrap.

`breps(#)` sets the number of bootstrap replications. The default is `breps(1000)`.

`bootcc` performs case–control (stratified on *refvar*) sampling rather than cohort bootstrap sampling.

`nobstrata` ignores covariate stratification in bootstrap sampling.

`nodots` suppresses bootstrap replicate dots.

Reporting

`level(#)`; see [R] **estimation options**.

Options for parametric ROC estimation, using bootstrap

Model

`probit` fits the probit model. This option is required and implies parametric estimation.

`roccov(`*varlist*`)` specifies the covariates that will affect the ROC curve.

`fprpts(#)` sets the number of false-positive rate points to use in modeling the ROC curve. These points form an equispaced grid on (0,1). The default is `fprpts(10)`.

`ctrlfprall` models the ROC curve at each false-positive rate in the control population.

`cluster(`*varname*`)` specifies the variable identifying resampling clusters.

`ctrlcov(`*varlist*`)` specifies the covariates to be used to adjust the control population.

`ctrlmodel(strata|linear)` specifies how to model the control population of classifiers on `ctrlcov()`. When `ctrlmodel(linear)` is specified, linear regression is used. The default is `ctrlmodel(strata)`; that is, the control population of classifiers is stratified on the control variables.

`pvc(empirical|normal)` determines how the percentile values of the control population will be calculated. When `pvc(normal)` is specified, the standard normal CDF is used for calculation. Specifying `pvc(empirical)` will use the empirical CDFs of the control population classifiers for calculation. The default is `pvc(empirical)`.

`tiecorrected` adjusts the percentile values for ties. For each value of the classifier, one half the probability that the classifier equals that value under the control population is added to the percentile value. `tiecorrected` is not allowed with `pvc(normal)`.

Bootstrap

`nobootstrap` specifies that bootstrap standard errors not be calculated.

`bseed(#)` specifies the random-number seed to be used in the bootstrap.

`breps(#)` sets the number of bootstrap replications. The default is `breps(1000)`.

`bootcc` performs case–control (stratified on *refvar*) sampling rather than cohort bootstrap sampling.

`nobstrata` ignores covariate stratification in bootstrap sampling.

`nodots` suppresses bootstrap replicate dots.

`bsave(`*filename*`, ...)` saves bootstrap replicates from parametric estimation in the given *filename* with specified options (that is, `replace`). `bsave()` is only allowed with parametric analysis using bootstrap.

`bfile(`*filename*`)` specifies to use the bootstrap replicates dataset for estimation replay. `bfile()` is only allowed with parametric analysis using bootstrap.

Reporting

`level(#)`; see [R] **estimation options**.

Options for parametric ROC estimation, using maximum likelihood

Model

`probit` fits the probit model. This option is required and implies parametric estimation.

`ml` fits the probit model by maximum likelihood estimation. This option is required and must be specified with `probit`.

`roccov(`*varlist*`)` specifies the covariates that will affect the ROC curve.

`cluster(`*varname*`)` specifies the variable used for clustering.

`ctrlcov(`*varlist*`)` specifies the covariates to be used to adjust the control population.

Reporting

level(#); see [R] estimation options.

display_options: noomitted, cformat(%*fmt*), pformat(%*fmt*), sformat(%*fmt*), and nolstretch; see [R] estimation options.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] maximize. These options are seldom used. The technique(bhhh) option is not allowed.

Remarks and examples

Remarks are presented under the following headings:

Introduction
ROC statistics
Covariate-adjusted ROC curves
Parametric ROC curves: Estimating equations
Parametric ROC curves: Maximum likelihood

Introduction

Receiver operating characteristic (ROC) analysis provides a quantitative measure of the accuracy of diagnostic tests to discriminate between two states or conditions. These conditions may be referred to as normal and abnormal, nondiseased and diseased, or control and case. We will use these terms interchangeably. The discriminatory accuracy of a diagnostic test is measured by its ability to correctly classify known control and case subjects.

The analysis uses the ROC curve, a graph of the sensitivity versus 1 − specificity of the diagnostic test. The sensitivity is the fraction of positive cases that are correctly classified by the diagnostic test, whereas the specificity is the fraction of negative cases that are correctly classified. Thus the sensitivity is the true-positive rate, and the specificity is the true-negative rate. We also call 1 − specificity the false-positive rate.

These rates are functions of the possible outcomes of the diagnostic test. At each outcome, a decision will be made by the user of the diagnostic test to classify the tested subject as either normal or abnormal. The true-positive and false-positive rates measure the probability of correct classification or incorrect classification of the subject as abnormal. Given the classification role of the diagnostic test, we will refer to it as the classifier.

Using this basic definition of the ROC curve, Pepe (2000) and Pepe (2003) describe how ROC analysis can be performed as a two-stage process. In the first stage, the control distribution of the classifier is estimated. The specificity is then determined as the percentiles of the classifier values calculated based on the control population. The false-positive rates are calculated as 1 − specificity. In the second stage, the ROC curve is estimated as the cumulative distribution of the case population's "false-positive" rates, also known as the survival function under the case population of the previously calculated percentiles. We use the terms ROC value and true-positive value interchangeably.

This formulation of ROC curve analysis provides simple, nonparametric estimates of several ROC curve summary parameters: area under the ROC curve, partial area under the ROC curve, ROC value for a given false-positive rate, and false-positive rate (also known as invROC) for a given ROC value. In the next section, we will show how to use rocreg to compute these estimates with bootstrap inference. There we will also show how rocreg complements the other nonparametric Stata ROC commands roctab and roccomp.

Other factors beyond condition status and the diagnostic test may affect both stages of ROC analysis. For example, a test center may affect the control distribution of the diagnostic test. Disease severity may affect the distribution of the standardized diagnostic test under the case population. Our analysis of the ROC curve in these situations will be more accurate if we take these covariates into account.

In a nonparametric ROC analysis, covariates may only affect the first stage of estimation; that is, they may be used to adjust the control distribution of the classifier. In a parametric ROC analysis, it is assumed that ROC follows a normal distribution, and thus covariates may enter the model at both stages; they may be used to adjust the control distribution and to model ROC as a function of these covariates and the false-positive rate. In parametric models, both sets of covariates need not be distinct but, in fact, they are often the same.

To model covariate effects on the first stage of ROC analysis, Janes and Pepe (2009) propose a covariate-adjusted ROC curve. We will demonstrate the covariate adjustment capabilities of `rocreg` in *Covariate-adjusted ROC curves*.

To account for covariate effects at the second stage, we assume a parametric model. Particularly, the ROC curve is a generalized linear model of the covariates. We will thus have a separate ROC curve for each combination of the relevant covariates. In *Parametric ROC curves: Estimating equations*, we show how to fit the model with estimating equations and bootstrap inference using `rocreg`. This method, documented as the "pdf" approach in Alonzo and Pepe (2002), works well with weak assumptions about the control distribution.

Also in *Parametric ROC curves: Estimating equations*, we show how to fit a constant-only parametric model (involving no covariates) of the ROC curve with weak assumptions about the control distribution. The constant-only model capabilities of `rocreg` in this context will be compared with those of `rocfit`. `roccomp` has the `binormal` option, which will allow it to compute area under the ROC curve according to a normal ROC curve, equivalent to that obtained by `rocfit`. We will compare this functionality with that of `rocreg`.

In *Parametric ROC curves: Maximum likelihood*, we demonstrate maximum likelihood estimation of the ROC curve model with `rocreg`. There we assume a normal linear model for the classifier on the covariates and case–control status. This method is documented in Pepe (2003). We will also demonstrate how to use this method with no covariates, and we will compare `rocreg` under the constant-only model with `rocfit` and `roccomp`.

The `rocregplot` command is used repeatedly in this entry. This command provides graphical output for `rocreg` and is documented in [R] **rocregplot**.

ROC statistics

`roctab` computes the ROC curve by calculating the false-positive rate and true-positive rate empirically at every value of the input classifier. It makes no distributional assumptions about the case or control distributions. We can get identical behavior from `rocreg` by using the default option settings.

▷ Example 1: Nonparametric ROC, AUC

Hanley and McNeil (1982) presented data from a study in which a reviewer was asked to classify, using a five-point scale, a random sample of 109 tomographic images from patients with neurological problems. The rating scale was as follows: 1 is definitely normal, 2 is probably normal, 3 is questionable, 4 is probably abnormal, and 5 is definitely abnormal. The true disease status was normal for 58 of the patients and abnormal for the remaining 51 patients.

Here we list 9 of the 109 observations:

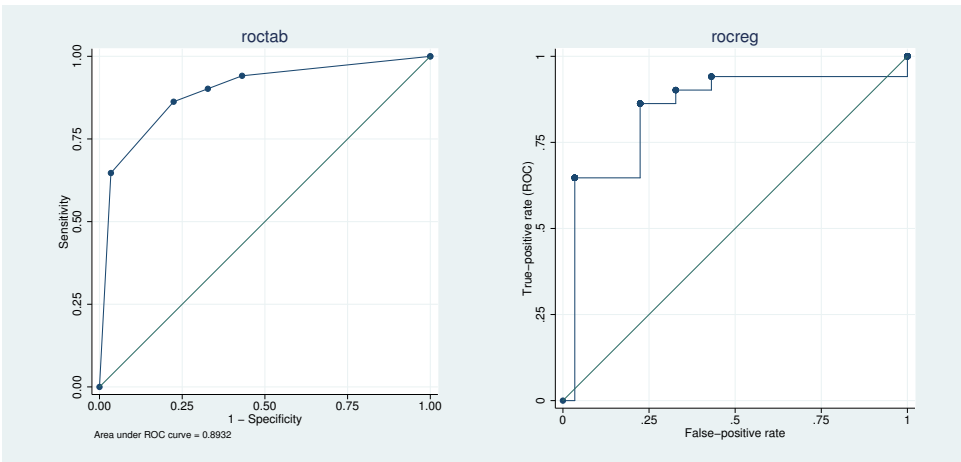
```
. use http://www.stata-press.com/data/r13/hanley
. list disease rating in 1/9
```

	disease	rating
1.	1	5
2.	0	1
3.	1	5
4.	0	4
5.	0	1
6.	0	3
7.	1	5
8.	0	5
9.	0	1

For each observation, `disease` identifies the true disease status of the subject (`0` is normal, `1` is abnormal), and `rating` contains the classification value assigned by the reviewer.

We run `roctab` on these data, specifying the `graph` option so that the ROC curve is rendered. We then calculate the false-positive and true-positive rates of the ROC curve by using `rocreg`. We graph the rates with `rocregplot`. Because we focus on `rocreg` output later, for now we use the `quietly` prefix to omit the output of `rocreg`. Both graphs are combined using `graph combine` (see [G-2] **graph combine**) for comparison. To ease the comparison, we specify the `aspectratio(1)` option in `roctab`; this is the default aspect ratio in `rocregplot`.

```
. roctab disease rating, graph aspectratio(1) name(a) nodraw title("roctab")
. quietly rocreg disease rating
. rocregplot, name(b) nodraw legend(off) title("rocreg")
. graph combine a b
```



Both `roctab` and `rocreg` compute the same false-positive rate and ROC values. The stairstep line connection style of the graph on the right emphasizes the empirical nature of its estimates. The control distribution of the classifier is estimated using the empirical CDF estimate. Similarly, the ROC curve, the distribution of the resulting case observation false-positive rate values, is estimated using the empirical CDF. Note the footnote in the `roctab` plot. By default, `roctab` will estimate the area

under the ROC curve (AUC) using a trapezoidal approximation to the estimated false-positive rate and true-positive rate points.

The AUC can be interpreted as the probability that a randomly selected member of the case population will have a larger classifier value than a randomly selected member of the control population. It can also be viewed as the average ROC value, averaged uniformly over the (0,1) false-positive rate domain (Pepe 2003).

The nonparametric estimator of the AUC (DeLong, DeLong, and Clarke-Pearson 1988; Hanley and Hajian-Tilaki 1997) used by `rocreg` is equivalent to the sample mean of the percentile values of the case observations. Thus to calculate the nonparametric AUC estimate, we only need to calculate the percentile values of the case observations with respect to the control distribution.

This estimate can differ from the trapezoidal approximation estimate. Under discrete classification data, like we have here, there may be ties between classifier values from case to control. The trapezoidal approximation uses linear interpolation between the classifier values to correct for ties. Correcting the nonparametric estimator involves adding a correction term to each observation's percentile value, which measures the probability that the classifier is equal to (instead of less than) the observation's classifier value.

The tie-corrected nonparametric estimate (trapezoidal approximation) is used when we think the true ROC curve is smooth. This means that the classifier we measure is a discretized approximation of a true latent and a continuous classifier.

We now recompute the ROC curve of `rating` for classifying `disease` and calculate the AUC. Specifying the `tiecorrected` option allows tie correction to be used in the `rocreg` calculation. Under nonparametric estimation, `rocreg` bootstraps to obtain standard errors and confidence intervals for requested statistics. We use the default 1,000 bootstrap replications to obtain confidence intervals for our parameters. This is a reasonable lower bound to the number of replications (Mooney and Duval 1993) required for estimating percentile confidence intervals. By specifying the `summary` option in `roctab`, we will obtain output showing the trapezoidal approximation of the AUC estimate, along with standard error and confidence interval estimates for the trapezoidal approximation suggested by DeLong, DeLong, and Clarke-Pearson (1988).

```

------------------------------------------------------------------------------
```

The estimates of AUC match well. The standard error from `roctab` is close to the bootstrap standard error calculated by `rocreg`. The bootstrap standard error generalizes to the more complex models that we consider later, whereas the `roctab` standard-error calculation does not.

◁

The AUC can be used to compare different classifiers. It is the most popular summary statistic for comparisons (Pepe, Longton, and Janes 2009). `roccomp` will compute the trapezoidal approximation of the AUC and graph the ROC curves of multiple classifiers. Using the DeLong, DeLong, and Clarke-Pearson (1988) covariance estimates for the AUC estimate, `roccomp` performs a Wald test of the null hypothesis that all classifier AUC values are equal. `rocreg` has similar capabilities.

▷ Example 2: Nonparametric ROC, AUC, multiple classifiers

Hanley and McNeil (1983) presented data from an evaluation of two computer algorithms designed to reconstruct CT images from phantoms. We will call these two algorithms modalities 1 and 2. A sample of 112 phantoms was selected; 58 phantoms were considered normal, and the remaining 54 were abnormal. Each of the two modalities was applied to each phantom, and the resulting images were rated by a reviewer using a six-point scale: 1 is definitely normal, 2 is probably normal, 3 is possibly normal, 4 is possibly abnormal, 5 is probably abnormal, and 6 is definitely abnormal. Because each modality was applied to the same sample of phantoms, the two sets of outcomes are correlated.

We list the first seven observations:

```
. use http://www.stata-press.com/data/r13/ct, clear
. list in 1/7, sep(0)
```

	mod1	mod2	status
1.	2	1	0
2.	5	5	1
3.	2	1	0
4.	2	3	0
5.	5	6	1
6.	2	2	0
7.	3	2	0

Each observation corresponds to one phantom. The `mod1` variable identifies the rating assigned for the first modality, and the `mod2` variable identifies the rating assigned for the second modality. The true status of the phantoms is given by `status==0` if they are normal and `status==1` if they are abnormal. The observations with at least one missing rating were dropped from the analysis.

A fictitious dataset was created from this true dataset, adding a third test modality. We will use `roccomp` to compute the AUC statistic for each modality in these data and compare the AUC of the three modalities. We obtain the same behavior from `rocreg`. As before, the `tiecorrected` option is specified so that the AUC is calculated with the trapezoidal approximation.

```
. use http://www.stata-press.com/data/r13/ct2
. roccomp status mod1 mod2 mod3, summary
```

Ha: At least one classifier has a different AUC value.

P-value:     .0389797                 Test based on bootstrap (N) assumptions.
```

We see that the AUC estimates are equivalent, and the standard errors are quite close as well. The p-value for the tests of equal AUC under `rocreg` leads to similar inference as the p-value from `roccomp`. The Wald test performed by `rocreg` uses the joint bootstrap estimate variance matrix of the three AUC estimators rather than the DeLong, DeLong, and Clarke-Pearson (1988) variance estimate used by `roccomp`.

`roccomp` is used here on potentially correlated classifiers that are recorded in wide-format data. It can also be used on long-format data to compare independent classifiers. Further details can be found in [R] **roccomp**.

◁

Citing the AUC's lack of clinical relevance, there is argument against using it as a key summary statistic of the ROC curve (Pepe 2003; Cook 2007). Pepe, Longton, and Janes (2009) suggest using the estimate of the ROC curve itself at a particular point, or the estimate of the false-positive rate at a given ROC value, also known as invROC.

Recall from example 1 how nonparametric rocreg graphs look, with the stairstep pattern in the ROC curve. In an ideal world, the graph would be a smooth one-to-one function, and it would be trivial to map a false-positive rate to its corresponding true-positive rate and vice versa.

However, smooth ROC curves can only be obtained by assuming a parametric model that uses linear interpolation between observed false-positive rates and between observed true-positive rates, and rocreg is certainly capable of that; see example 1 of [R] **rocregplot**. However, under nonparametric estimation, the mapping between false-positive rates and true-positive rates is not one to one, and estimates tend to be less reliable the further you are from an observed data point. This is somewhat mitigated by using tie-corrected rates (the tiecorrected option).

When we examine continuous data, the difference between the tie-corrected estimates and the standard estimates becomes negligible, and the empirical estimate of the ROC curve becomes close to the smooth ROC curve obtained by linear interpolation. So the nonparametric ROC and invROC estimates work well.

Fixing one rate value of interest can be difficult and subjective (Pepe 2003). A compromise measure is the partial area under the ROC curve (pAUC) (McClish 1989; Thompson and Zucchini 1989). This is the integral of the ROC curve from 0 and above to a given false-positive rate (perhaps the largest clinically acceptable value). Like the AUC estimate, the nonparametric estimate of the pAUC can be written as a sample average of the case observation percentiles, but with an adjustment based on the prescribed maximum false-positive rate (Dodd and Pepe 2003). A tie correction may also be applied so that it reflects the trapezoidal approximation.

We cannot compare rocreg with roctab or roccomp on the estimation of pAUC, because pAUC is not computed by the latter two.

▷ Example 3: Nonparametric ROC, other statistics

To see how rocreg estimates ROC, invROC, and pAUC, we will examine a new study. Wieand et al. (1989) examined a pancreatic cancer study with two continuous classifiers, here called y1 (CA 19-9) and y2 (CA 125). This study was also examined in Pepe, Longton, and Janes (2009). The indicator of cancer in a subject is recorded as d. The study was a case–control study, stratifying participants on disease status.

We list the first five observations:

```
. use http://labs.fhcrc.org/pepe/book/data/wiedat2b, clear
(S. Wieand - Pancreatic cancer diagnostic marker data)
. list in 1/5
```

	y1	y2	d
1.	28	13.3	no
2.	15.5	11.1	no
3.	8.2	16.7	no
4.	3.4	12.6	no
5.	17.3	7.4	no

We will estimate the ROC curves at a large value (0.7) and a small value (0.2) of the false-positive rate. These values are specified in roc(). The false-positive rate for ROC or sensitivity value of 0.6 will also be estimated by specifying invroc(). Percentile confidence intervals for these parameters are displayed in the graph obtained by rocregplot after rocreg. The pAUC statistic will be calculated for the false-positive rate of 0.5, which is specified as an argument to the pauc() option. Following Pepe, Longton, and Janes (2009), we use a stratified bootstrap, sampling separately from the case

and control populations by specifying the bootcc option. This reflects the case–control nature of the study.

All four statistics can be estimated simultaneously by rocreg. For clarity, however, we will estimate each statistic with a separate call to rocreg. rocregplot is used after estimation to graph the ROC and false-positive rate estimates. The display of the individual, observation-specific false-positive rate and ROC values will be omitted in the plot. This is accomplished by specifying msymbol(i) in our plot1opts() and plot2opts() options to rocregplot.

We also find significant evidence supporting the hypothesis that the pAUC for y1 up to a false-positive rate of 0.5 differs from the area of the same region under the ROC curve of y2.

◁

Covariate-adjusted ROC curves

When covariates affect the control distribution of the diagnostic test, thresholds for the test being classified as abnormal may be chosen that vary with the covariate values. These conditional thresholds will be more accurate than the marginal thresholds that would normally be used, because they take into account the specific distribution of the diagnostic test under the given covariate values as opposed to the marginal distribution over all covariate values.

By using these covariate-specific thresholds, we are essentially creating new classifiers for each covariate-value combination, and thus we are creating multiple ROC curves. As explained in Pepe (2003), when the case and control distributions of the covariates are the same, the marginal ROC curve will always be bound above by these covariate-specific ROC curves. So using conditional thresholds will never provide a less powerful test diagnostic in this case.

In the marginal ROC curve calculation, the classifiers are standardized to percentiles according to the control distribution, marginalized over the covariates. Thus the ROC curve is the CDF of the standardized case observations. The covariate-adjusted ROC curve is the CDF of one minus the conditional control percentiles for the case observations, and the marginal ROC curve is the CDF of one minus the marginal control percentiles for the case observations (Pepe and Cai 2004). Thus the standardization of classifier to false-positive rate value is conditioned on the specific covariate values under the covariate-adjusted ROC curve.

The covariate-adjusted ROC curve (Janes and Pepe 2009) at a given false-positive rate t is equivalent to the expected value of the covariate-specific ROC at t over all covariate combinations. When the covariates in question do not affect the case distribution of the classifier, the covariate-specific ROC will have the same value at each covariate combination. So here the covariate-adjusted ROC is equivalent to the covariate-specific ROC, regardless of covariate values.

When covariates do affect the case distribution of the classifier, users of the diagnostic test would likely want to model the covariate-specific ROC curves separately. Tools to do this can be found in the parametric modeling discussion in the following two sections. Regardless, the covariate-adjusted ROC curve can serve as a meaningful summary of covariate-adjusted accuracy.

Also note that the ROC summary statistics defined in the previous section have covariate-adjusted analogs. These analogs are estimated in a similar manner as under the marginal ROC curve (Janes, Longton, and Pepe 2009). The options for their calculation in `rocreg` are identical to those given in the previous section. Further details can be found in *Methods and formulas*.

▷ Example 4: Nonparametric ROC, linear covariate adjustment

Norton et al. (2000) studied data from a neonatal audiology study on three tests to identify hearing impairment in newborns. These data were also studied in Janes, Longton, and Pepe (2009). Here we list 5 of the 5,058 observations.

```
. use http://www.stata-press.com/data/r13/nnhs, clear
(Norton - neonatal audiology data)
. list in 1/5
```

	id	ear	male	currage	d	y1	y2	y3
1.	B0157	R	M	42.42	0	-3.1	-9	-1.5
2.	B0157	L	M	42.42	0	-4.5	-8.7	-2.71
3.	B0158	R	M	40.14	1	-3.2	-13.2	-2.64
4.	B0161	L	F	38.14	0	-22.1	-7.8	-2.59
5.	B0167	R	F	37	0	-10.9	-6.6	-1.42

The classifiers `y1` (DPOAE 65 at 2 kHz), `y2` (TEOAE 80 at 2 kHz), and `y3` (ABR) and the hearing impairment indicator `d` are recorded along with some relevant covariates. The infant's age is recorded in months as `currage`, and the infant's gender is indicated by `male`. Over 90% of the newborns were tested in each ear (`ear`), so we will cluster on infant ID (`id`).

Following the strategy of Janes, Longton, and Pepe (2009), we will first perform ROC analysis for the classifiers while adjusting for the covariate effects of the infant's gender and age. This is done by specifying these variables in the `ctrlcov()` option. We adjust using a linear regression rule, by specifying `ctrlmodel(linear)`. This means that when a user of the diagnostic test chooses a threshold conditional on the age and gender covariates, they assume that the diagnostic test classifier has some linear dependence on age and gender and equal variance as their levels vary. Our cluster adjustment is made by specifying the `cluster()` option.

We will focus on the first classifier. The percentile, or specificity, values are calculated empirically by default, and thus so are the false-positive rates, (1 − specificity). Also by default, the ROC curve values are empirically defined by the false-positive rates. To draw the ROC curve, we again use `rocregplot`.

The AUC is calculated by default. For brevity, we specify the `nobootstrap` option so that bootstrap sampling is not performed. The AUC point estimate will be sufficient for our purposes.

Our covariate control adjustment model shows that `currage` has a negative effect on `y1` (DPOAE 65 at 2 kHz) under the control population. At the 0.001 significance level, we reject that its contribution to `y1` is zero, and the point estimate has a negative sign. This result does not directly tell us about the effect of `currage` on the ROC curve of `y1` as a classifier of `d`. None of the case observations are used in the linear regression, so information on `currage` for abnormal cases is not used in the model. This result does show us how to calculate false-positive rates for tests that use thresholds conditional on a child's sex and current age. We will see how `currage` affects the ROC curve when `y1` is used as a classifier and conditional thresholds are used based on `male` and `currage` in the following section, *Parametric ROC curves: Estimating equations*.

❑ Technical note

Under this nonparametric estimation, `rocreg` saved the false-positive rate for each observation's `y1` values in the utility variable `_fpr_y1`. The true-positive rates are stored in the utility variable `_roc_y1`. For other models, say with classifier *yname*, these variables would be named `_fpr_`*yname* and `_roc_`*yname*. They will also be overwritten with each call of `rocreg`. The variables `_roc_*` and `_fpr_*` are usually for internal `rocreg` use only and are overwritten with each call of `rocreg`. They are only created for nonparametric models or parametric models that do not involve ROC covariates. In these models, covariates may only affect the first stage of estimation, the control distribution, and not the ROC curve itself. In parametric models that allow ROC covariates, different covariate values would lead to different ROC curves.

❑

To see how the covariate-adjusted ROC curve estimate differs from the standard marginal estimate, we will reestimate the ROC curve for classifier `y1` without covariate adjustment. We rename these variables before the new estimation and then draw an overlaid `twoway line` (see [G-2] **graph twoway line**) plot to compare the two.

```
. rename _fpr_y1 o_fpr_y1
. rename _roc_y1 o_roc_y1
. label variable o_roc_y1 "covariate_adjusted"
. rocreg d y1, cluster(id) nobootstrap

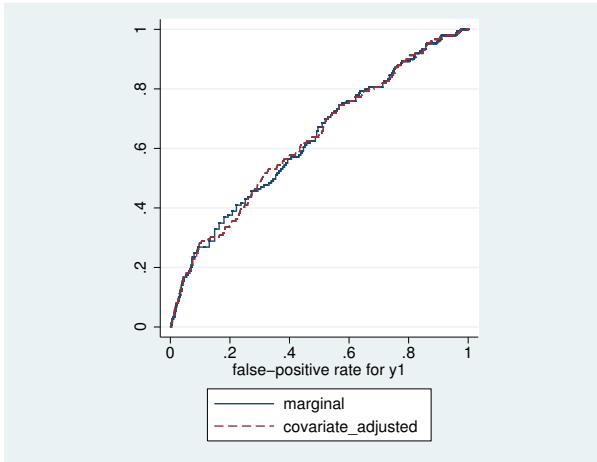
```

AUC	Observed Coef.	Bias	Bootstrap Std. Err.	[95% Conf.	Interval]	
	.6279645	.	.	.	.	(N)
				.	.	(P)
				.	.	(BC)

```
. label variable _roc_y1 "marginal"
. twoway line _roc_y1 _fpr_y1, sort(_fpr_y1 _roc_y1) connect(J) ||
>         line o_roc_y1 o_fpr_y1, sort(o_fpr_y1 o_roc_y1)
>         connect(J) lpattern(dash) aspectratio(1) legend(cols(1))
```



Though they are close, particularly in AUC, there are clearly some points of difference between the estimates. So the covariate-adjusted ROC curve may be useful here.

◁

In our examples thus far, we have used the empirical CDF estimator to estimate the control distribution. `rocreg` allows some flexibility here. The `pvc(normal)` option may be specified to calculate the percentile values according to a Gaussian distribution of the control.

Covariate adjustment in `rocreg` may also be performed with stratification instead of linear regression. Under the stratification method, the unique values of the stratified covariates each define separate parameters for the control distribution of the classifier. A user of the diagnostic test chooses a threshold based on the control distribution conditioned on the unique covariate value parameters.

We will demonstrate the use of normal percentile values and covariate stratification in our next example.

Example 5: Nonparametric ROC, covariate stratification

The hearing test study of Stover et al. (1996) examined the effectiveness of negative signal-to-noise ratio, `nsnr`, as a classifier of hearing loss. The test was administered under nine different settings, corresponding to different frequency, `xf`, and intensity, `xl`, combinations. Here we list 10 of the 1,848 observations.

```
. use http://www.stata-press.com/data/r13/dp, clear
(Stover - DPOAE test data)
. list in 1/10
```

	id	d	nsnr	xf	xl	xd
1.	101	1	18	10.01	5.5	3.5
2.	101	1	19	20.02	5.5	3
3.	101	1	7.6	10.01	6	3.5
4.	101	1	15	20.02	6	3
5.	101	1	16	10.01	6.5	3.5
6.	101	1	5.8	20.02	6.5	3
7.	102	0	-2.6	10.01	5.5	.
8.	102	0	-3	14.16	5.5	.
9.	102	1	10	20.02	5.5	1
10.	102	0	-5.8	10.01	6	.

Hearing loss is represented by `d`. The covariate `xd` is a measure of the degree of hearing loss. We will use this covariate in later analysis, because it only affects the case distribution of the classifier. Multiple measurements are taken for each individual, `id`, so we will cluster by individual.

We evaluate the effectiveness of `nsnr` using `xf` and `xl` as stratification covariates with `rocreg`; the default method of covariate adjustment.

As mentioned before, the default false-positive rate calculation method in `rocreg` estimates the conditional control distribution of the classifiers empirically. For comparison, we will also estimate a separate ROC curve using false-positive rates assuming the conditional control distribution is normal. This behavior is requested by specifying the `pvc(normal)` option. Using the `rocregplot` option `name()` to store the ROC plots and using the `graph combine` command, we are able to compare the Gaussian and empirical ROC curves side by side. As before, for brevity we specify the `nobootstrap` option to suppress bootstrap sampling.

```
. rocreg d nsnr, ctrlcov(xf xl) cluster(id) nobootstrap

Control variables      : xf xl
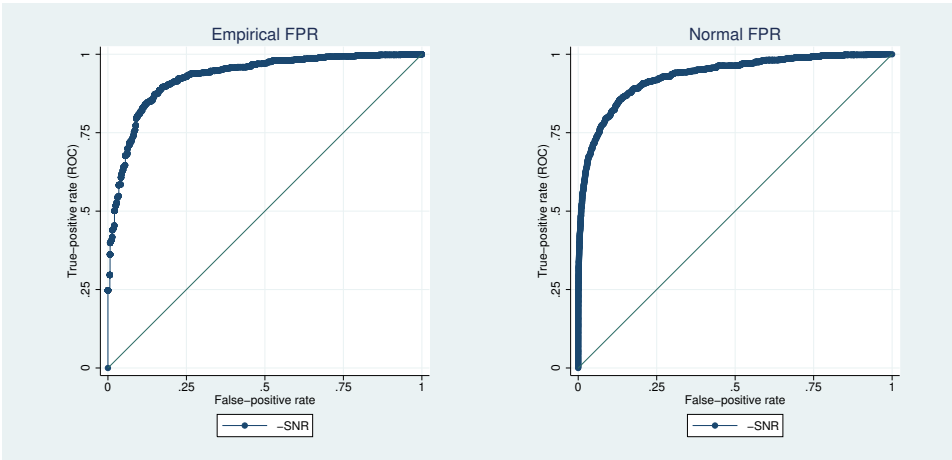
Control standardization: normal
ROC method             : empirical
Area under the ROC curve
   Status    : d
   Classifier: nsnr
```

AUC	Observed Coef.	Bias	Bootstrap Std. Err.	[95% Conf.	Interval]	
	.9309901	.	.	.	.	(N)
				.	.	(P)
				.	.	(BC)

```
. rocregplot, title(Normal FPR) name(b) nodraw
. graph combine a b, xsize(5)
```



On cursory visual inspection, we see little difference between the two curves. The AUC values are close as well. So it is sensible to assume that we have Gaussian percentile values for control standardization. ◁

Parametric ROC curves: Estimating equations

We now assume a parametric model for covariate effects on the second stage of ROC analysis. Particularly, the ROC curve is a probit model of the covariates. We will thus have a separate ROC curve for each combination of the relevant covariates.

Under weak assumptions about the control distribution of the classifier, we can fit this model by using estimating equations as described in Alonzo and Pepe (2002). This method can be also be used without covariate effects in the second stage, assuming a parametric model for the single (constant only) ROC curve. Covariates may still affect the first stage of estimation, so we parametrically model the single covariate-adjusted ROC curve (from the previous section). The marginal ROC curve, involving no covariates in either stage of estimation, can be fit parametrically as well.

In addition to the Alonzo and Pepe (2002) explanation, further details are given in Pepe, Longton, and Janes (2009); Janes, Longton, and Pepe (2009); Pepe (2003); and Janes and Pepe (2009).

The parametric models that we consider assume that the ROC curve is a cumulative distribution function g invoked with input of a linear polynomial in the corresponding quantile function invoked on the false-positive rate u. In this context, we assume that g corresponds to a standard normal cumulative distribution function, Φ. So the corresponding quantile function is Φ^{-1}. The constant intercept of the polynomial may depend on covariates, but the slope term α (the quantile coefficient) may not.

$$\text{ROC}(u) = g\{\mathbf{x}'\boldsymbol{\beta} + \alpha g^{-1}(u)\}$$

The first step of the algorithm involves the choice of false-positive rates to use in the parametric fit. These are typically a set of equispaced points spanning the interval (0,1). Alonzo and Pepe (2002) examined the effect of fitting large and small sets of points, finding that relatively small sets could be used with little loss of efficiency. Alternatively, the set can be formed by using the observed false-positive rates in the data (Pepe 2003). Further details on the algorithm are provided in *Methods and formulas*.

Under parametric estimation, all the summary measures we defined earlier, except the AUC, are not calculated until postestimation. In models with covariates, each covariate combination would yield a different ROC curve and thus different summary parameters, so no summary parameters are initially estimated. In marginal parametric models (where there are no ROC covariates, but there are potentially control covariates), we will calculate the AUC and leave the other measures for postestimation; see [R] **rocreg postestimation**. As with the other parameters, we bootstrap for standard errors and inference.

We will now demonstrate how `rocreg` performs the Alonzo and Pepe (2002) algorithm using the previous section's examples and others.

▷ Example 6: Parametric ROC, linear covariate adjustment

We return to the neonatal audiology study with gender and age covariates (Norton et al. 2000), which we discussed in example 4. Janes, Longton, and Pepe (2009) suspected the current age of the infant would play a role in the case distribution of the classifier `y1` (DPOAE 65 at 2 kHz). They postulated a probit link between the ROC curve and the covariate-adjusted false-positive rates. We follow their investigation and reach similar results.

In example 4, we saw the results of adjusting for the `currage` and `male` variables in the control population for classifier `y1`. Now we see how `currage` affects the ROC curve when `y1` is used with thresholds conditioned on `male` and `currage`.

We specify the covariates that should affect the ROC curve in the `roccov()` option. By default, `rocreg` will choose 10 equally spaced false-positive rates in the (0,1) interval as fitting points. The `fprpts()` option allows the user to specify more or fewer points. We specify the `bsave()` option with the `nnhs2y1` dataset so that we can use the bootstrap resamples in postestimation.

```
. use http://www.stata-press.com/data/r13/nnhs, clear
(Norton - neonatal audiology data)
. rocreg d y1, probit ctrlcov(currage male) ctrlmodel(linear) roccov(currage)
> cluster(id) bseed(56930)  bsave(nnhs2y1) nodots
Bootstrap results                                 Number of obs      =      5056
                                                  Replications       =      1000

```

Note how the number of clusters—here infants—changes from the covariate control adjustment model fit to the ROC model. The control fit is limited to control cases and thus fewer infants. The ROC is fit on all the data, so the variance is adjusted for all clustering on all infants.

With a 0.05 level of statistical significance, we cannot reject the null hypothesis that `currage` has no effect on the ROC curve at a given false-positive rate. This is because each of our 95% bootstrap confidence intervals contains 0. This corresponds with the finding in Janes, Longton, and Pepe (2009) where the reported 95% intervals each contained 0. We cannot reject that the intercept parameter β_0, reported as `_cons` in the main table, is 0 at the 0.05 level either. The slope parameter α, reported

as _cons in the probit table, is close to 1 and cannot be rejected as being 1 at the 0.05 level. Under the assumption that the ROC coefficients except α are 0 and that $\alpha = 1$, the ROC curve at false-positive rate u is equal to u. In other words, we cannot reject that the false-positive rate is equal to the true-positive rate, and so the test is noninformative. Further investigation of the results requires postestimation; see [R] **rocreg postestimation**.

◁

The fitting point set can be formed by using the observed false-positive rates (Pepe 2003). Our next example will illustrate this.

▷ Example 7: Parametric ROC, covariate stratification

We return to the hearing test study of Stover et al. (1996), which we discussed in example 5. Pepe (2003) suspected that intensity, xd, would play a role in the case distribution of the negative signal-to-noise ratio (nsnr) classifier. A ROC regression was fit with covariate adjustment for xf and xl with stratification, and for ROC covariates xf, xl, and xd. There is no prohibition against the same covariate being used in the first and second stages of ROC calculation. The false-positive rate fitting point set was composed of all observed false-positive rates in the control data.

We fit the model with rocreg here. Using observed false-positive rates as the fitting point set can make the dataset very large, so fitting the model is computationally intensive. We demonstrate the fitting algorithm without precise confidence intervals, focusing instead on the coefficient estimates and standard errors. We will thus perform only 50 bootstrap replications, a reasonable number to obtain accurate standard error estimates (Mooney and Duval 1993). The number of replications is specified in the breps() option.

The ROC covariates are specified in roccov(). We specify that all observed false-positive rates in the control observations be used as fitting points with the ctrlfprall option. The nobstrata option specifies that the bootstrap is not stratified. The covariate stratification in the first stage of estimation does not affect the resampling. We will return to this example in postestimation, so we save the bootstrap results in the nsnrf dataset with the bsave() option.

```
. use http://www.stata-press.com/data/r13/dp
(Stover - DPOAE test data)
. rocreg d nsnr, probit ctrlcov(xf xl) roccov(xf xl xd) ctrlfprall cluster(id)

We obtain results similar to those reported in Pepe (2003, 159). We find that the coefficients for `xl` and `xd` differ from 0 at the 0.05 level of significance. So over certain covariate combinations, we can have a variety of informative tests using `nsnr` as a classifier.

◁

As mentioned before, when there are no covariates, `rocreg` can still fit a parametric model for the ROC curve of a classifier by using the Alonzo and Pepe (2002) method. `roccomp` and `rocfit` can fit marginal probit models as well. We will compare the behavior of `rocreg` with that of `roccomp` and `rocfit` for probit models without covariates.

When the `binormal` option is specified, `roccomp` calculates the AUC for input classifiers according to the maximum likelihood algorithm of `rocfit`. The `rocfit` algorithm expects discrete classifiers but can slice continuous classifiers into discrete partitions. Further, the case and control distributions are both assumed normal. Actually, the observed classification values are taken as discrete indicators

of the latent normally distributed classification values. This method is documented in Dorfman and Alf (1969).

Alonzo and Pepe (2002) compared their estimating equations probability density function method (with empirical estimation of the false-positive rates) to the maximum likelihood approach of Dorfman and Alf (1969) and found that they had similar efficiency and mean squared error. So we should expect `rocfit` and `rocreg` to give similar results when fitting a simple probit model.

▷ Example 8: Parametric ROC, marginal model

We return to the Hanley and McNeil (1982) data. We will fit a probit model to the ROC curve, assuming that the `rating` variable is a discrete indicator of an underlying latent normal random variable in both the case and control populations of `disease`. We invoke `rocfit` with the default options. `rocreg` is invoked with the `probit` option. The percentile values are calculated empirically. Because there are fewer categories than 10, there will be fewer than 10 false-positive rates that trigger a different true-positive rate value. So for efficiency, we invoke `rocreg` with the `ctrlfprall` option.

				.837113	.9605498	(P)
				.8468336	.9630486	(BC)

We see that the intercept and slope parameter estimates are close. The intercept (`_cons` in the main table) is clearly nonzero. Under `rocreg`, the slope (`_cons` in the `probit` table) and its percentile and bias-corrected confidence intervals are close to those of `rocfit`. The area under the ROC curve for each of the `rocreg` and `rocfit` estimators also matches closely.

◁

Now we will compare the parametric fit of `rocreg` under the constant probit model with `roccomp`.

▷ Example 9: Parametric ROC, marginal model, multiple classifiers

We now use the fictitious dataset generated from Hanley and McNeil (1983). To fit a probit model using `roccomp`, we specify the `binormal` option. Our specification of `rocreg` remains the same as before.

`rocregplot` is used to render the model produced by `rocreg`. We specify several graph options to both `roccomp` and `rocregplot` to ease comparison. When the `binormal` option is specified along with `graph`, `roccomp` will draw the binormal fitted lines in addition to connected line plots of the empirical false-positive and true-positive rates.

In this plot, we overlay scatterplots of the empirical false-positive rates (because percentile value calculation defaulted to `pvc(empirical)`) and the parametric true-positive rates.

We see differing true-positive rate values in the scattered points, which is expected because `roccomp` gives the empirical estimate and `rocreg` gives the parametric estimate. However, the estimated curves and areas under the ROC curve look similar. Using the Wald test based on the bootstrap covariance, `rocreg` rejects the null hypothesis that each test has the same AUC at the 0.1 significance level. `roccomp` formulates the asymptotic covariance using the `rocfit` estimates of AUC. Examination of its output leads to rejection of the null hypothesis that the AUCs are equal across each test at the 0.05 significance level.

Parametric ROC curves: Maximum likelihood

The Alonzo and Pepe (2002) method of fitting a parametric model to the ROC curve is powerful because it can be generally applied, but that can be a limitation as well. Whenever we invoke the method and want anything other than point estimates of the parameters, we must perform bootstrap resampling.

An alternative is to use maximum likelihood inference to fit the ROC curve. This method can save computational time by avoiding the bootstrap.

`rocreg` implements maximum likelihood estimation for ROC curve analysis when both the case and control populations are normal. Particularly, the classifier is a normal linear model on certain covariates, and the covariate effect and variance of the classifier may change between the case and control populations. This model is defined in Pepe (2003, 145).

$$y = \mathbf{z}'\boldsymbol{\beta_0} + D\mathbf{x}'\boldsymbol{\beta_1} + \sigma\left(D\right)\epsilon$$

Our error term, ϵ, is a standard normal random variable. The variable D is our true status variable, being 1 for the case population observations and 0 for the control population observations. The variance function σ is defined as

$$\sigma\left(D\right) = \sigma_0\left(D=0\right) + \sigma_1\left(D=1\right)$$

This provides two variance parameters in the model and does not depend on covariate values.

Suppose a covariate x_i is present in $\mathbf{z}$ and $\mathbf{x}$. The coefficient β_{1i} represents the interaction effect of the x_i and D. It is the extra effect that x_i has on classifier y under the case population, $D = 1$, beyond the main effect β_{0i}. These $\boldsymbol{\beta_1}$ coefficients are directly related to the ROC curve of y.

Under this model, the ROC curve is derived to be

$$\text{ROC}(u) = \Phi\left[\frac{1}{\sigma_1}\{\mathbf{x}'\boldsymbol{\beta_1} + \sigma_0\Phi^{-1}(u)\}\right]$$

For convenience, we reparameterize the model at this point, creating the parameters $\beta_i = \sigma_1^{-1}\beta_{1i}$ and $\alpha = \sigma_1^{-1}\sigma_0$. We refer to β_0 as the constant intercept, `i_cons`. The parameter α is referred to as the constant slope, `s_cons`.

$$\text{ROC}(u) = \Phi\{\mathbf{x}'\boldsymbol{\beta} + \alpha\Phi^{-1}(u)\}$$

We may interpret the final coefficients as the standardized linear effect of the ROC covariate on the classifier under the case population. The marginal effect of the covariate on the classifier in the control population is removed, and it is rescaled by the case population standard deviation of the classifier when all ROC covariate effects are removed. An appreciable effect on the classifier by a ROC covariate in this measure leads to an appreciable effect on the classifier's ROC curve by the ROC covariate.

The advantage of estimating the control coefficients $\boldsymbol{\beta}_0$ is similar to the gains of estimating the covariate control models in the estimating equations ROC method and nonparametric ROC estimation. This model would similarly apply when evaluating a test that is conditioned on control covariates.

Again we note that under parametric estimation, all the summary measures we defined earlier except the AUC are not calculated until postestimation. In models with covariates, each covariate combination would yield a different ROC curve and thus different summary parameters, so no summary parameters are estimated initially. In marginal parametric models, we will calculate the AUC and leave the other measures for postestimation. There is a simple closed-form formula for the AUC under the probit model. Using this formula, the delta method can be invoked for inference on the AUC. Details on AUC estimation for probit marginal models are found in *Methods and formulas*.

We will demonstrate the maximum likelihood method of `rocreg` by revisiting the models of the previous section.

▷ Example 10: Maximum likelihood ROC, single classifier

Returning to the hearing test study of Stover et al. (1996), we use a similar covariate grouping as before. The frequency `xf` and intensity `xl` are control covariates ($\mathbf{z}$), while all three covariates `xf`, `xl`, and hearing loss degree `xd` are case covariates ($\mathbf{x}$). In example 7, we fit this model using the Alonzo and Pepe (2002) method. Earlier we stratified on the control covariates and estimated the conditioned control distribution of `nsnr` empirically. Now we assume a normal linear model for `nsnr` on `xf` and `xl` under the control population.

We fit the model by specifying the control covariates in the `ctrlcov()` option and the case covariates in the `roccov()` option. The `ml` option tells `rocreg` to perform maximum likelihood estimation.

s_cons	.9688578	.0623476	15.54	0.000	.8466587	1.091057

We find the results are similar to those of example 7. Frequency (`xf`) and intensity (`xl`) have a negative effect on the classifier `nsnr` in the control population.

The negative control effect is mitigated for `xf` in the case population, but the effect for `xl` is even more negative there. Hearing loss severity, `xd`, has a positive effect on `nsnr` in the case population, and it is undefined in the control population.

The ROC coefficients are shown in the `ROC Model` table. Each are different from 0 at the 0.05 level. At this level, we also cannot conclude that the variances differ from case to control populations, because 1 is in the 95% confidence interval for `s_cons`, the ratio of the case to control standard deviation parameters.

Both frequency (xf) and hearing loss severity (xd) make a positive contribution to the ROC curve and thus make the test more powerful. Intensity (xl) has a negative effect on the ROC curve and weakens the test. We previously saw in example 5 that the control distribution appears to be normal, so using maximum likelihood to fit this model is a reasonable approach.

This model was also fit in Pepe (2003, 147). Pepe used separate least-squares estimates for the case and control samples. We obtain similar results for the coefficients, but the maximum likelihood fitting yields slightly different standard deviations by considering both case and control observations concurrently. In addition, a misprint in Pepe (2003, 147) reports a coefficient of −4.91 for xl in the case population instead of −3.19 as reported by Stata.

◁

Inference on multiple classifiers using the Alonzo and Pepe (2002) estimating equation method is performed by fitting each model separately and bootstrapping to determine the dependence of the estimates. Using the maximum likelihood method, we also fit each model separately. We use suest (see [R] **suest**) to estimate the joint variance–covariance of our parameter estimates.

For our models, we can view the score equation for each model as an estimating equation. The estimate that solves the estimating equation (that makes the score 0) is asymptotically normal with a variance matrix that can be estimated using the inverse of the squared scores. By stacking the score equations of the separate models, we can estimate the variance matrix for all the parameter estimates by using this rule. This is an informal explanation; further details can be found in [R] **suest** and in the references Rogers (1993); White (1982 and 1996).

Now we will examine a case with multiple classification variables.

▷ Example 11: Maximum likelihood ROC, multiple classifiers

We return to the neonatal audiology study with gender and age covariates (Norton et al. 2000). In example 6, we fit a model with male and currage as control covariates, and currage as a ROC covariate for the classifier y1 (DPOAE 65 at 2 kHz). We will refit this model, extending it to include the classifier y2 (TEOAE 80 at 2 kHz).

s_cons	.7184563	.0565517	12.70	0.000	.607617	.8292957

Both classifiers have similar results. The results for `y1` show the same direction as the estimating equation results in example 6. However, we can now reject the null hypothesis that the ROC `currage` coefficient is 0 at the 0.05 level.

In example 6, we could not reject that the slope parameter `s_cons` was 1 and that the constant intercept or ROC coefficient for current age was 0. The resulting ROC curve implied a noninformative test using `y1` as a classifier. This is not the case with our current results. As `currage` increases, we expect a steeper ROC curve and thus a more powerful test, for both classifiers `y1` (DPOAE 65 at 2 kHz) and `y2` (TEOAE 80 at 2 kHz).

In example 10, the clustering of observations within infant `id` was adjusted in the individual fit of `nsnr`. In our current example, the adjustment for the clustering of observations within `id` is performed during concurrent estimation, as opposed to during the individual classifier fits (as in example 10). This adjustment, performed by `suest`, is still accurate.

◁

Now we will fit constant probit models and compare `rocreg` with `rocfit` and `roccomp` with the `binormal` option. Our first applications of `rocfit` and `roccomp` are taken directly from examples 8 and 9. The Dorfman and Alf (1969) algorithm that `rocfit` works with uses discrete classifiers or uses slicing to make a classifier discrete. So we are applying the maximum likelihood method of `rocreg` on discrete classification data here, where it expects continuous data. We expect to see some discrepancies, but we do not find great divergence in the estimates. After revisiting examples 8 and 9, we will fit a probit model with a continuous classifier and no covariates using `rocreg`, and we will compare the results with those from `rocfit`.

▷ Example 12: Maximum likelihood ROC, marginal model

Using the Hanley and McNeil (1982) data, discussed in example 1 and in example 8, we fit a constant probit model of the classifier `rating` with true status `disease`. `rocreg` is invoked with the `ml` option and compared with `rocfit`.

```

   Status    : disease
   ROC Model :
```

	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
rating						
i_cons	2.090802	.2941411	7.11	0.000	1.514297	2.667308
s_cons	1.181151	.1603263	7.37	0.000	.8669177	1.495385
auc	.9116494	.0261658	34.84	0.000	.8603654	.9629333

We compare the estimates for these models:

	rocfit	rocreg, ml
slope	0.7130	1.1812
SE of slope	0.2159	0.1603
intercept	1.6568	2.0908
SE of intercept	0.3105	0.2941
AUC	0.9113	0.9116
SE of AUC	0.0295	0.0262

We find that both the intercept and the slope are estimated as higher with the maximum likelihood method under rocreg than with rocfit. The AUC (ROC area in rocfit) is close for both commands. We find that the standard errors of each of these estimates is slightly lower under rocreg than rocfit as well.

Both rocfit and rocreg suggest that the slope parameter of the ROC curve (slope in rocfit and s_cons in rocreg) is not significantly different from 1. Thus we cannot reject that the classifier has the same variance in both case and control populations. There is, however, significant evidence that the intercepts (i_cons in rocreg and intercept in rocfit) differ from 0. Because of the positive direction of the intercept estimates, the ROC curve for rating as a classifier of disease suggests that rating provides an informative test. This is also suggested by the high AUC, which is significantly different from 0.5, that is, a flip of a coin.

◁

▷ Example 13: Maximum likelihood ROC, marginal model, multiple classifiers

We use the fictitious dataset generated from Hanley and McNeil (1983), which we previously used in example 2 and in example 9. To fit a probit model using roccomp, we specify the binormal option. We perform parametric, maximum likelihood ROC analysis using rocreg. We use rocregplot to plot the ROC curves created by rocreg.

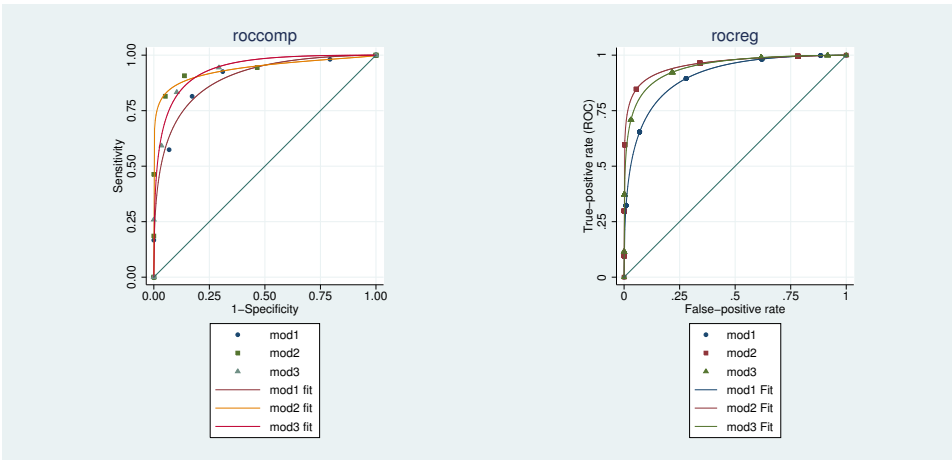
> plot1opts(msymbol(o)) plot2opts(msymbol(s)) plot3opts(msymbol(t))
. graph combine a b, xsize(5)
```



We compare the AUC estimates for these models:

	roccomp	rocreg, ml
mod1	0.8945	0.9047
mod2	0.9382	0.9580
mod3	0.9376	0.9453

Each classifier has a higher estimated AUC under rocreg than roccomp. Each curve appears to be raised and smoothed in the rocreg fit as compared with roccomp. They are different, but not drastically different. The inference on whether the curve areas are the same is similar to example 9. We reject equality at the 0.10 level under rocreg and at the 0.05 level under roccomp.

Each intercept is significantly different from 0 at the 0.05 level and is estimated in a positive direction. Though all but classifier mod2 has 1 in their slope confidence intervals, the high intercepts suggest steep ROC curves and powerful tests.

Also note that the false-positive and true-positive rate points are calculated empirically in the roccomp graph and parametrically in rocreg. In example 9, the false-positive rates calculated by rocreg were calculated empirically, similar to roccomp. But in this example, the rates are calculated based on normal percentiles.

◁

Now we will generate an example to compare rocfit and rocreg under maximum likelihood estimation of a continuous classifier.

▷ Example 14: Maximum likelihood ROC, graphical comparison with rocfit

We generate 500 realizations of a population under threat of disease. One quarter of the population has the disease. A classifier x is measured, which has a control distribution of $N(1,3)$ and a case distribution of $N(1+5,2)$. We will invoke rocreg with the ml option on this generated data. We specify the continuous() option for rocfit and invoke it on the data as well. The continuous() option tells rocfit how many discrete slices to partition the data into before fitting.

For comparison of the two curves, we will use the rocfit postestimation command, rocplot; see [R] **rocfit postestimation**. This command graphs the empirical false-positive and true-positive rates with an overlaid fit of the binormal curve estimated by rocfit. rocplot also supports an addplot() option. We use the saved variables from rocreg in this option to overlay a line plot of the rocreg fit.

```
. clear

We find that the curves are close. As before, the `rocfit` estimates are lower for the slope and intercept than under `rocreg`. The AUC estimates are close. Though the slope confidence interval contains 1, a high ROC intercept suggests a steep ROC curve and thus a powerful test.

◁

Stored results

Functions

e(sample)	marks estimation sample

Parametric, bootstrap `rocreg` stores the following in `e()`:

Scalars

`e(N)`	number of observations
`e(N_strata)`	number of covariate strata
`e(N_clust)`	number of clusters
`e(rank)`	rank of `e(V)`

Macros

`e(cmd)`	`rocreg`
`e(cmdline)`	command as typed
`e(title)`	title in estimation output
`e(classvars)`	classification variable list
`e(refvar)`	status variable, reference variable
`e(ctrlmodel)`	covariate-adjustment specification
`e(ctrlcov)`	covariate-adjustment variables
`e(pvc)`	percentile value calculation method
`e(title)`	title in estimation output
`e(tiecorrected)`	indicates whether tie correction was used
`e(probit)`	`probit`
`e(roccov)`	ROC covariates
`e(fprpts)`	number of points used as false-positive rate fit points
`e(ctrlfprall)`	indicates whether all observed false-positive rates were used as fit points
`e(nobootstrap)`	indicates that bootstrap was performed
`e(bseed)`	seed used in bootstrap
`e(breps)`	number of bootstrap resamples
`e(cc)`	indicates whether case–control groups were used as resampling strata
`e(nobstrata)`	indicates whether resampling should stratify based on control covariates
`e(clustvar)`	name of cluster variable
`e(vce)`	`bootstrap`
`e(properties)`	`b V` (or `b` if `nobootstrap` is specified)
`e(predict)`	program used to implement `predict`

Matrices

`e(b)`	coefficient vector
`e(V)`	variance–covariance matrix of the estimators
`e(b_bs)`	bootstrap estimates
`e(reps)`	number of nonmissing results
`e(bias)`	estimated biases
`e(se)`	estimated standard errors
`e(z0)`	median biases
`e(ci_normal)`	normal-approximation confidence intervals
`e(ci_percentile)`	percentile confidence intervals
`e(ci_bc)`	bias-corrected confidence intervals

Functions

`e(sample)`	marks estimation sample

Parametric, maximum likelihood `rocreg` stores the following in `e()`:

Scalars

`e(N)`	number of observations
`e(N_clust)`	number of clusters
`e(rank)`	rank of `e(V)`

Macros

`e(cmd)`	`rocreg`
`e(cmdline)`	command as typed

Methods and formulas

Assume that we applied a diagnostic test to each of N_0 control and N_1 case subjects. Further assume that the higher the outcome value of the diagnostic test, the higher the risk of the subject being abnormal. Let $y_{1i}, i = 1, 2, \ldots, N_1$, and $y_{0j}, j = 1, 2, \ldots, N_0$, be the values of the diagnostic test for the case and control subjects, respectively. The true status variable D identifies an observation as case $D = 1$ or control $D = 0$. The CDF of the classifier Y is F. Conditional on D, we write the CDF as F_D.

Methods and formulas are presented under the following headings:

ROC statistics
Covariate-adjusted ROC curves
Parametric ROC curves: Estimating equations
Parametric ROC curves: Maximum likelihood

ROC statistics

We obtain these definitions and their estimates from Pepe (2003) and Pepe, Longton, and Janes (2009). The false-positive and true-positive rates at cutoff c are defined as

$$\text{FPR}(y) = P\left(Y \geq y \middle| D = 0\right)$$

$$\text{TPR}(y) = P\left(Y \geq y \middle| D = 1\right)$$

The true-positive rate, or ROC value at false-positive rate u, is given by

$$\text{ROC}(u) = P\left(1 - F_0(Y) \leq u \middle| D = 1\right)$$

When Y is continuous, the false-positive rate can be written as

$$\text{FPR}(y) = 1 - F_0(y)$$

The empirical CDF for the sample $z_1, \ldots, z_n$ is given by

$$\widehat{F}(z) = \sum_{i=1}^{n} \frac{I(z < z_i)}{n}$$

The empirical estimates $\widehat{\text{FPR}}$ and $\widehat{\text{ROC}}$ both use this empirical CDF estimator.

The area under the ROC curve is defined as

$$\text{AUC} = \int_0^1 \text{ROC}(u)\, d_u$$

The partial area under the ROC curve for false-positive rate a is defined as

$$\text{pAUC}(a) = \int_0^a \text{ROC}(u)\, d_u$$

The nonparametric estimate for the AUC is given by

$$\widehat{\text{AUC}} = \sum_{i=1}^{N_1} \frac{1 - \widehat{\text{FPR}}(y_{1i})}{N_1}$$

The nonparametric estimate of pAUC is given by

$$\widehat{\text{pAUC}}(a) = \sum_{i=1}^{N_1} \frac{\max\left\{1 - \widehat{\text{FPR}}(y_{1i}) - (1-a), 0\right\}}{N_1}$$

For discrete classifiers, a correction term is subtracted from the false-positive rate estimate so that the $\widehat{\text{AUC}}$ and $\widehat{\text{pAUC}}$ estimates correspond with a trapezoidal approximation to the area of the ROC curve.

$$\text{FPR}^c(y) = 1 - \widehat{F}_0(y) - \frac{1}{2}\sum_{j=1}^{N_0} \frac{I(y = y_{0j})}{N_0}$$

In the nonparametric estimation of the ROC curve, all inference is performed using the `bootstrap` command (see [R] **bootstrap**). `rocreg` also allows users to calculate the ROC curve and related statistics by assuming a normal control distribution. So these formulas are updated by replacing F_0 by Φ (with adjustment of the marginal mean and variance of the control distribution).

Covariate-adjusted ROC curves

Suppose we observe covariate vector Z in addition to the classifier Y. Let $Z_{1i}, i = 1, 2, \ldots, N_1$, and $Z_{0j}, j = 1, 2, \ldots, N_0$, be the values of the covariates for the case and control subjects, respectively.

The covariate-adjusted ROC curve is defined by Janes and Pepe (2009) as

$$\text{AROC}(t) = E\left\{\text{ROC}\left(t\middle|Z_0\right)\right\}$$

It is calculated by replacing the marginal control CDF estimate, $\widehat{F}_0$, with the conditional control CDF estimate, $\widehat{F}_{0Z}$. If we used a normal control CDF, then we would replace the marginal control mean and variance with the conditional control mean and variance. The formulas of the previous section can be updated for covariate-adjustment by making this substitution of the conditional CDF for the marginal CDF in the false-positive rate calculation.

Because the calculation of the ROC value is now performed based on the conditionally calculated false-positive rate, no further conditioning is made in its calculation under nonparametric estimation.

`rocreg` supports covariate adjustment with stratification and linear regression. Under stratification, separate parameters are estimated for the control distribution at each level of the covariates. Under linear regression, the classifier is regressed on the covariates over the control distribution, and the resulting coefficients serve as parameters for $\widehat{F}_{0Z}$.

Parametric ROC curves: Estimating equations

Under nonparametric estimation of the ROC curve with covariate adjustment, no further conditioning occurs in the ROC curve calculation beyond the use of covariate-adjusted false-positive rates as inputs.

Under parametric estimation of the ROC curve, we can relax this restriction. We model the ROC curve as a cumulative distribution function g (standard normal Φ) invoked with input of a linear polynomial in the corresponding quantile function (here Φ^{-1}) invoked on the false-positive rate u. The constant intercept of the polynomial may depend on covariates; the slope term α (quantile coefficient) may not.

$$\text{ROC}(u) = g\{\mathbf{x}'\boldsymbol{\beta} + \alpha g^{-1}(u)\}$$

Pepe (2003) notes that having a binormal ROC ($g = \Phi$) is equivalent to specifying that some monotone transformation of the data exists to make the case and control classifiers normally distributed. This specification applies to the marginal case and control.

Under weak assumptions about the control distribution of the classifier, we can fit this model by using estimating equations (Alonzo and Pepe 2002). The method can be used without covariate effects in the second stage, assuming a parametric model for the single ROC curve. Using the Alonzo and Pepe (2002) method, the covariate-adjusted ROC curve may be fit parametrically. The marginal ROC curve, involving no covariates in either stage of estimation, can be fit parametrically as well. In addition to the Alonzo and Pepe (2002) explanation, further details are given in Pepe, Longton, and Janes (2009); Janes, Longton, and Pepe (2009); Pepe (2003); and Janes and Pepe (2009).

The algorithm can be described as follows:

1. Estimate the false-positive rates of the classifier `fpr`. These may be computed in any fashion outlined so far: covariate-adjusted, empirically, etc.
2. Determine a set of n_p false-positive rates to use as fitting points $f_1, \ldots, f_{n_p}$. These may be an equispaced grid on $(0, 1)$ or the set of observed false-positive rates from part 1.

3. Expand the case observation portion of the data to include a subobservation for each fitting point. So there are now $N_1(n_p - 1)$ additional observations in the data.
4. Generate a new dummy variable `u`. For subobservation j, $\texttt{u} = I\,(\texttt{fpr} \leq f_j)$.
5. Generate a new variable `quant` containing the quantiles of the false-positive rate fitting points. For subobservation j, $\texttt{quant} = g^{-1}\,(f_j)$.
6. Perform a binary regression (probit, $g = \Phi$) of `fpr` on the covariates `x` and quantile variable `quant`.

The coefficients of part 6 are the coefficients of the ROC model. The coefficients of the covariates coincide naturally with estimates of $\boldsymbol{\beta}$, and the α parameter is estimated by the coefficient on `quant`. Because the method is so general and makes few distributional assumptions, bootstrapping must be performed for inference. If multiple classifiers are to be fit, the algorithm is performed separately for each in each bootstrap, and the bootstrap is used to estimate covariances.

We mentioned earlier that in parametric estimation, the AUC was the only summary parameter that could be estimated initially. This is true when we fit the marginal probit model because there are no covariates in part 6 of the algorithm.

To calculate the AUC statistic under a marginal probit model, we use the formula

$$\text{AUC} = \Phi\left(\frac{\beta_0}{\sqrt{1+\alpha^2}}\right)$$

Alternatively, the AUC for the probit model can be calculated as pAUC(1) in postestimation. Under both models, bootstrapping is performed for inference on the AUC.

Parametric ROC curves: Maximum likelihood

`rocreg` supports another form of parametric ROC estimation: maximum likelihood with a normally distributed classifier. This method assumes that the classifier is a normal linear model on certain covariates, and the covariate effect and variance of the classifier may change between the case and control populations. The model is defined in Pepe (2003, 145).

$$y = \mathbf{z}'\boldsymbol{\beta_0} + D\mathbf{x}'\boldsymbol{\beta_1} + \sigma\,(D)\,\epsilon$$

Our error term, ϵ, is a standard normal random variable. The variable D is our true status variable, being 1 for the case population observations and 0 for the control population observations. The variance function σ is defined as

$$\sigma\,(D) = \sigma_0\,(D = 0) + \sigma_1\,(D = 1)$$

This provides two variance parameters in the model and does not depend on covariate values.

Under this model, the ROC curve is easily derived to be

$$\text{ROC}\,(u) = \Phi\left[\frac{1}{\sigma_1}\left\{\mathbf{x}'\boldsymbol{\beta_1} + \sigma_0\Phi^{-1}\,(u)\right\}\right]$$

We reparameterize the model, creating the parameters $\beta_i = \sigma_1^{-1}\beta_{1i}$ and $\alpha = \sigma_1^{-1}\sigma_0$. We refer to β_0 as the constant intercept, `i_cons`. The parameter α is referred to as the constant slope, `s_cons`.

$$\text{ROC}\,(u) = \Phi\{\mathbf{x}'\boldsymbol{\beta} + \alpha\Phi^{-1}\,(u)\}$$

The original model defining the classifier y leads to the following single observation likelihoods for $D = 0$ and $D = 1$:

$$L(\boldsymbol{\beta_0}, \boldsymbol{\beta_1}, \sigma_1, \sigma_0, \big| D = 0, y, \mathbf{z}, \mathbf{x}) = \frac{1}{\sqrt{2\pi}\sigma_0} \exp \frac{-(y - \mathbf{z}'\boldsymbol{\beta_0})^2}{2\sigma_0^2}$$

$$L(\boldsymbol{\beta_0}, \boldsymbol{\beta_1}, \sigma_1, \sigma_0, \big| D = 1, y, \mathbf{z}, \mathbf{x}) = \frac{1}{\sqrt{2\pi}\sigma_1} \exp \frac{-(y - \mathbf{z}'\boldsymbol{\beta_0} - \mathbf{x}'\boldsymbol{\beta_1})^2}{2\sigma_1^2}$$

These can be combined to yield the observation-level log likelihood:

$$\begin{aligned} \ln L(\boldsymbol{\beta_0}, \boldsymbol{\beta_1}, \sigma_1, \sigma_0, \big| D, y, \mathbf{z}, \mathbf{x}) = & -\frac{\ln 2\pi}{2} \\ & - I(D = 0) \left\{ \ln\sigma_0 + \frac{(y - \mathbf{z}'\boldsymbol{\beta_0})^2}{2\sigma_0^2} \right\} \\ & - I(D = 1) \left\{ \ln\sigma_1 + \frac{(y - \mathbf{z}'\boldsymbol{\beta_0} - \mathbf{x}'\boldsymbol{\beta_1})^2}{2\sigma_1^2} \right\} \end{aligned}$$

When there are multiple classifiers, each classifier is fit separately with maximum likelihood. Then the results are combined by stacking the scores and using the sandwich variance estimator. For more information, see [R] **suest** and the references White (1982); Rogers (1993); and White (1996).

Acknowledgments

We thank Margaret S. Pepe, Holly Janes, and Gary Longton of the Fred Hutchinson Cancer Research Center for providing the inspiration for the `rocreg` command and for illuminating many useful datasets for its documentation.

Description

The following commands are of special interest after `rocreg`:

Command	Description
`estat nproc`	nonparametric ROC curve estimation, keeping fit information from `rocreg`
`rocregplot`	plot marginal and covariate-specific ROC curves

The following standard postestimation commands are also available:

Command	Description
`estimates`	cataloging estimation results
`lincom`	point estimates, standard errors, testing, and inference for linear combinations
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions for parametric ROC curve estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

Special-interest postestimation command

The `estat nproc` command allows calculation of all the ROC curve summary statistics for covariate-specific ROC curves, as well as for a nonparametric ROC estimation. Under nonparametric estimation, a single ROC curve is estimated by `rocreg`. Covariates can affect this estimation, but there are no separate covariate-specific ROC curves. Thus the input arguments for `estat nproc` are taken in the command line rather than from the data as variable values.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic options]
```

statistic	Description
Main	
`at(`*varname*`)`	input variable for statistic
`auc`	total area under the ROC curve; the default
`roc`	ROC values for given false-positive rates in `at()`
`invroc`	false-positive rate for given ROC values in `at()`
`pauc`	partial area under the ROC curve up to each false-positive rate in `at()`
`classvar(`*varname*`)`	statistic for given classifier

options	Description
Options	
`intpts(#)`	points in numeric integration of pAUC calculation
`se(`*newvar*`)`	predict standard errors
`ci(`*stubname*`)`	produce confidence intervals, stored as variables with prefix *stubname* and suffixes `_l` and `_u`
`level(#)`	set confidence level; default is `level(95)`
* `bfile(`*filename*`, ...)`	load dataset containing bootstrap replicates from `rocreg`
* `btype(n | p | bc)`	produce normal-based (`n`), percentile (`p`), or bias-corrected (`bc`) confidence intervals; default is `btype(n)`

* `bfile()` and `btype()` are only allowed with parametric analysis using bootstrap inference.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`at(`*varname*`)` records the variable to be used as input for the above predictions.

`auc` predicts the total area under the ROC curve defined by the covariate values in the data. This is the default statistic.

`roc` predicts the ROC values for false-positive rates stored in *varname* specified in `at()`.

`invroc` predicts the false-positive rates for given ROC values stored in *varname* specified in `at()`.

`pauc` predicts the partial area under the ROC curve up to each false-positive rate stored in *varname* specified in `at()`.

`classvar(`*varname*`)` performs the prediction for the specified classifier.

Options

`intpts(#)` specifies that # points be used in the pAUC calculation.

`se(`*newvar*`)` specifies that standard errors be produced and stored in *newvar*.

`ci(`*stubname*`)` requests that confidence intervals be produced and the lower and upper bounds be stored in *stubname*`_l` and *stubname*`_u`, respectively.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see **[U] 20.7 Specifying the width of confidence intervals**.

`bfile(`*filename*`, ...)` uses bootstrap replicates of parameters from `rocreg` stored in *filename* to estimate standard errors and confidence intervals of predictions.

`btype(n | p | bc)` specifies whether to produce normal-based (`n`), percentile (`p`), or bias-corrected (`bc`) confidence intervals. The default is `btype(n)`.

Syntax for estat nproc

```
estat nproc [ , estat_nproc_options ]
```

estat_nproc_options	Description
Main	
`auc`	estimate total area under the ROC curve
`roc(`*numlist*`)`	estimate ROC values for given false-positive rates
`invroc(`*numlist*`)`	estimate false-positive rate for given ROC values
`pauc(`*numlist*`)`	estimate partial area under the ROC curve up to each false-positive rate

At least one option must be specified.

Menu for estat

Statistics > Postestimation > Reports and statistics

Options for estat nproc

Main

`auc` estimates the total area under the ROC curve.

`roc(`*numlist*`)` estimates the ROC for each of the false-positive rates in *numlist*. The values in *numlist* must be in the range (0,1).

`invroc(`*numlist*`)` estimates the false-positive rate for each of the ROC values in *numlist*. The values in *numlist* must be in the range (0,1).

`pauc(`*numlist*`)` estimates the partial area under the ROC curve up to each false-positive rate in *numlist*. The values in *numlist* must be in the range (0,1].

Remarks and examples

Remarks are presented under the following headings:

Using predict after rocreg
Using estat nproc

Using predict after rocreg

`predict`, after parametric `rocreg`, predicts the AUC, the ROC value, the false-positive rate (invROC), or the pAUC value. The default is `auc`.

We begin by estimating the area under the ROC curve for each of the three age-specific ROC curves in example 1 of [R] **rocregplot**: 30, 40, and 50 months.

▷ Example 1: Parametric ROC, AUC

In example 6 of [R] **rocreg**, a probit ROC model was fit to audiology test data from Norton et al. (2000). The estimating equations method of Alonzo and Pepe (2002) was used to fit the model. Gender and age were covariates that affected the control distribution of the classifier `y1` (DPOAE 65 at 2 kHz). Age was a ROC covariate for the model, so we fit separate ROC curves at each age.

Following Janes, Longton, and Pepe (2009), we drew the ROC curves for ages 30, 40, and 50 months in example 1 of [R] **rocregplot**. Now we use `predict` to estimate the AUC for the ROC curve at each of those ages.

The bootstrap dataset saved by `rocreg` in example 6 of [R] **rocreg**, `nnhs2y1.dta`, is used in the `bfile()` option.

We will store the AUC prediction in the new variable `predAUC`. We specify the `se()` option with the new variable name `seAUC` to produce an estimate of the prediction's standard error. By specifying the stubname `cin` in `ci()`, we tell `predict` to create normal-based confidence intervals (the default) as new variables `cin_l` and `cin_u`.

5059.	30	.5209999	.0712928	.3812686	.6607312
5060.	40	.6479176	.0286078	.5918474	.7039879
5061.	50	.7601378	.0746157	.6138937	.9063819

As expected, we find the AUC to increase with age.

Essentially, we have a stored bootstrap sample of ROC covariate coefficient estimates in `nnhs2y1.dta`. We calculate the AUC using each set of coefficient estimates, resulting in a sample of AUC estimates. Then the bootstrap standard error and confidence intervals are calculated based on this AUC sample. Further details of the computation of the standard error and percentile confidence intervals can be found in *Methods and formulas* and in [R] **bootstrap**.

We can also produce percentile or bias-corrected confidence intervals by specifying `btype(p)` or `btype(bc)`, which we now demonstrate.

```
. drop *AUC*
. predict predAUC in 5059/5061, auc se(seAUC) ci(cip) bfile(nnhs2y1) btype(p)
. list currage predAUC cip* in 5059/5061
```

	currage	predAUC	cip_l	cip_u
5059.	30	.5209999	.3760555	.6513149
5060.	40	.6479176	.5893397	.7032645
5061.	50	.7601378	.5881404	.8836223

```
. drop *AUC*
. predict predAUC in 5059/5061, auc se(seAUC) ci(cibc) bfile(nnhs2y1) btype(bc)
. list currage predAUC cibc* in 5059/5061
```

	currage	predAUC	cibc_l	cibc_u
5059.	30	.5209999	.3736968	.6500064
5060.	40	.6479176	.588947	.7010052
5061.	50	.7601378	.5812373	.8807758

◁

`predict` can also estimate the ROC value and the false-positive rate (invROC).

▷ Example 2: Parametric ROC, invROC, and ROC value

In example 7 of [R] **rocreg**, we fit the ROC curve for status variable hearing loss (`d`) and classifier negative signal-to-noise ratio `nsnr` with ROC covariates frequency (`xf`), intensity (`xl`), and hearing loss severity (`xd`). The data were obtained from Stover et al. (1996). The model fit was probit with bootstrap resampling. We saved 50 bootstrap replications in the dataset `nsnrf.dta`.

The covariate value combinations `xf = 10.01`, `xl = 5.5`, and `xd = .5`, and `xf = 10.01`, `xl = 6.5`, and `xd = 4` are of interest. In example 3 of [R] **rocregplot**, we estimated the ROC values for false-positive rates 0.2 and 0.7 and the false-positive rate for a ROC value of 0.5 by using `rocregplot`. We will use `predict` to replicate the estimation.

We begin by appending observations with our desired covariate combinations to the data. We also create two new variables: `rocinp`, which contains the ROC values for which we wish to predict the corresponding invROC values, and `invrocinp`, which contains the invROC values corresponding to the ROC values we wish to predict.

```
. clear
. input xf xl xd rocinp invrocinp
           xf         xl         xd     rocinp  invrocinp
  1. 10.01 5.5 .5 .2 .
  2. 10.01 6.5 4  .2 .
  3. 10.01 5.5 .5 .7 .5
  4. 10.01 6.5 4  .7 .5
  5. end
. save newdata
file newdata.dta saved
. use http://www.stata-press.com/data/r13/dp
(Stover - DPOAE test data)
. quietly rocreg d nsnr, ctrlcov(xf xl) roccov(xf xl xd) probit cluster(id)
> nobstrata ctrlfprall bseed(156385) breps(50) ctrlmodel(strata) bsave(nsnrf)
. append using newdata
. list xf xl xd invrocinp rocinp in 1849/1852
```

	xf	xl	xd	invroc~p	rocinp
1849.	10.01	5.5	.5	.	.2
1850.	10.01	6.5	4	.	.2
1851.	10.01	5.5	.5	.5	.7
1852.	10.01	6.5	4	.5	.7

Now we will use `predict` to estimate the ROC value for the false-positive rates stored in `rocinp`. We specify the `roc` option, and we specify `rocinp` in the `at()` option. The other options, `se()` and `ci()`, are used to obtain standard errors and confidence intervals, respectively. The dataset of bootstrap samples, `nsnrf.dta`, is specified in `bfile()`. After prediction, we list the point estimates and standard errors.

```
. predict rocit in 1849/1852, roc at(rocinp) se(seroc) ci(cin) bfile(nsnrf)
. list xf xl xd rocinp rocit seroc if !missing(rocit)
```

	xf	xl	xd	rocinp	rocit	seroc
1849.	10.01	5.5	.5	.2	.7652956	.0735506
1850.	10.01	6.5	4	.2	.9672505	.0227977
1851.	10.01	5.5	.5	.7	.9835816	.0204353
1852.	10.01	6.5	4	.7	.999428	.0011309

These results match example 3 of [R] **rocregplot**. We list the confidence intervals next. These also conform to the `rocregplot` results from example 3 in [R] **rocregplot**. We begin with the confidence intervals for ROC under the covariate values `xf=10.01`, `xl=5.5`, and `xd=.5`.

```
. list xf xl xd rocinp rocit cin* if inlist(_n, 1849, 1851)
```

	xf	xl	xd	rocinp	rocit	cin_l	cin_u
1849.	10.01	5.5	.5	.2	.7652956	.6211391	.9094521
1851.	10.01	5.5	.5	.7	.9835816	.9435292	1.023634

Now we list the ROC confidence intervals under the covariate values `xf=10.01`, `xl=6.5`, and `xd=4`.

```
. list xf xl xd rocinp rocit cin* if inlist(_n, 1850, 1852)
```

	xf	xl	xd	rocinp	rocit	cin_l	cin_u
1850.	10.01	6.5	4	.2	.9672505	.9225678	1.011933
1852.	10.01	6.5	4	.7	.999428	.9972115	1.001644

Now we will predict the false-positive rate for a ROC value by specifying the `invroc` option. We pass the `invrocinp` variable as an argument to the `at()` option. Again we list the point estimates and standard errors first.

```
. drop ci*
. predict invrocit in 1849/1852, invroc at(invrocinp) se(serocinv) ci(cin)
> bfile(nsnrf)
. list xf xl xd invrocinp invrocit serocinv if !missing(invrocit)
```

	xf	xl	xd	invroc~p	invrocit	serocinv
1851.	10.01	5.5	.5	.5	.0615144	.0254042
1852.	10.01	6.5	4	.5	.0043298	.0045938

These also match those of example 3 of [R] **rocregplot**. Listing the confidence intervals shows identical results as well. First we list the confidence intervals under the covariate values `xf=10.01`, `xl=5.5`, and `xd=.5`.

```
. list xf xl xd invrocinp invrocit cin* in 1851
```

	xf	xl	xd	invroc~p	invrocit	cin_l	cin_u
1851.	10.01	5.5	.5	.5	.0615144	.0117231	.1113057

Now we list the confidence intervals for false-positive rate under the covariate values `xf=10.01`, `xl=6.5`, and `xd=4`.

```
. list xf xl xd invrocinp invrocit cin* in 1852
```

	xf	xl	xd	invroc~p	invrocit	cin_l	cin_u
1852.	10.01	6.5	4	.5	.0043298	-.004674	.0133335

◁

The `predict` command can also be used after a maximum-likelihood ROC model is fit.

▷ Example 3: Maximum likelihood ROC, invROC, and ROC value

In the previous example, we revisited the estimating equations fit of a probit model with ROC covariates frequency (xf), intensity (xl), and hearing loss severity (xd) to the Stover et al. (1996) audiology study data. A maximum likelihood fit of the same model was performed in example 10 of [R] **rocreg**. In example 2 of [R] **rocregplot**, we used rocregplot to estimate ROC values and false-positive rates for this model under two covariate configurations. We will use predict to obtain the same estimates. We will also estimate the partial area under the ROC curve.

We append the data as in the previous example. This leads to the following four final observations in the data.

```
. use http://www.stata-press.com/data/r13/dp, clear
(Stover - DPOAE test data)
. rocreg d nsnr, probit ctrlcov(xf xl) roccov(xf xl xd) ml cluster(id)
  (output omitted)
. append using newdata
. list xf xl xd invrocinp rocinp in 1849/1852
```

	xf	xl	xd	invroc~p	rocinp
1849.	10.01	5.5	.5	.	.2
1850.	10.01	6.5	4	.	.2
1851.	10.01	5.5	.5	.5	.7
1852.	10.01	6.5	4	.5	.7

Now we predict the ROC value for false-positive rates of 0.2 and 0.7. Under maximum likelihood prediction, only Wald-type confidence intervals are produced. We specify a new variable name for the standard error in the se() option and a stubname for the confidence interval variables in the ci() option.

```
. predict rocit in 1849/1852, roc at(rocinp) se(seroc) ci(ci)
. list xf xl xd rocinp rocit seroc ci_l ci_u if !missing(rocit), noobs
```

xf	xl	xd	rocinp	rocit	seroc	ci_l	ci_u
10.01	5.5	.5	.2	.7608593	.0510501	.660803	.8609157
10.01	6.5	4	.2	.9499408	.0179824	.914696	.9851856
10.01	5.5	.5	.7	.978951	.0097382	.9598644	.9980376
10.01	6.5	4	.7	.9985001	.0009657	.9966073	1.000393

These results match our estimates in example 2 of [R] **rocregplot**. We also match example 2 of [R] **rocregplot** when we estimate the false-positive rate for a ROC value of 0.5.

```
. drop ci*
. predict invrocit in 1851/1852, invroc at(invrocinp) se(serocinv) ci(ci)
. list xf xl xd invrocinp invrocit serocinv ci_l ci_u if !missing(invrocit),
> noobs
```

xf	xl	xd	invroc~p	invrocit	serocinv	ci_l	ci_u
10.01	5.5	.5	.5	.0578036	.0198626	.0188736	.0967336
10.01	6.5	4	.5	.0055624	.0032645	-.0008359	.0119607

◁

Example 4: Maximum likelihood ROC, pAUC, and ROC value

In example 13 of [R] **rocreg**, we fit a maximum-likelihood marginal probit model to each classifier of the fictitious dataset generated from Hanley and McNeil (1983). In example 5 of [R] **rocregplot**, `rocregplot` was used to draw the ROC for the `mod1` and `mod3` classifiers. Estimates of the ROC value and false-positive rate were also obtained with Wald-type confidence intervals.

We return to this example, this time using `predict` to estimate the ROC value and false-positive rate. We will also estimate the pAUC for the false-positive rates of 0.3 and 0.8.

First, we add the input variables to the data. The variable `paucinp` will hold the 0.3 and 0.8 false-positive rates that we will input to pAUC. The variable `invrocinp` holds the ROC value of 0.8 for which we will estimate the false-positive rate. Finally, the variable `rocinp` holds the false-positive rates of 0.15 and 0.75 for which we will estimate the ROC value.

```
. use http://www.stata-press.com/data/r13/ct2, clear
. rocreg status mod1 mod2 mod3, probit ml
  (output omitted)
. quietly generate paucinp = .3 in 111
. quietly replace paucinp = .8 in 112
. quietly generate invrocinp = .8 in 112
. quietly generate rocinp = .15 in 111
. quietly replace rocinp = .75 in 112
```

Then, we estimate the ROC value for false-positive rates 0.15 and 0.75 under classifier `mod1`. The point estimate is stored in `roc1`. Wald confidence intervals and standard errors are also estimated. We find that these results match those of example 5 of [R] **rocregplot**.

```
. predict roc1 in 111/112, classvar(mod1) roc at(rocinp) se(sr1) ci(cir1)
. list rocinp roc1 sr1 cir1* in 111/112
```

	rocinp	roc1	sr1	cir1_l	cir1_u
111.	.15	.7934935	.0801363	.6364293	.9505578
112.	.75	.9931655	.0069689	.9795067	1.006824

Now we perform the same estimation under the classifier `mod3`.

```
. predict roc3 in 111/112, classvar(mod3) roc at(roci) se(sr3) ci(cir3)
. list rocinp roc3 sr3 cir3* in 111/112
```

	rocinp	roc3	sr3	cir3_l	cir3_u
111.	.15	.8888596	.0520118	.7869184	.9908009
112.	.75	.9953942	.0043435	.9868811	1.003907

Next we estimate the false-positive rate for the ROC value of 0.8. These results also match example 5 of [R] **rocregplot**.

```
. predict invroc1 in 112, classvar(mod1) invroc at(invrocinp) se(sir1) ci(ciir1)
. list invrocinp invroc1 sir1 ciir1* in 112
```

	invroc~p	invroc1	sir1	ciir1_l	ciir1_u
112.	.8	.1556435	.069699	.0190361	.292251

```
. predict invroc3 in 112, classvar(mod3) invroc at(invrocinp) se(sir3) ci(ciir3)
. list invrocinp invroc3 sir3 ciir3* in 112
```

	invroc~p	invroc3	sir3	ciir3_l	ciir3_u
112.	.8	.0661719	.045316	-.0226458	.1549896

Finally, we estimate the pAUC for false-positive rates of 0.3 and 0.8. The point estimate is calculated by numeric integration. Wald confidence intervals are obtained with the delta method. Further details are presented in *Methods and formulas*.

```
. predict pauc1 in 111/112, classvar(mod1) pauc at(paucinp) se(sp1) ci(cip1)
. list paucinp pauc1 sp1 cip1* in 111/112
```

	paucinp	pauc1	sp1	cip1_l	cip1_u
111.	.3	.221409	.0240351	.174301	.268517
112.	.8	.7033338	.0334766	.6377209	.7689466

```
. predict pauc3 in 111/112, classvar(mod3) pauc at(paucinp) se(sp3) ci(cip3)
. list paucinp pauc3 sp3 cip3* in 111/112
```

	paucinp	pauc3	sp3	cip3_l	cip3_u
111.	.3	.2540215	.0173474	.2200213	.2880217
112.	.8	.7420408	.0225192	.6979041	.7861776

Using estat nproc

When you initially use `rocreg` to fit a nonparametric ROC curve, you can obtain bootstrap estimates of a ROC value, false-positive rate, area under the ROC curve, and partial area under the ROC curve. The `estat nproc` command allows the user to estimate these parameters after `rocreg` has originally been used.

The seed and resampling settings used by `rocreg` are used by `estat nproc`. So the results for these new statistics are identical to what they would be if they had been initially estimated in the `rocreg` command. These new statistics, together with those previously estimated in `rocreg`, are returned in `r()`.

We demonstrate with an example.

▷ Example 5: Nonparametric ROC, invROC, and pAUC

In example 3 of [R] **rocreg**, we examined data from a pancreatic cancer study (Wieand et al. 1989). Two continuous classifiers, `y1` (CA 19-9) and `y2` (CA 125), were used for the true status variable `d`. In that example, we estimated various quantities including the false-positive rate for a ROC value of 0.6 and the pAUC for a false-positive rate of 0.5. Here we replicate that estimation with a call to `rocreg` to estimate the former and follow that with a call to `estat nproc` to estimate the latter. For simplicity, we restrict estimation to classifier `y1` (CA 19-9).

We start by executing `rocreg`, estimating the false-positive rate for a ROC value of 0.6. This value is specified in `invroc()`. Case–control resampling is used by specifying the `bootcc` option.

```
. use http://labs.fhcrc.org/pepe/book/data/wiedat2b, clear
(S. Wieand - Pancreatic cancer diagnostic marker data)
. rocreg d y1, invroc(.6) bseed(8378923) bootcc nodots
Bootstrap results
Number of strata   =         2                  Number of obs      =       141
                                                 Replications       =      1000
Nonparametric ROC estimation
Control standardization: empirical
ROC method             : empirical
False-positive rate
   Status    : d
   Classifier: y1
```

invROC	Observed Coef.	Bias	Bootstrap Std. Err.	[95% Conf.	Interval]	
.6	0	.0158039	.0267288	-.0523874	.0523874	(N)
				0	.0784314	(P)
				0	.1372549	(BC)

Now we will estimate the pAUC for the false-positive rate of 0.5 using `estat nproc` and the `pauc()` option.

```
. matrix list e(b)

```

◁

The advantages of using `estat nproc` are twofold. First, you can estimate additional parameters of interest without having to respecify the bootstrap settings you did with `rocreg`; instead `estat nproc` uses the bootstrap settings that were stored by `rocreg`. Second, parameters estimated with `estat nproc` are added to those parameters estimated by `rocreg` and returned in the matrices `r(b)` (parameter estimates) and `r(V)` (variance–covariance matrix). Thus you can also obtain correlations between any quantities you wish to estimate.

Stored results

`estat nproc` stores the following in `r()`:

`r(b)`	coefficient vector
`r(V)`	variance–covariance matrix of the estimators
`r(ci_normal)`	normal-approximation confidence intervals
`r(ci_percentile)`	percentile confidence intervals
`r(ci_bc)`	bias-corrected confidence intervals

Methods and formulas

Details on computation of the nonparametric ROC curve and the estimation of the parametric ROC curve model coefficients can be found in [R] **rocreg**. Here we describe how to estimate the ROC curve summary statistics for a parametric model. The cumulative distribution function, g, can be the standard normal cumulative distribution function, Φ.

Methods and formulas are presented under the following headings:

Parametric model: Summary parameter definition
Maximum likelihood estimation
Estimating equations estimation

Parametric model: Summary parameter definition

Conditioning on covariates $\mathbf{x}$, we have the following ROC curve model:

$$\text{ROC}(u) = g\{\mathbf{x}'\boldsymbol{\beta} + \alpha g^{-1}(u)\}$$

$\mathbf{x}$ can be constant, and $\boldsymbol{\beta} = \beta_0$, the constant intercept.

We can solve this equation to obtain the false-positive rate value u for a ROC value of r:

$$u = g\left[\{g^{-1}(r) - \mathbf{x}'\boldsymbol{\beta}\}\alpha^{-1}\right]$$

The partial area under the ROC curve for the false-positive rate u is defined by

$$\text{pAUC}(u) = \int_o^u g\{\mathbf{x}'\boldsymbol{\beta} + \alpha g^{-1}(t)\}dt$$

The area under the ROC curve is defined by

$$\text{AUC} = \int_o^1 g\{\mathbf{x}'\boldsymbol{\beta} + \alpha g^{-1}(t)\}dt$$

When g is the standard normal cumulative distribution function Φ, we can express the AUC as

$$\text{AUC} = \Phi\left(\frac{\mathbf{x}'\boldsymbol{\beta}}{\sqrt{1+\alpha^2}}\right)$$

Maximum likelihood estimation

We allow maximum likelihood estimation under probit parametric models, so $g = \Phi$. The ROC value, false-positive rate, and AUC parameters all have closed-form expressions in terms of the covariate values $\mathbf{x}$, coefficient vector $\boldsymbol{\beta}$, and slope parameter α. So to estimate these three types of summary parameters, we use the delta method (Oehlert 1992; Phillips and Park 1988). Particularly, we use the `nlcom` command (see [R] **nlcom**) to implement the delta method.

To estimate the partial area under the ROC curve for false-positive rate u, we use numeric integration. A trapezoidal approximation is used in calculating the integrals. A numeric integral of the $\text{ROC}(t)$ function conditioned on the covariate values $\mathbf{x}$, coefficient vector estimate $\widehat{\boldsymbol{\beta}}$, and slope parameter estimate $\widehat{\alpha}$ is computed over the range $t = [0, u]$. This gives us the point estimate of $\text{pAUC}(u)$.

To calculate the standard error and confidence intervals for the point estimate of $\text{pAUC}(u)$, we again use the delta method. Details on the delta method algorithm can be found in *Methods and formulas* of [R] **nlcom** and the earlier mentioned references.

Under maximum likelihood estimation, the coefficient estimates $\widehat{\boldsymbol{\beta}}$ and slope estimate $\widehat{\alpha}$ are asymptotically normal with variance matrix $\mathbf{V}$. For convenience, we rename the parameter vector $[\boldsymbol{\beta}', \alpha]$ to the k-parameter vector $\boldsymbol{\theta} = [\theta_1, \ldots, \theta_k]$. We will also explicitly refer to the conditioning of the ROC curve by $\boldsymbol{\theta}$ in its mention as $\text{ROC}(t, \boldsymbol{\theta})$.

Under the delta method, the continuous scalar function of the estimate $\widehat{\boldsymbol{\theta}}$, $f(\widehat{\boldsymbol{\theta}})$ has asymptotic mean $f(\boldsymbol{\theta})$ and asymptotic covariance

$$\widehat{\text{Var}}\left\{f(\widehat{\boldsymbol{\theta}})\right\} = \mathbf{f}\mathbf{V}\mathbf{f}'$$

where $\mathbf{f}$ is the $1 \times k$ matrix of derivatives for which

$$\mathbf{f}_{1j} = \frac{\partial f(\boldsymbol{\theta})}{\partial \theta_j} \qquad j = 1, \ldots, k$$

The asymptotic covariance of $f(\widehat{\boldsymbol{\theta}})$ is estimated and then used in conjunction with $f(\widehat{\boldsymbol{\theta}})$ for further inference, including Wald confidence intervals, standard errors, and hypothesis testing.

In the case of pAUC(u) estimation, our $f(\widehat{\boldsymbol{\theta}})$ is the aforementioned numeric integral of the ROC curve. It estimates $f(\boldsymbol{\theta})$, the true integral of the ROC curve on the $[0, u]$ range. The $\mathbf{V}$ variance matrix is estimated using the likelihood information that `rocreg` calculated, and the estimation is performed by `rocreg` itself.

The partial derivatives of $f(\boldsymbol{\theta})$ can be determined by using Leibnitz's rule (Weisstein 2011):

$$\mathbf{f}_{1j} = \frac{\partial}{\partial \theta_j} \int_0^u \text{ROC}(t, \boldsymbol{\theta}) dt = \int_0^u \frac{\partial}{\partial \theta_j} \text{ROC}(t, \boldsymbol{\theta}) dt \qquad j = 1, \ldots, k$$

When θ_j corresponds with the slope parameter α, we obtain the following partial derivative:

$$\frac{\partial}{\partial \alpha} \text{pAUC}(u) = \int_0^u \phi\{\mathbf{x}'\boldsymbol{\beta} + \alpha\Phi^{-1}(t)\}\Phi^{-1}(t)\, dt$$

The partial derivative of $f(\boldsymbol{\theta})$ [pAUC(u)] for β_0 is the following:

$$\frac{\partial}{\partial \beta_0} \text{pAUC}(u) = \int_0^u \phi\{\mathbf{x}'\boldsymbol{\beta} + \alpha\Phi^{-1}(t)\} dt$$

For a nonintercept coefficient, we obtain the following:

$$\frac{\partial}{\partial \beta_i} \text{pAUC}(u) = \int_0^u x_i \phi\{\mathbf{x}'\boldsymbol{\beta} + \alpha\Phi^{-1}(t)\} dt$$

We can estimate each of these integrals by numeric integration, plugging in the estimates $\widehat{\boldsymbol{\beta}}$ and $\widehat{\alpha}$ for the parameters. This, together with the previously calculated estimate $\widehat{\mathbf{V}}$, provides an estimate of the asymptotic covariance of $f(\widehat{\boldsymbol{\theta}}) = \widehat{\text{pAUC}}(u)$, which allows us to perform further statistical inference on pAUC(u).

Estimating equations estimation

When we fit a model using the Alonzo and Pepe (2002) estimating equations method, we use the bootstrap to perform inference on the ROC curve summary parameters. Each bootstrap sample provides a sample of the coefficient estimates $\boldsymbol{\beta}$ and the slope estimates α. Using the formulas in *Parametric model: Summary parameter definition* under *Methods and formulas*, we can obtain an estimate of the ROC, false-positive rate, or AUC for each resample. Using numeric integration (with the trapezoidal approximation), we can also estimate the pAUC of the resample.

By making these calculations, we obtain a bootstrap sample of our summary parameter estimate. We then obtain bootstrap standard errors, normal approximation confidence intervals, percentile confidence intervals, and bias-corrected confidence intervals using this bootstrap sample. Further details can be found in [R] **bootstrap**.

boot_options	Description
Bootstrap	
† `bfile(`*filename*`)`	load dataset containing bootstrap replicates from `rocreg`
`btype(n | p | bc)`	plot normal-based (`n`), percentile (`p`), or bias-corrected (`bc`) confidence intervals; default is `btype(n)`

† `bfile()` is only allowed with parametric analysis using bootstrap inference; in which case this option is required with `roc()` or `invroc()`.

Menu

Statistics > Epidemiology and related > ROC analysis > ROC curves after rocreg

Description

Under parametric estimation, `rocregplot` plots the fitted ROC curves for specified covariate values and classifiers. If `rocreg, probit` or `rocreg, probit ml` were previously used, the false-positive rates (for specified ROC values) and ROC values (for specified false-positive rates) for each curve may also be plotted, along with confidence intervals.

Under nonparametric estimation, `rocregplot` will plot the fitted ROC curves using the `_fpr_*` and `_roc_*` variables produced by `rocreg`. Point estimates and confidence intervals for false-positive rates and ROC values that were computed in `rocreg` may be plotted as well.

probit_options

Main

`at(`*varname*`=# . . . )` requests that the covariates specified by *varname* be set to #. By default, `rocreg` evaluates the function by setting each covariate to its mean value. This option causes the ROC curve to be evaluated at the value of the covariates listed in `at()` and at the mean of all unlisted covariates.

`at1(`*varname*`=# ...)`, `at2(`*varname*`=# ...)`, ..., `at10(`*varname*`=# ...)` specify that ROC curves (up to 10) be plotted on the same graph. `at1()`, `at2()`, ..., `at10()` work like the `at()` option. They request that the function be evaluated at the value of the covariates specified and at the mean of all unlisted covariates. `at1()` specifies the values of the covariates for the first curve, `at2()` specifies the values of the covariates for the second curve, and so on.

`roc(`*numlist*`)` specifies that estimated ROC values for given false-positive rates be graphed.

`invroc(`*numlist*`)` specifies that estimated false-positive rates for given ROC values be graphed.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see **[U] 20.7 Specifying the width of confidence intervals**. `level()` may be specified with either `roc()` or `invroc()`.

Curve

`line#opts(`*cline_options*`)` affects the rendition of ROC curve #. See [G-3] ***cline_options***.

common_options

Main

`classvars(`*varlist*`)` restricts plotting ROC curves to specified classification variables.

`norefline` suppresses plotting the reference line.

Scatter

`plot#opts(`*scatter_options*`)` affects the rendition of classifier #'s false-positive rate and ROC scatter points. This option applies only to non-ROC covariate estimation graphing. See [G-2] **graph twoway scatter**.

Reference line

`rlopts(`*cline_options*`)` affects rendition of the reference line. See [G-3] ***cline_options***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and options for saving the graph to disk (see [G-3] ***saving_option***).

boot_options

Bootstrap

`bfile(`*filename*`)` uses bootstrap replicates of parameters from `rocreg` stored in *filename* to estimate standard errors and confidence intervals of predictions. `bfile()` must be specified with either `roc()` or `invroc()` if parametric estimation with bootstrapping was used.

`btype(n | p | bc)` indicates the desired type of confidence interval rendering. `n` draws normal-based, `p` draws percentile, and `bc` draws bias-corrected confidence intervals for specified false-positive rates and ROC values in `roc()` and `invroc()`. The default is `btype(n)`.

Remarks and examples

Remarks are presented under the following headings:

Plotting covariate-specific ROC curves
Plotting marginal ROC curves

Plotting covariate-specific ROC curves

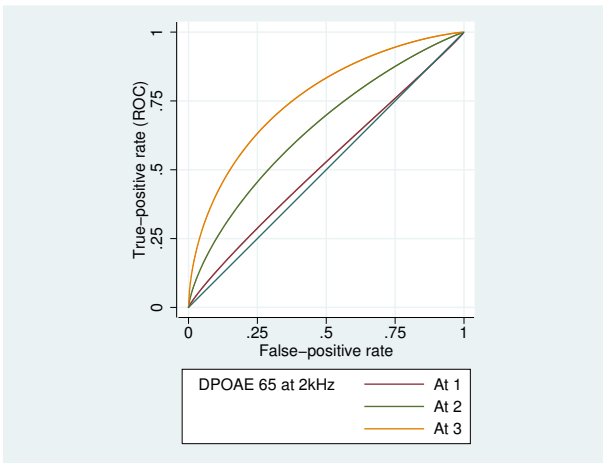
The `rocregplot` command is also demonstrated in [R] **rocreg**. We will further demonstrate its use with several examples. Particularly, we will show how `rocregplot` can draw the ROC curves of covariate models that have been fit using `rocreg`.

▷ Example 1: Parametric ROC

In example 6 of [R] **rocreg**, we fit a probit ROC model to audiology test data from Norton et al. (2000). The estimating equation method of Alonzo and Pepe (2002) was used to the fit the model. Gender and age were covariates that affected the control distribution of the classifier `y1` (DPOAE 65 at 2 kHz). Age was a ROC covariate for the model, so we fit separate ROC curves at each age.

Following Janes, Longton, and Pepe (2009), we draw the ROC curves for ages 30, 40, and 50 months. The `at1()`, `at2()`, and `at3()` options are used to specify the age covariates.

```
. use http://www.stata-press.com/data/r13/nnhs
(Norton - neonatal audiology data)
. rocreg d y1, probit ctrlcov(currage male) ctrlmodel(linear) roccov(currage)
> cluster(id) bseed(56930) bsave(nnhs2y1, replace)
  (output omitted)
. rocregplot, at1(currage=30) at2(currage=40) at3(currage=50)
```



Here we use the default entries of the legend, which indicate the "at #" within the specified `at*` options and the classifier to which the curve corresponds. ROC curve one corresponds with `currage=30`, two with `currage=40`, and three with `currage=50`. The positive effect of age on the ROC curve is evident. At an age of 30 months (`currage=30`), the ROC curve of `y1` (DPOAE 65 at 2 kHz) is nearly equivalent to that of a noninformative test that gives equal probability to hearing loss. At age 50 months (`currage=50`), corresponding to some of the oldest children in the study, the ROC curve shows that test `y1` (DPOAE 65 at 2 kHz) is considerably more powerful than the noninformative test.

You may create your own legend by specifying the `legend()` option. The default legend is designed for the possibility of multiple covariates. Here we could change the legend entries to `currage` values and gain some extra clarity. However, this may not be feasible when there are many covariates present.

◁

We can also use `rocregplot` after maximum likelihood estimation.

▷ Example 2: Maximum likelihood ROC

We return to the audiology study with frequency (`xf`), intensity (`xl`), and hearing loss severity (`xd`) covariates from Stover et al. (1996) that we examined in example 10 of [R] **rocreg**. Negative signal-to-noise ratio is again used as a classifier. Using maximum likelihood, we fit a probit model to these data with the indicated ROC covariates.

After fitting the model, we wish to compare the ROC curves of two covariate combinations. The first has an intensity value of 5.5 (the lowest intensity, corresponding to 55 decibels) and a frequency of 10.01 (the lowest frequency, corresponding to 1001 hertz). We give the first combination a hearing loss severity value of 0.5 (the lowest). The second covariate combination has the same frequency, but the highest intensity value of 6.5 (65 decibels). We give this second covariate set a higher severity value of 4. We will visually compare the two ROC curves resulting from these two covariate value combinations.

We specify false-positive rates of 0.7 first followed by 0.2 in the `roc()` option to visually compare the size of the ROC curve at large and small false-positive rates. Because maximum likelihood estimation was used to fit the model, a Wald confidence interval is produced for the estimated ROC value and false-positive rate parameters. Further details are found in *Methods and formulas*.

```
. use http://www.stata-press.com/data/r13/dp
(Stover - DPOAE test data)

. rocreg d nsnr, probit ctrlcov(xf xl) roccov(xf xl xd) ml cluster(id)
  (output omitted)
```

```
. rocregplot, at1(xf=10.01, xl=5.5, xd=.5) at2(xf=10.01, xl=6.5, xd=4) roc(.7)
ROC curve
   Status    : d
   Classifier: nsnr
Under covariates:
```

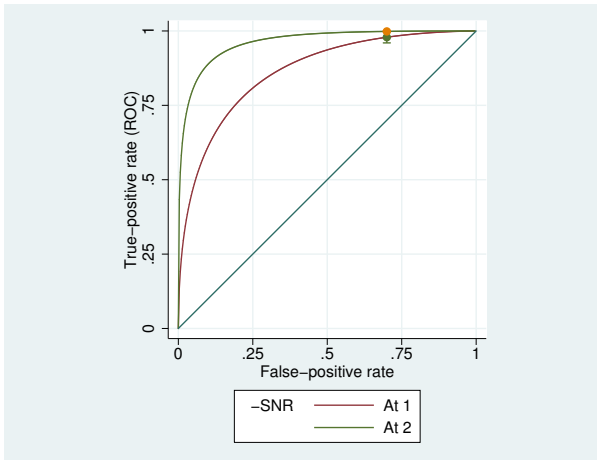
	at1
xf	10.01
xl	5.5
xd	.5

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.7	.978951	.0097382	.9598645	.9980376

Under covariates:

	at2
xf	10.01
xl	6.5
xd	4

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.7	.9985001	.0009657	.9966073	1.000393



At the higher false-positive rate value of 0.7, we see little difference in the ROC values and note that the confidence intervals nearly overlap. Now we view the same curves with the lower false-positive rate compared.

```
. rocregplot, at1(xf=10.01, xl=5.5, xd=.5) at2(xf=10.01, xl=6.5, xd=4) roc(.2)
ROC curve
   Status    : d
   Classifier: nsnr
Under covariates:
```

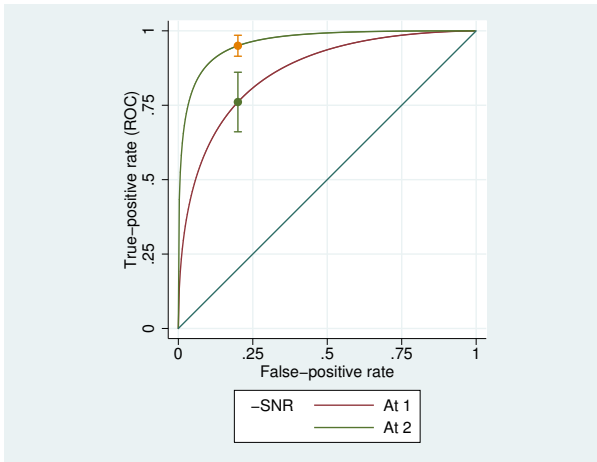
	at1
xf	10.01
xl	5.5
xd	.5

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.2	.7608593	.0510501	.660803	.8609157

Under covariates:

	at2
xf	10.01
xl	6.5
xd	4

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.2	.9499408	.0179824	.914696	.9851856



The lower false-positive rate of 0.2 shows clearly distinguishable ROC values. Now we specify option `invroc(.5)` to view how the false-positive rates vary at a ROC value of 0.5.

```
. rocregplot, at1(xf=10.01, xl=5.5, xd=.5) at2(xf=10.01, xl=6.5, xd=4) invroc(.5)
False-positive rate
   Status    : d
   Classifier: nsnr
Under covariates:
```

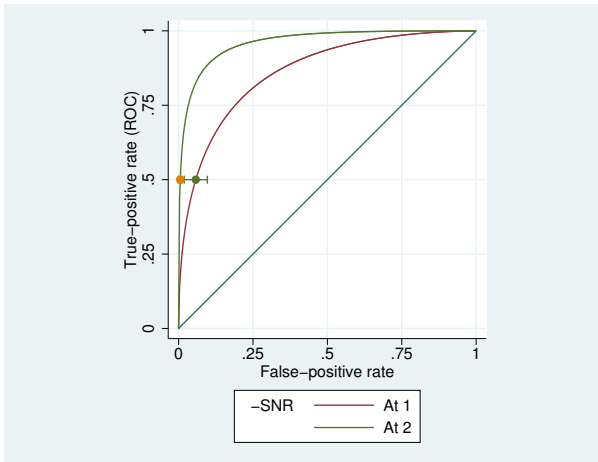
	at1
xf	10.01
xl	5.5
xd	.5

invROC	Coef.	Std. Err.	[95% Conf.	Interval]
.5	.0578036	.0198626	.0188736	.0967336

Under covariates:

	at2
xf	10.01
xl	6.5
xd	4

invROC	Coef.	Std. Err.	[95% Conf.	Interval]
.5	.0055624	.0032645	-.0008359	.0119607



At a ROC value of 0.5, the false-positive rates for both curves are small and close to one another. ◁

❑ Technical note

We can use the `testnl` command to support our visual observations with statistical inference. We use it to perform a Wald test of the null hypothesis that the two ROC curves just rendered are equal at a false-positive rate of 0.7.

```
. testnl normal(_b[i_cons]+10.01*_b[xf]+5.5*_b[xl]
>                + .5*_b[xd]+_b[s_cons]*invnormal(.7)) =
>       normal(_b[i_cons]+10.01*_b[xf]+6.5*_b[xl]
>                + 4*_b[xd]+_b[s_cons]*invnormal(.7))

(1)  normal(_b[i_cons]+10.01*_b[xf]+5.5*_b[xl] +.5*_b[xd]+_b[s_cons]*invnormal(.7))=
     normal(_b[i_cons]+10.01*_b[xf]+6.5*_b[xl] + 4*_b[xd]+_b[s_cons]*invnormal(.7))

           chi2(1) =        4.53
       Prob > chi2 =        0.0332
```

The test is significant at the 0.05 level, and thus we find that the two curves are significantly different. Now we will use `testnl` again to test equality of the false-positive rates for each curve with a ROC value of 0.5. The inverse ROC formula used is derived in *Methods and formulas*.

```
. testnl normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+5.5*_b[xl]+.5*_b[xd]))
>                /_b[s_cons]) =
>       normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+6.5*_b[xl]+4*_b[xd]))
>                /_b[s_cons])

  (1)  normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+5.5*_b[xl]+.5*_b[xd]))
             /_b[s_cons]) =
       normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+6.5*_b[xl]+4*_b[xd]))
             /_b[s_cons])

           chi2(1) =        8.01
       Prob > chi2 =        0.0046
```

We again reject the null hypothesis that the two curves are equal at the 0.05 level.

❑

The model of our last example was also fit using the estimating equations method in example 7 of [R] **rocreg**. We will demonstrate `rocregplot` after that model fit as well.

▷ Example 3: Parametric ROC, invROC, and ROC value

In example 2, we used `rocregplot` after a maximum likelihood model fit of the ROC curve for classifier `nsnr` and covariates frequency (`xf`), intensity (`xl`), and hearing loss severity (`xd`). The data were obtained from the audiology study described in Stover et al. (1996). In example 7 of [R] **rocreg**, we fit the model using the estimating equations method of Alonzo and Pepe (2002). Under this method, bootstrap resampling is used to make inferences. We saved 50 bootstrap replications in `nsnrf.dta`, which we re-create below.

We use `rocregplot` to draw the ROC curves for `nsnr` under the covariate values `xf = 10.01`, `xl = 5.5`, and `xd = .5`, and `xf = 10.01`, `xl = 6.5`, and `xd = 4`. The `at#()` options are used to specify the covariate values. The previous bootstrap results are made available to `rocregplot` with the `bfile()` option. As before, we will specify 0.2 and 0.7 as false-positive rates in the `roc()` option and 0.5 as a ROC value in the `invroc()` option. We do not specify `btype()` and thus our graph will contain normal-based bootstrap confidence bands, the default.

```

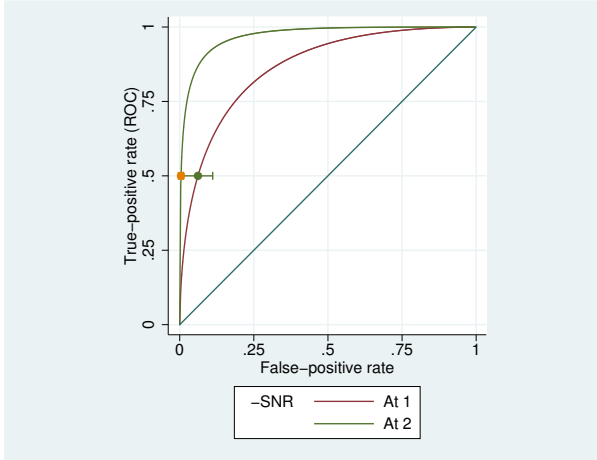
				.0224352	.1265046	(BC)

Under covariates:

	at2
xf	10.01
xl	6.5
xd	4

(Replications based on 208 clusters in id)

invROC	Observed Coef.	Bias	Bootstrap Std. Err.	[95% Conf.	Interval]	
.5	.0043298	-.0012579	.0045938	-.004674	.0133335	(N)
				.0002773	.0189199	(P)
				.0001292	.0134801	(BC)



The point estimates of the ROC value and false-positive rate are both computed directly using the point estimates of the ROC coefficients. Calculation of the standard errors and confidence intervals is slightly more complicated. Essentially, we have stored a sample of our ROC covariate coefficient estimates in `nsnrf.dta`. We then calculate the ROC value or false-positive rate estimates using each set of coefficient estimates, resulting in a sample of point estimates. Then the bootstrap standard error and confidence intervals are calculated based on these bootstrap samples. Details of the computation of the standard error and percentile confidence intervals can be found in *Methods and formulas* and in [R] **bootstrap**.

As mentioned in [R] **rocreg**, 50 resamples is a reasonable lower bound for obtaining bootstrap standard errors (Mooney and Duval 1993). However, it may be too low for obtaining percentile and bias-corrected confidence intervals. Normal-based confidence intervals are valid when the bootstrap distribution exhibits normality. See [R] **bootstrap postestimation** for more details.

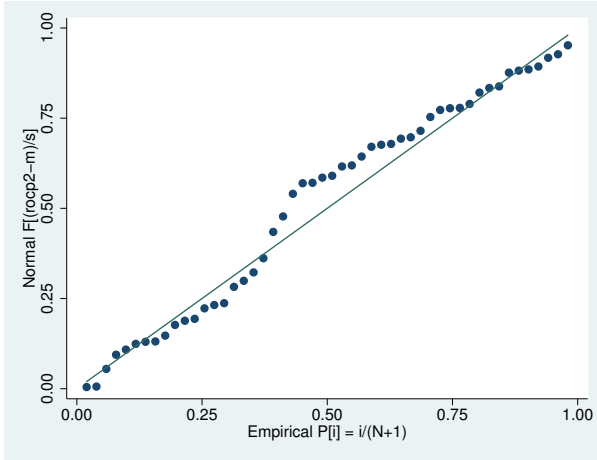
We can assess the normality of the bootstrap distribution by using a normal probability plot. Stata provides this in the `pnorm` command (see [R] **diagnostic plots**). We will use `nsnrf.dta` to draw a normal probability plot for the ROC estimate corresponding to a false-positive rate of 0.2. We use the covariate values `xf = 10.01`, `xl = 6.5`, and `xd = 4`.

```
. use nsnrf
(bootstrap: rocregstat)

. generate double rocp2 = nsnr_b_i_cons + 10.01*nsnr_b_xf + 6.5*nsnr_b_xl +
> 4*nsnr_b_xd+nsnr_b_s_cons*invnormal(.2)

. replace rocp2 = normal(rocp2)
(50 real changes made)
```

```
. pnorm rocp2
```



The closeness of the points to the horizontal line on the normal probability plot shows us that the bootstrap distribution is approximately normal. So it is reasonable to use the normal-based confidence intervals for ROC at a false-positive rate of 0.2 under covariate values `xf = 10.01`, `xl = 6.5`, and `xd = 4`.

◁

Plotting marginal ROC curves

The `rocregplot` command can also be used after fitting models with no covariates. We will demonstrate this with an empirical ROC model fit in [R] **rocreg**.

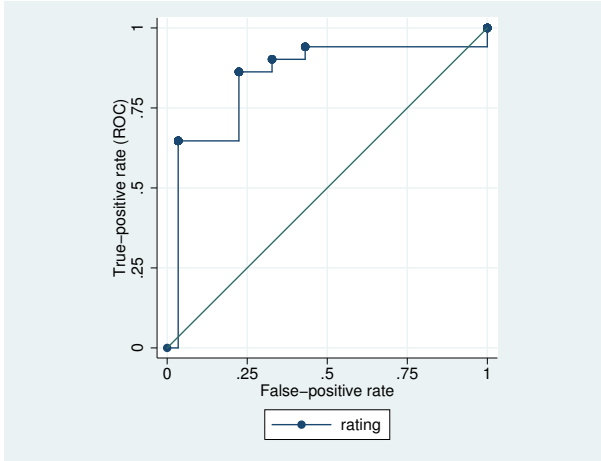
▷ Example 4: Nonparametric ROC

We run `rocregplot` after fitting the single-classifier, empirical ROC model shown in example 1 of [R] **rocreg**. There we empirically predicted the ROC curve of the classifier `rating` for the true status variable `disease` from the Hanley and McNeil (1982) data. The `rocreg` command saves variables `_roc_rating` and `_fpr_rating`, which give the ROC values and false-positive rates, respectively, for every value of `rating`. These variables are used by `rocregplot` to render the ROC curve.

```
. use http://www.stata-press.com/data/r13/hanley, clear
. rocreg disease rating, noboot
Nonparametric ROC estimation
Control standardization: empirical
ROC method             : empirical
Area under the ROC curve
   Status    : disease
   Classifier: rating
```

AUC	Observed Coef.	Bias	Bootstrap Std. Err.	[95% Conf.	Interval]	
	.8407708	.	.	.	.	(N)
				.	.	(P)
				.	.	(BC)

```
. rocregplot
```



We end our discussion of `rocregplot` by showing its use after a marginal probit model.

▷ Example 5: Maximum likelihood ROC, invROC, and ROC value

In example 13 of [R] **rocreg**, we fit a maximum-likelihood probit model to each classifier of the fictitious dataset generated from Hanley and McNeil (1983).

We use `rocregplot` after the original `rocreg` command to draw the ROC curves for classifiers `mod1` and `mod3`. This is accomplished by specifying the two variables in the `classvars()` option. We will use the `roc()` option to obtain confidence intervals for ROC values at false-positive rates of 0.15 and 0.75. We will specify the `invroc()` option to obtain false-positive rate confidence intervals for a ROC value of 0.8. As mentioned previously, these are Wald confidence intervals.

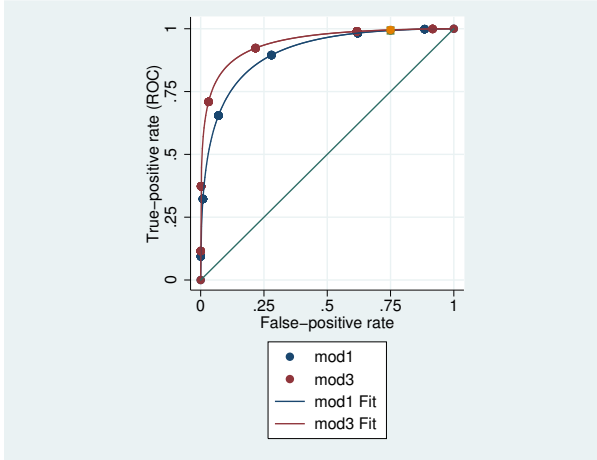
First, we will view results for a false-positive rate of 0.75.

```
. use http://www.stata-press.com/data/r13/ct2, clear
. rocreg status mod1 mod2 mod3, probit ml
  (output omitted)
. rocregplot, classvars(mod1 mod3) roc(.75)
ROC curve
   Status     : status
   Classifier: mod1
```

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.75	.9931655	.0069689	.9795067	1.006824

```
   Status     : status
   Classifier: mod3
```

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.75	.9953942	.0043435	.9868811	1.003907



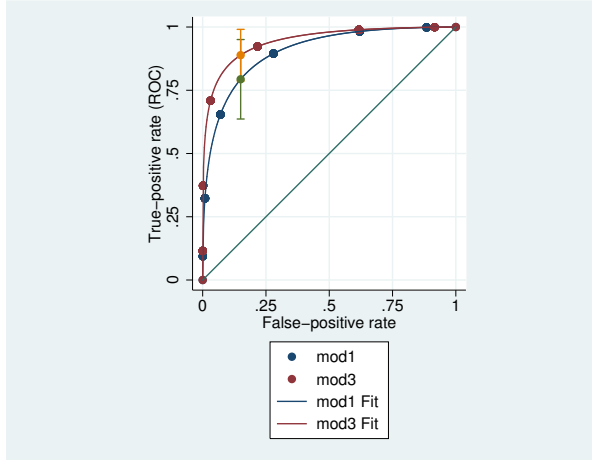
We see that the estimates for each of the two ROC curves are close. Because this is a marginal model, the actual false-positive rate and the true-positive rate for each observation are plotted in the graph. The added point estimates of the ROC value at false-positive rate 0.75 are shown as diamond (`mod3`) and circle (`mod1`) symbols in the upper-right-hand corner of the graph at FPR $= 0.75$. Confidence bands are also plotted at FPR $= 0.75$ but are so narrow that they are barely noticeable. Under both classifiers, the ROC value at 0.75 is very high. Now we will compare these results to those with a lower false-positive rate of 0.15.

```
. rocregplot, classvars(mod1 mod3) roc(.15)
ROC curve
   Status     : status
   Classifier: mod1
```

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.15	.7934935	.0801363	.6364292	.9505578

```
   Status     : status
   Classifier: mod3
```

ROC	Coef.	Std. Err.	[95% Conf.	Interval]
.15	.8888596	.0520118	.7869184	.9908008



The ROC value for the false-positive rate of 0.15 is more separated in the two classifiers. Here we see that `mod3` has a larger ROC value than `mod1` for this false-positive rate, but the confidence intervals of the estimates overlap.

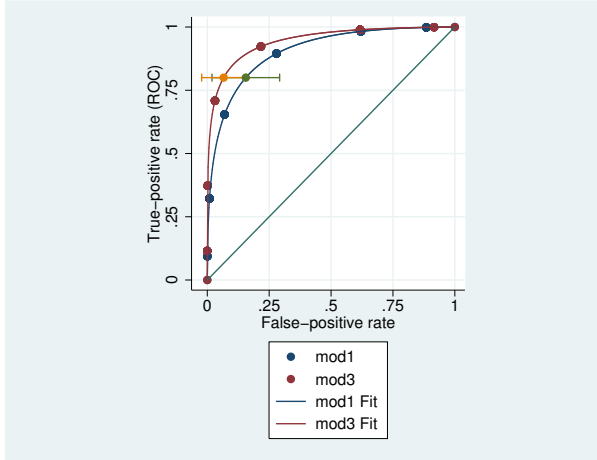
By specifying `invroc(.8)`, we obtain invROC confidence intervals corresponding to a ROC value of 0.8.

```
. rocregplot, classvars(mod1 mod3) invroc(.8)
False-positive rate
   Status     : status
   Classifier: mod1
```

invROC	Coef.	Std. Err.	[95% Conf.	Interval]
.8	.1556435	.069699	.019036	.2922509

```
   Status     : status
   Classifier: mod3
```

invROC	Coef.	Std. Err.	[95% Conf.	Interval]
.8	.0661719	.045316	-.0226458	.1549896



For estimation of the false-positive rate at a ROC value of 0.8, the confidence intervals overlap. Both classifiers require only a small false-positive rate to achieve a ROC value of 0.8.

◁

Methods and formulas

Details on computation of the nonparametric ROC curve and the estimation of the parametric ROC curve model coefficients can be found in [R] **rocreg**. Here we describe how to estimate the ROC values and false-positive rates of a parametric model. The cumulative distribution function g can be the standard normal cumulative distribution function.

Methods and formulas are presented under the following headings:

Parametric model: Summary parameter definition
Maximum likelihood estimation
Estimating equations estimation

Parametric model: Summary parameter definition

Conditioning on covariates $\mathbf{x}$, we have the following ROC curve model:

$$\text{ROC}\,(u) = g\{\mathbf{x}'\boldsymbol{\beta} + \alpha g^{-1}\,(u)\}$$

$\mathbf{x}$ can be constant, and $\boldsymbol{\beta} = \beta_0$, the constant intercept.

With simple algebra, we can solve this equation to obtain the false-positive rate value u for a ROC value of r:

$$u = g\left[\{g^{-1}\,(r) - \mathbf{x}'\boldsymbol{\beta}\}\alpha^{-1}\right]$$

Maximum likelihood estimation

We allow maximum likelihood estimation under probit parametric models, so $g = \Phi$. The ROC value and false-positive rate parameters all have closed-form expressions in terms of the covariate values $\mathbf{x}$, coefficient vector $\boldsymbol{\beta}$, and slope parameter α. Thus to estimate these two types of summary parameters, we use the delta method (Oehlert 1992; Phillips and Park 1988). Particularly, we use the `nlcom` command (see [R] **nlcom**) to implement the delta method.

Under maximum likelihood estimation, the coefficient estimates $\widehat{\boldsymbol{\beta}}$ and slope estimate $\widehat{\alpha}$ are asymptotically normal with variance matrix $\mathbf{V}$. For convenience, we rename the parameter vector $[\boldsymbol{\beta}', \alpha]$ to the k-parameter vector $\boldsymbol{\theta} = [\theta_1, \ldots, \theta_k]$. We will also explicitly refer to the conditioning of the ROC curve by $\boldsymbol{\theta}$ in its mention as $\text{ROC}(t, \boldsymbol{\theta})$.

Under the delta method, the continuous scalar function of the estimate $\widehat{\boldsymbol{\theta}}$, $f(\widehat{\boldsymbol{\theta}})$ has asymptotic mean $f(\boldsymbol{\theta})$ and asymptotic covariance

$$\widehat{\text{Var}}\left\{f(\widehat{\boldsymbol{\theta}})\right\} = \mathbf{f}\mathbf{V}\mathbf{f}'$$

where $\mathbf{f}$ is the $1 \times k$ matrix of derivatives for which

$$\mathbf{f}_{1j} = \frac{\partial f(\boldsymbol{\theta})}{\partial \theta_j} \qquad j = 1, \ldots, k$$

The asymptotic covariance of $f(\widehat{\boldsymbol{\theta}})$ is estimated and then used in conjunction with $f(\widehat{\boldsymbol{\theta}})$ for further inference, including Wald confidence intervals, standard errors, and hypothesis testing.

Estimating equations estimation

When we fit a model using the Alonzo and Pepe (2002) estimating equations method, we use the bootstrap to perform inference on the ROC curve summary parameters. Each bootstrap sample provides a sample of the coefficient estimates $\boldsymbol{\beta}$ and the slope estimates α. Using the formulas above, we can obtain an estimate of the ROC value or false-positive rate for each resample.

By making these calculations, we obtain a bootstrap sample of our summary parameter estimate. We then obtain bootstrap standard errors, normal approximation confidence intervals, percentile confidence intervals, and bias-corrected confidence intervals using this bootstrap sample. Further details can be found in [R] **bootstrap**.

Statistics > Epidemiology and related > ROC analysis > Nonparametric ROC analysis without covariates

Description

The above command is used to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data.

The two variables *refvar* and *classvar* must be numeric. The reference variable indicates the true state of the observation, such as diseased and nondiseased or normal and abnormal, and must be coded as 0 and 1. The rating or outcome of the diagnostic test or test modality is recorded in *classvar*, which must be at least ordinal, with higher values indicating higher risk.

`roctab` performs nonparametric ROC analyses. By default, `roctab` calculates the area under the ROC curve. Optionally, `roctab` can plot the ROC curve, display the data in tabular form, and produce Lorenz-like plots.

See [R] **rocfit** for a command that fits maximum-likelihood ROC models.

Options

Main

`lorenz` specifies that Gini and Pietra indices be reported. Optionally, `graph` will plot the Lorenz-like curve.

`binomial` specifies that exact binomial confidence intervals be calculated.

`nolabel` specifies that numeric codes be displayed rather than value labels.

`detail` outputs a table displaying the sensitivity, specificity, the percentage of subjects correctly classified, and two likelihood ratios for each possible cutpoint of *classvar*.

`table` outputs a $2 \times k$ contingency table displaying the raw data.

`bamber` specifies that the standard error for the area under the ROC curve be calculated using the method suggested by Bamber (1975). Otherwise, standard errors are obtained as suggested by DeLong, DeLong, and Clarke-Pearson (1988).

`hanley` specifies that the standard error for the area under the ROC curve be calculated using the method suggested by Hanley and McNeil (1982). Otherwise, standard errors are obtained as suggested by DeLong, DeLong, and Clarke-Pearson (1988).

`graph` produces graphical output of the ROC curve. If `lorenz` is specified, graphical output of a Lorenz-like curve will be produced.

`norefline` suppresses plotting the 45-degree reference line from the graphical output of the ROC curve.

`summary` reports the area under the ROC curve, its standard error, and its confidence interval. If `lorenz` is specified, Lorenz indices are reported. This option is needed only when also specifying `graph`.

`specificity` produces a graph of sensitivity versus specificity instead of sensitivity versus (1 − specificity). `specificity` implies `graph`.

`level(#)` specifies the confidence level, as a percentage, for the confidence intervals. The default is `level(95)` or as set by `set level`; see [R] **level**.

Plot

`plotopts(`*plot_options*`)` affects the rendition of the plotted ROC curve—the curve's plotted points connected by lines. The *plot_options* can affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] ***marker_options***, [G-3] ***marker_label_options***, and [G-3] ***cline_options***.

Reference line

`rlopts(`*cline_options*`)` affects the rendition of the reference line; see [G-3] ***cline_options***.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph; see [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples

Remarks are presented under the following headings:

Introduction
Nonparametric ROC curves
Lorenz-like curves

Introduction

The `roctab` command provides nonparametric estimation of the ROC for a given classifier and true-status reference variable. The Lorenz curve functionality of `roctab`, which provides an alternative to standard ROC analysis, is discussed in *Lorenz-like curves*.

See Pepe (2003) for a discussion of ROC analysis. Pepe has posted Stata datasets and programs used to reproduce results presented in the book (http://www.stata.com/bookstore/pepe.html).

Nonparametric ROC curves

The points on the nonparametric ROC curve are generated using each possible outcome of the diagnostic test as a classification cutpoint and computing the corresponding sensitivity and 1−specificity. These points are then connected by straight lines, and the area under the resulting ROC curve is computed using the trapezoidal rule.

▷ Example 1

Hanley and McNeil (1982) presented data from a study in which a reviewer was asked to classify, using a five-point scale, a random sample of 109 tomographic images from patients with neurological problems. The rating scale was as follows: 1 = definitely normal, 2 = probably normal, 3 = questionable, 4 = probably abnormal, and 5 = definitely abnormal. The true disease status was normal for 58 of the patients and abnormal for the remaining 51 patients.

Here we list 9 of the 109 observations:

```
. use http://www.stata-press.com/data/r13/hanley
. list disease rating in 1/9
```

	disease	rating
1.	1	5
2.	0	1
3.	1	5
4.	0	4
5.	0	1
6.	0	3
7.	1	5
8.	0	5
9.	0	1

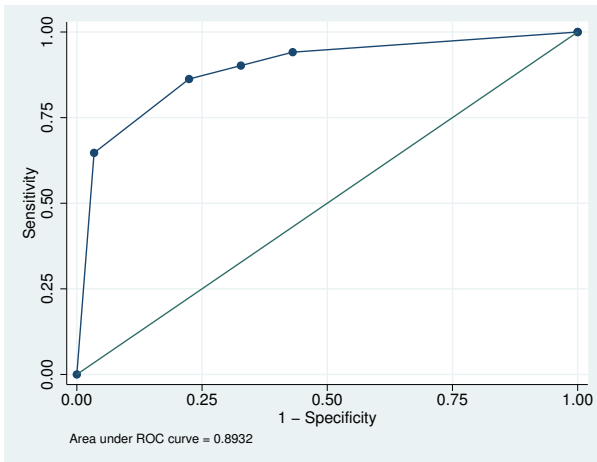
For each observation, `disease` identifies the true disease status of the subject (0 = normal, 1 = abnormal), and `rating` contains the classification value assigned by the reviewer.

We can use `roctab` to calculate and plot the nonparametric ROC curve by specifying both the `summary` and `graph` options. By also specifying the `table` option, we obtain a contingency table summarizing our dataset.

```
. roctab disease rating, table graph summary
```

	rating					
disease	1	2	3	4	5	Total
0	33	6	6	11	2	58
1	3	2	2	11	33	51
Total	36	8	8	22	35	109

			Asymptotic Normal	
Obs	ROC Area	Std. Err.	[95% Conf.	Interval]
109	0.8932	0.0307	0.83295	0.95339



By default, `roctab` reports the area under the curve, its standard error, and its confidence interval. The `graph` option can be used to plot the ROC curve.

The ROC curve is plotted by computing the sensitivity and specificity using each value of the rating variable as a possible cutpoint. A point is plotted on the graph for each of the cutpoints. These plotted points are joined by straight lines to form the ROC curve, and the area under the ROC curve is computed using the trapezoidal rule.

We can tabulate the computed sensitivities and specificities for each of the possible cutpoints by specifying `detail`.

```
. roctab disease rating, detail
Detailed report of sensitivity and specificity
```

Cutpoint	Sensitivity	Specificity	Correctly Classified	LR+	LR-
(>= 1)	100.00%	0.00%	46.79%	1.0000	
(>= 2)	94.12%	56.90%	74.31%	2.1835	0.1034
(>= 3)	90.20%	67.24%	77.98%	2.7534	0.1458
(>= 4)	86.27%	77.59%	81.65%	3.8492	0.1769
(>= 5)	64.71%	96.55%	81.65%	18.7647	0.3655
(> 5)	0.00%	100.00%	53.21%		1.0000

Obs	ROC Area	Std. Err.	Asymptotic Normal [95% Conf.	Interval]
109	0.8932	0.0307	0.83295	0.95339

Each cutpoint in the table indicates the ratings used to classify tomographs as being from an abnormal subject. For example, the first cutpoint (`>= 1`) indicates that all tomographs rated as 1 or greater are classified as coming from abnormal subjects. Because all tomographs have a rating of 1 or greater, all are considered abnormal. Consequently, all abnormal cases are correctly classified (sensitivity = 100%), but none of the normal patients is classified correctly (specificity = 0%). For the second cutpoint (`>=2`), tomographs with ratings of 1 are classified as normal, and those with ratings of 2 or greater are classified as abnormal. The resulting sensitivity and specificity are 94.12% and 56.90%, respectively. Using this cutpoint, we correctly classified 74.31% of the 109 tomographs. Similar interpretations can be used on the remaining cutpoints. As mentioned, each cutpoint corresponds to a point on the nonparametric ROC curve. The first cutpoint (`>=1`) corresponds to the point at (1,1), and the last cutpoint (> 5) corresponds to the point at (0,0).

`detail` also reports two likelihood ratios suggested by Choi (1998): the likelihood ratio for a positive test result (LR+) and the likelihood ratio for a negative test result (LR–). The LR+ is the ratio of the probability of a positive test among the truly positive subjects to the probability of a positive test among the truly negative subjects. The LR– is the ratio of the probability of a negative test among the truly positive subjects to the probability of a negative test among the truly negative subjects. Choi points out that LR+ corresponds to the slope of the line from the origin to the point on the ROC curve determined by the cutpoint. Similarly, LR– corresponds to the slope from the point (1,1) to the point on the ROC curve determined by the cutpoint.

By default, `roctab` calculates the standard error for the area under the curve by using an algorithm suggested by DeLong, DeLong, and Clarke-Pearson (1988) and asymptotic normal confidence intervals. Optionally, standard errors based on methods suggested by Bamber (1975) or Hanley and McNeil (1982) can be computed by specifying `bamber` or `hanley`, respectively, and an exact binomial confidence interval can be obtained by specifying `binomial`.

◁

Lorenz-like curves

For applications where it is known that the risk status increases or decreases monotonically with increasing values of the diagnostic test, the ROC curve and associated indices are useful in assessing the overall performance of a diagnostic test. When the risk status does not vary monotonically with increasing values of the diagnostic test, however, the resulting ROC curve can be nonconvex and its indices can be unreliable. For these situations, Lee (1999) proposed an alternative to the ROC analysis based on Lorenz-like curves and the associated Pietra and Gini indices.

Lee (1999) mentions at least three specific situations where results from Lorenz curves are superior to those obtained from ROC curves: 1) a diagnostic test with similar means but very different standard deviations in the abnormal and normal populations, 2) a diagnostic test with bimodal distributions in either the normal or abnormal population, and 3) a diagnostic test distributed symmetrically in the normal population and skewed in the abnormal.

When the risk status increases or decreases monotonically with increasing values of the diagnostic test, the ROC and Lorenz curves yield interchangeable results.

▷ Example 2

To illustrate the use of the `lorenz` option, we constructed a fictitious dataset that yields results similar to those presented in Table III of Lee (1999). The data assume that a 12-point rating scale was used to classify 442 diseased and 442 healthy subjects. We list a few of the observations.

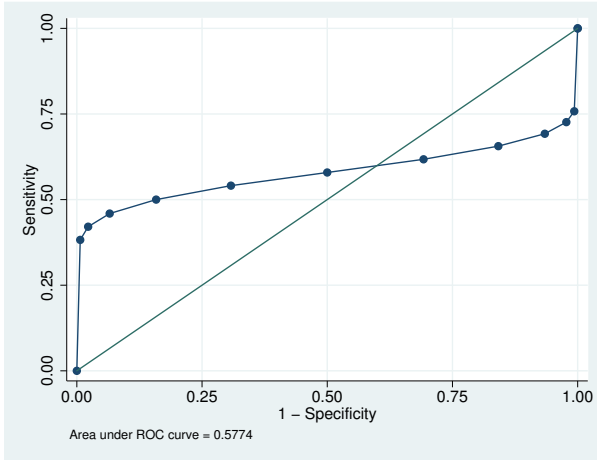
```
. use http://www.stata-press.com/data/r13/lorenz, clear
. list in 1/7, noobs sep(0)
```

disease	class	pop
0	5	66
1	11	17
0	6	85
0	3	19
0	10	19
0	2	7
1	4	16

The data consist of 24 observations: 12 observations from diseased individuals and 12 from nondiseased individuals. Each observation corresponds to one of the 12 classification values of the rating-scale variable, `class`. The number of subjects represented by each observation is given by the `pop` variable, making this a frequency-weighted dataset. The data were generated assuming a binormal distribution of the latent variable with similar means for the normal and abnormal populations but with the standard deviation for the abnormal population five times greater than that of the normal population.

```
. roctab disease class [fweight=pop], graph summary
```

Obs	ROC Area	Std. Err.	Asymptotic Normal [95% Conf.	Interval]
884	0.5774	0.0215	0.53517	0.61959



The resulting ROC curve is nonconvex or, as termed by Lee, "wiggly". Lee argues that for this and similar situations, the Lorenz curve and indices are preferred.

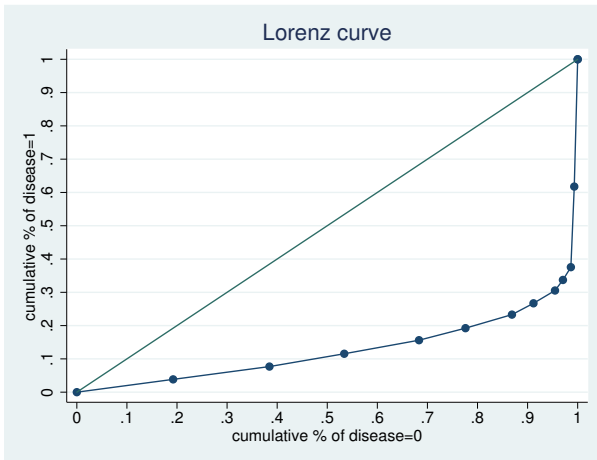
Lorenz curve
------------------------------
Pietra index =   0.6493
Gini index   =   0.7441
```



Like ROC curves, a more bowed Lorenz curve suggests a better diagnostic test. This bowedness is quantified by the Pietra index, which is geometrically equivalent to twice the largest triangle that can be inscribed in the area between the curve and the diagonal line, and the Gini index, which is

equivalent to twice the area between the Lorenz curve and the diagonal. Lee (1999) provides several additional interpretations for the Pietra and Gini indices.

◁

Stored results

roctab stores the following in r():

Scalars

r(N)	number of observations
r(se)	standard error for the area under the ROC curve
r(lb)	lower bound of CI for the area under the ROC curve
r(ub)	upper bound of CI for the area under the ROC curve
r(area)	area under the ROC curve
r(pietra)	Pietra index
r(gini)	Gini index

Methods and formulas

Assume that we applied a diagnostic test to each of N_n normal and N_a abnormal subjects. Further assume that the higher the outcome value of the diagnostic test, the higher the risk of the subject being abnormal. Let $\widehat{\theta}$ be the estimated area under the curve, and let $X_i, i = 1, 2, \ldots, N_a$ and $Y_j, j = 1, 2, \ldots, N_n$ be the values of the diagnostic test for the abnormal and normal subjects, respectively.

The points on the nonparametric ROC curve are generated using each possible outcome of the diagnostic test as a classification cutpoint and computing the corresponding sensitivity and 1−specificity. These points are then connected by straight lines, and the area under the resulting ROC curve is computed using the trapezoidal rule.

The default standard error for the area under the ROC curve is computed using the algorithm described by DeLong, DeLong, and Clarke-Pearson (1988). For each abnormal subject, i, define

$$V_{10}(X_i) = \frac{1}{N_n} \sum_{j=1}^{N_n} \psi(X_i, Y_j)$$

and for each normal subject, j, define

$$V_{01}(Y_j) = \frac{1}{N_a} \sum_{i=1}^{N_a} \psi(X_i, Y_j)$$

where

$$\psi(X, Y) = \begin{cases} 1 & Y < X \\ \frac{1}{2} & Y = X \\ 0 & Y > X \end{cases}$$

Define

$$S_{10} = \frac{1}{N_a - 1} \sum_{i=1}^{N_a} \{V_{10}(X_i) - \widehat{\theta}\}^2$$

and

$$S_{01} = \frac{1}{N_n - 1} \sum_{j=1}^{N_n} \{V_{01}(Y_j) - \widehat{\theta}\}^2$$

The variance of the estimated area under the ROC curve is given by

$$\mathrm{var}(\widehat{\theta}) = \frac{1}{N_a} S_{10} + \frac{1}{N_n} S_{01}$$

The `hanley` standard error for the area under the ROC curve is computed using the algorithm described by Hanley and McNeil (1982). It requires the calculation of two quantities: Q_1 is Pr(two randomly selected abnormal subjects will both have a higher score than a randomly selected normal subject), and Q_2 is Pr(one randomly selected abnormal subject will have a higher score than any two randomly selected normal subjects). The Hanley and McNeil variance of the estimated area under the ROC curve is

$$\mathrm{var}(\widehat{\theta}) = \frac{\widehat{\theta}(1-\widehat{\theta}) + (N_a - 1)(Q_1 - \widehat{\theta}^2) + (N_n - 1)(Q_2 - \widehat{\theta}^2)}{N_a N_n}$$

The `bamber` standard error for the area under the ROC curve is computed using the algorithm described by Bamber (1975). For any two Y values, Y_j and Y_k, and any X_i value, define

$$b_{yyx} = p(Y_j, Y_k < X_i) + p(X_i < Y_j, Y_k) - 2p(Y_j < X_i < Y_k)$$

and similarly, for any two X values, X_i and X_l, and any Y_j value, define

$$b_{xxy} = p(X_i, X_l < Y_j) + p(Y_j < X_i, X_l) - 2p(X_i < Y_j < X_l)$$

Bamber's unbiased estimate of the variance for the area under the ROC curve is

$$\mathrm{var}(\widehat{\theta}) = \frac{1}{4}(N_a - 1)(N_n - 1)\{p(X \neq Y) + (N_a - 1)b_{xxy} + (N_n - 1)b_{yyx} - 4(N_a + N_n - 1)(\widehat{\theta} - 0.5)^2\}$$

Asymptotic confidence intervals are constructed and reported by default, assuming a normal distribution for the area under the ROC curve.

Exact binomial confidence intervals are calculated as described in [R] **ci**, with p equal to the area under the ROC curve.

Syntax

```
rologit depvar indepvars [if] [in] [weight], group(varname) [options]
```

options	Description
Model	
* `group(`*varname*`)`	identifier variable that links the alternatives
`offset(`*varname*`)`	include *varname* in model with coefficient constrained to 1
`incomplete(#)`	use # to code unranked alternatives; default is `incomplete(0)`
`reverse`	reverse the preference order
`notestrhs`	keep right-hand-side variables that do not vary within group
`ties(`*spec*`)`	method to handle ties: `exactm`, `breslow`, `efron`, or `none`
SE/Robust	
`vce(`*vcetype*`)`	*vcetype* may be `oim`, `robust`, `cluster` *clustvar*, `bootstrap`, or `jackknife`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
`coeflegend`	display legend instead of statistics

*`group(`*varname*`)` is required.

indepvars may contain factor variables; see **[U] 11.4.3 Factor variables**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, and `statsby` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see **[R] bootstrap**.

`fweights`, `iweights`, and `pweights` are allowed, except with `ties(efron)`; see **[U] 11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Statistics > Ordinal outcomes > Rank-ordered logistic regression

Description

`rologit` fits the rank-ordered logistic regression model by maximum likelihood (Beggs, Cardell, and Hausman 1981). This model is also known as the Plackett–Luce model (Marden 1995), as the exploded logit model (Punj and Staelin 1978), and as the choice-based method of conjoint analysis (Hair et al. 2010).

`rologit` expects the data to be in long form, similar to `clogit` (see [R] **clogit**), in which each of the ranked alternatives forms an observation; all observations related to an individual are linked together by the variable that you specify in the `group()` option. The distinction from `clogit` is that *depvar* in `rologit` records the rankings of the alternatives, whereas for `clogit`, *depvar* marks only the best alternative by a value not equal to zero. `rologit` interprets equal scores of *depvar* as ties. The ranking information may be incomplete "at the bottom" (least preferred alternatives). That is, unranked alternatives may be coded as 0 or as a common value that may be specified with the `incomplete()` option.

If your data record only the unique best alternative, `rologit` fits the same model as `clogit`.

Options

Model

`group(`*varname*`)` is required, and it specifies the identifier variable (numeric or string) that links the alternatives for an individual, which have been compared and rank ordered with respect to one another.

`offset(`*varname*`)`; see [R] **estimation options**.

`incomplete(#)` specifies the numeric value used to code alternatives that are not ranked. It is assumed that unranked alternatives are less preferred than the ranked alternatives (that is, the data record the ranking of the most preferred alternatives). It is not assumed that subjects are indifferent between the unranked alternatives. # defaults to 0.

`reverse` specifies that in the preference order, a higher number means a less attractive alternative. The default is that higher values indicate more attractive alternatives. The rank-ordered logit model is not symmetric in the sense that reversing the ordering simply leads to a change in the signs of the coefficients.

`notestrhs` suppresses the test that the independent variables vary within (at least some of) the groups. Effects of variables that are always constant are not identified. For instance, a rater's gender cannot directly affect his or her rankings; it could affect the rankings only via an interaction with a variable that does vary over alternatives.

`ties(`*spec*`)` specifies the method for handling ties (indifference between alternatives) (see [ST] **stcox** for details):

`exactm`	exact marginal likelihood (default)
`breslow`	Breslow's method (default if `pweights` specified)
`efron`	Efron's method (default if robust VCE)
`none`	no ties allowed

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

If `ties(exactm)` is specified, *vcetype* may be only `oim`, `bootstrap`, or `jackknife`.

Reporting

level(#); see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(*style*), cformat(%*fmt*), pformat(%*fmt*), sformat(%*fmt*), and nolstretch; see [R] estimation options.

Maximization

maximize_options: iterate(#), trace, [no]log, tolerance(#), ltolerance(#), nrtolerance(#), and nonrtolerance; see [R] maximize. These options are seldom used.

The following option is available with rologit but is not shown in the dialog box:

coeflegend; see [R] estimation options.

Remarks and examples

The rank-ordered logit model can be applied to analyze how decision makers combine attributes of alternatives into overall evaluations of the attractiveness of these alternatives. The model generalizes a version of McFadden's choice model without alternative-specific covariates, as fit by the clogit command. It uses richer information about the comparison of alternatives, namely, how decision-makers rank the alternatives rather than just specifying the alternative that they like best.

Remarks are presented under the following headings:

Examples
Comparing respondents
Incomplete rankings and ties
Clustered choice data
Comparison of rologit and clogit
On reversals of rankings

Examples

A popular way to study employer preferences for characteristics of employees is the quasi-experimental "vignette method". As an example, we consider the research by de Wolf on the labor market position of social science graduates (de Wolf 2000). This study addresses how the educational portfolio (for example, general skills versus specific knowledge) affects short-term and long-term labor-market opportunities. De Wolf asked 22 human resource managers (the respondents) to rank order the six most suitable candidates of 20 fictitious applicants and to rank order these six candidates for three jobs, namely, 1) researcher, 2) management trainee, and 3) policy adviser. Applicants were described by 10 attributes, including their age, gender, details of their portfolio, and work experience. In this example, we analyze a subset of the data. Also, to simplify the output, we drop, at random, 10 nonselected applicants per case. The resulting dataset includes 29 cases, consisting of 10 applicants each. The data are in long form: observations correspond to alternatives (the applications), and alternatives that figured in one decision task are identified by the variable caseid. We list the observations for caseid==7, in which the respondent considered applicants for a social-science research position.

```
. use http://www.stata-press.com/data/r13/evignet
(Vignet study employer prefs (Inge de Wolf 2000))
. list pref female age grades edufit workexp boardexp if caseid==7, noobs
```

pref	female	age	grades	edufit	workexp	boardexp
0	yes	28	A/B	no	none	no
0	no	25	C/D	yes	one year	no
0	no	25	C/D	yes	none	yes
0	yes	25	C/D	no	internship	yes
1	no	25	C/D	yes	one year	yes
2	no	25	A/B	yes	none	no
3	yes	25	A/B	yes	one year	no
4	yes	25	A/B	yes	none	yes
5	no	25	A/B	yes	internship	no
6	yes	28	A/B	yes	one year	yes

Here six applicants were selected. The rankings are stored in the variable `pref`, where a value of 6 corresponds to "best among the candidates", a value of 5 corresponds to "second-best among the candidates", etc. The applicants with a ranking of 0 were not among the best six candidates for the job. The respondent was not asked to express his preferences among these four applicants, but by the elicitation procedure, it is known that he ranks these four applicants below the six selected applicants. The best candidate was a female, 28 years old, with education fitting the job, with good grades (A/B), with 1 year of work experience, and with experience being a board member of a fraternity, a sports club, etc. The profiles of the other candidates read similarly. Here the respondent completed the task; that is, he selected and rank ordered the six most suitable applicants. Sometimes the respondent performed only part of the task.

```
. list pref female age grades edufit workexp boardexp if caseid==18, noobs
```

pref	female	age	grades	edufit	workexp	boardexp
0	no	25	C/D	yes	none	yes
0	no	25	C/D	no	internship	yes
0	no	28	C/D	no	internship	yes
0	yes	25	A/B	no	one year	no
2	yes	25	A/B	no	none	yes
2	no	25	A/B	no	none	yes
2	no	25	A/B	no	one year	yes
5	no	25	A/B	no	none	yes
5	no	25	A/B	no	none	yes
5	yes	25	A/B	no	none	no

The respondent selected the six best candidates and segmented these six candidates into two groups: one group with the three best candidates, and a second group of three candidates that were "still acceptable". The numbers 2 and 5, indicating these two groups, are arbitrary apart from the implied ranking of the groups. The ties between the candidates in a group indicate that the respondent was not able to rank the candidates within the group.

The purpose of the vignette experiment was to explore and test hypotheses about which of the employees' attributes are valued by employers, how these attributes are weighted depending on the type of job (described by variable `job` in these data), etc. In the psychometric tradition of Thurstone (1927), *value* is assumed to be linear in the attributes, with the coefficients expressing the direction and weight of the attributes. In addition, it is assumed that *valuation* is to some extent a random procedure,

captured by an additive random term. For instance, if value depends only on an applicant's age and gender, we would have

$$\text{value}(\texttt{female}_i, \texttt{age}_i) = \beta_1 \texttt{female}_i + \beta_2 \texttt{age}_i + \epsilon_i$$

where the random residual, ϵ_i, captures all omitted attributes. Thus $\beta_1 > 0$ means that the employer assigns higher value to a woman than to a man. Given this conceptualization of value, it is straightforward to model the decision (selection) among alternatives or the ranking of alternatives: the alternative with the highest value is selected (chosen), or the alternatives are ranked according to their value. To complete the specification of a model of choice and of ranking, we assume that the random residual ϵ_i follows an "extreme value distribution of type I", introduced in this context by Luce (1959). This specific assumption is made mostly for computational convenience.

This model is known by many names. Among others, it is known as the rank-ordered logit model in economics (Beggs, Cardell, and Hausman 1981), as the exploded logit model in marketing research (Punj and Staelin 1978), as the choice-based conjoint analysis model (Hair et al. 2010), and as the Plackett–Luce model (Marden 1995). The model coefficients are estimated using the method of maximum likelihood. The implementation in `rologit` uses an analogy between the rank-ordered logit model and the Cox regression model observed by Allison and Christakis (1994); see *Methods and formulas*. The `rologit` command implements this method for rankings, whereas `clogit` deals with the variant of choices, that is, only the most highly valued alternative is recorded. In the latter case, the model is also known as the Luce–McFadden choice model. In fact, when the data record the most preferred (unique) alternative and no additional ranking information about preferences is available, `rologit` and `clogit` return the same information, though formatted somewhat differently.

```
. rologit pref female age grades edufit workexp boardexp if job==1, group(caseid)
Iteration 0:   log likelihood =  -95.41087
Iteration 1:   log likelihood = -71.180903
Iteration 2:   log likelihood =  -68.47734
Iteration 3:   log likelihood = -68.345918
Iteration 4:   log likelihood = -68.345389
Refining estimates:
Iteration 0:   log likelihood = -68.345389

                                                             avg =      10.00
                                                             max =         10
                                              LR chi2(6)         =      54.13
Log likelihood = -68.34539                    Prob > chi2        =     0.0000
```

pref	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
female	-.4487287	.3671307	-1.22	0.222	-1.168292	.2708343
age	-.0984926	.0820473	-1.20	0.230	-.2593024	.0623172
grades	3.064534	.6148245	4.98	0.000	1.8595	4.269568
edufit	.7658064	.3602366	2.13	0.034	.0597556	1.471857
workexp	1.386427	.292553	4.74	0.000	.8130341	1.959821
boardexp	.6944377	.3762596	1.85	0.065	-.0430176	1.431893

Focusing only on the variables whose coefficients are significant at the 10% level (we are analyzing 8 respondents only!), the estimated value of an applicant for a job of type 1 (research positions) can be written as

```
value = 3.06*grades + 0.77*edufit + 1.39*workexp + 0.69*boardexp
```

Thus employers prefer applicants for a research position (`job==1`) whose educational portfolio fits the job, who have better grades, who have more relevant work experience, and who have (extracurricular) board experience. They do not seem to care much about the sex and age of applicants, which is comforting.

Given these estimates of the valuation by employers, we consider the probabilities that each of the applications is ranked first. Under the assumption that the ϵ_i are independent and follow an extreme value type I distribution, Luce (1959) showed that the probability, π_i, that alternative i is valued higher than alternatives $2, \ldots, k$ can be written in the multinomial logit form

$$\pi_i = \Pr\{\text{value}_1 > \max(\text{value}_2, \ldots, \text{value}_m)\} = \frac{\exp(\text{value}_i)}{\sum_{j=1}^{k} \exp(\text{value}_i)}$$

The probability of observing a specific ranking can be written as the *product* of such terms, representing a sequential decision interpretation in which the rater first chooses the most preferred alternative, and then the most preferred alternative among the rest, etc.

The probabilities for alternatives to be ranked first are conveniently computed by `predict`.

```
. predict p if e(sample)
(option pr assumed; conditional probability that alternative is ranked first)
(210 missing values generated)
. sort caseid pref p
. list pref p grades edufit workexp boardexp if caseid==7, noobs
```

pref	p	grades	edufit	workexp	boardexp
0	.0027178	C/D	yes	none	yes
0	.0032275	C/D	no	internship	yes
0	.0064231	A/B	no	none	no
0	.0217202	C/D	yes	one year	no
1	.0434964	C/D	yes	one year	yes
2	.0290762	A/B	yes	none	no
3	.2970933	A/B	yes	one year	no
4	.0371747	A/B	yes	none	yes
5	.1163203	A/B	yes	internship	no
6	.4427504	A/B	yes	one year	yes

There clearly is a positive relation between the stated ranking and the predicted probabilities for alternatives to be ranked first, but the association is not perfect. In fact, we would not have expected a perfect association, as the model specifies a (nondegenerate) probability distribution over the possible rankings of the alternatives. These predictions for sets of 10 candidates can also be used to make predictions for subsets of the alternatives. For instance, suppose that only the last three candidates listed in this table would be available. According to parameter estimates of the rank-ordered logit model, the probability that the last of these candidates is selected equals $0.443/(0.037+0.116+0.443) = 0.743$.

Comparing respondents

The `rologit` model assumes that all respondents, HR managers in large public-sector organizations in The Netherlands, use the *same* valuation function; that is, they apply the same decision weights. This is the substantive interpretation of the assumption that the β's are constant between the respondents. To probe this assumption, we could test whether the coefficients vary between different groups of respondents. For a metric characteristic of the HR manager, such as `firmsize`, we can consider a trend-model in the valuation weights,

$$\beta_{ij} = \alpha_{i0} + \alpha_{i1}\texttt{firmsize}_j$$

and we can test that the slopes α_{i1} of `firmsize` are zero.

```
. generate firmsize = employer
. rologit pref edufit grades workexp c.firmsize#c.(edufit grades workexp boardexp)
>  if job==1, group(caseid) nolog
Rank-ordered logistic regression              Number of obs      =        80
Group variable: caseid                        Number of groups   =         8
No ties in data                               Obs per group: min =        10
                                                             avg =     10.00
                                                             max =        10
                                              LR chi2(7)         =     57.17

```

The Wald test that the slopes of the interacted `firmsize` variables are jointly zero provides no evidence upon which we would reject the null hypothesis; that is, we do not find evidence against the assumption of constant valuation weights of the attributes by firms of different size. We did not enter `firmsize` as a predictor variable. Characteristics of the decision-making agent do not vary between alternatives. Thus an additive effect of these characteristics on the valuation of alternatives does *not* affect the agent's ranking of alternatives and his choice. Consequently the coefficient of `firmsize` is not identified. `rologit` would in fact have diagnosed the problem and dropped `firmsize` from the analysis. Diagnosing this problem can slow the estimation considerably; the test may be suppressed by specifying the `notestrhs` option.

Incomplete rankings and ties

`rologit` allows incomplete rankings and ties in the rankings as proposed by Allison and Christakis (1994). `rologit` permits rankings to be incomplete only "at the bottom"; namely, that the ranking of the least attractive alternatives for subjects may not be known—do not confuse this with the situation that a subject is indifferent between these alternatives. This form of incompleteness occurred in the example discussed here, because the respondents were instructed to select and rank only the top six alternatives. It may also be that respondents refused to rank the alternatives that are very unattractive. `rologit` does not allow other forms of incompleteness, for instance, data in which respondents indicate which of four cars they like best, and which one they like least, but not how they rank the two intermediate cars. Another example of incompleteness that cannot be analyzed with `rologit` is data in which respondents select the three alternatives they like best but are not requested to express their preferences among the three selected alternatives.

`rologit` also permits ties in rankings. `rologit` assumes that if a subject expresses a tie between two or more alternatives, he or she actually holds one particular strict preference ordering, but with all possibilities of a strict ordering consistent with the expressed weak ordering being equally probable. For instance, suppose that a respondent ranks alternative 1 highest. He prefers alternatives 2 and 3 over alternative 4, and he is indifferent between alternatives 2 and 3. We assume that this respondent either has the strict preference ordering $1 > 2 > 3 > 4$ or $1 > 3 > 2 > 4$, with both possibilities being equally likely. From a psychometric perspective, it may actually be more appropriate to also assume that the alternatives 2 and 3 are close; for instance, the difference between the associated valuations (utilities) is less than some threshold or minimally discernible difference. Computationally, however, this is a more demanding model.

Clustered choice data

We have seen that applicants with work experience are in a relatively favorable position. To test whether the effects of work experience vary between the jobs, we can include interactions between the type of job and the attributes of applicants. Such interactions can be obtained using factor variables.

Because some HR managers contributed data for more than one job, we cannot assume that their selection decisions for different jobs are independent. We can account for this by specifying the `vce(cluster` *clustvar*`)` option. By treating choice data as incomplete ranking data with only the most preferred alternative marked, `rologit` may be used to estimate the model parameters for clustered choice data.

```
. rologit pref job##c.(female grades edufit workexp), group(caseid)
> vce(cluster employer) nolog
2.job 3.job omitted because of no within-caseid variance
Rank-ordered logistic regression                Number of obs      =       290
Group variable: caseid                          Number of groups   =        29
Ties handled via the Efron method               Obs per group: min =        10
                                                               avg =     10.00
                                                               max =        10
                                                Wald chi2(12)      =     79.57
Log pseudolikelihood = -296.3855                Prob > chi2        =    0.0000
                                (Std. Err. adjusted for 22 clusters in employer)
```

The parameter estimates for the first job type are very similar to those that would have been obtained from an analysis isolated to these data. Differences are due only to an implied change in the method of handling ties. With clustered observations, `rologit` uses Efron's method. If we had specified the `ties(efron)` option with the separate analyses, then the parameter estimates would have been identical to the simultaneous results. Another difference is that `rologit` now reports robust standard errors, adjusted for clustering within respondents. These could have been obtained for the separate analyses, as well by specifying the `vce(robust)` option. In fact, this option would also have forced `rologit` to switch to Efron's method as well.

Given the combined results for the three types of jobs, we can test easily whether the weights for the attributes of applicants vary between the jobs, in other words, whether employers are looking for different qualifications in applicants for different jobs. A Wald test for the equality hypothesis of no difference can be obtained with the `testparm` command:

```
. testparm job#c.(female grades edufit workexp)
 ( 1)  2.job#c.female = 0
 ( 2)  3.job#c.female = 0
 ( 3)  2.job#c.grades = 0
 ( 4)  3.job#c.grades = 0
 ( 5)  2.job#c.edufit = 0
 ( 6)  3.job#c.edufit = 0
 ( 7)  2.job#c.workexp = 0
 ( 8)  3.job#c.workexp = 0
           chi2(  8) =   14.96
         Prob > chi2 =    0.0599
```

We find only mild evidence that employers look for different qualities in candidates according to the job for which they are being considered.

❑ Technical note

Allison (1999) stressed that the comparison between groups of the coefficients of logistic regression is problematic, especially in its latent-variable interpretation. In many common latent-variable models, only the regression coefficients divided by the scale of the latent variable are identified. Thus a comparison of logit regression coefficients between, say, men and women is meaningful only if one is willing to argue that the standard deviation of the latent residual does not differ between the sexes. The rank-ordered logit model is also affected by this problem. While we formulated the model with a scale-free residual, we can actually think of the model for the value of an alternative as being scaled by the standard deviation of the random term, representing other relevant attributes of alternatives. Again comparing attribute weights between jobs is meaningful to the extent that we are willing to defend the proposition that "all omitted attributes" are equally important for different kinds of jobs.

❑

Comparison of rologit and clogit

The rank-ordered logit model also has a sequential interpretation. A subject first chooses the best among the alternatives. Next he or she selects the best alternative among the remaining alternatives, etc. The decisions at each of the subsequent stages are described by a conditional logit model, and a subject is assumed to apply the same decision weights at each stage. Some authors have expressed concern that later choices may well be made more randomly than the first few decisions. A formalization of this idea is a heteroskedastic version of the rank-ordered logit model in which the scale of the random term increases with the number of decisions made (for example, Hausman and Ruud [1987]). This extended model is currently not supported by `rologit`. However, the hypothesis that the same decision weights are applied at the first stage and at later stages can be tested by applying a Hausman test.

First, we fit the rank-ordered logit model on the full ranking data for the first type of job,

```
. rologit pref age female edufit grades workexp boardexp if job==1,
> group(caseid) nolog
Rank-ordered logistic regression              Number of obs      =         80
Group variable: caseid                        Number of groups   =          8
No ties in data                               Obs per group: min =         10
                                                             avg =      10.00
                                                             max =         10
                                              LR chi2(6)         =      54.13
Log likelihood = -68.34539                    Prob > chi2        =     0.0000
```

pref	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
age	-.0984926	.0820473	-1.20	0.230	-.2593024	.0623172

boardexp	.6944377	.3762596	1.85	0.065	-.0430176	1.431893

and we save the estimates for later use with the `estimates` command.

```
. estimates store Ranking
```

To estimate the decision weights on the basis of the most preferred alternatives only, we create a variable, `best`, that is 1 for the best alternatives, and 0 otherwise. The `by` prefix is useful here.

```
. by caseid (pref), sort: gen best = pref == pref[_N] if job==1
(210 missing values generated)
```

By specifying `(pref)` with `by caseid`, we ensured that the data were sorted in increasing order on `pref` within `caseid`. Hence, the most preferred alternatives are last in the sort order. The expression `pref == pref[_N]` is true (1) for the most preferred alternatives, even if the alternative is not unique, and false (0) otherwise. If the most preferred alternatives were sometimes tied, we could still fit the model for the based-alternatives-only data via `rologit`, but `clogit` would yield different results because it deals with ties in a less appropriate way for continuous valuations. To ascertain whether there are ties in the selected data regarding applicants for research positions, we can combine `by` with `assert`:

```
. by caseid (pref), sort: assert pref[_N-1] != pref[_N] if job==1
```

There are no ties. We can now fit the model on the choice data by using either `clogit` or `rologit`.

```
. rologit best age edufit grades workexp boardexp if job==1, group(caseid) nolog
Rank-ordered logistic regression                Number of obs      =         80
Group variable: caseid                          Number of groups   =          8
No ties in data                                 Obs per group: min =         10
                                                               avg =      10.00
                                                               max =         10
                                                LR chi2(5)         =      17.27
Log likelihood = -9.783205                      Prob > chi2        =     0.0040
```

boardexp	1.765176	1.112763	1.59	0.113	-.4157988	3.946152

The parameters of the ranking and choice models look different, but the standard errors based on the choice data are much larger. Are we estimating parameters with the ranking data that are different from those with the choice data? A Hausman test compares two estimators of a parameter. One of the estimators should be efficient under the null hypothesis, namely, that choosing the second-best alternative is determined with the same decision weights as the best, etc. In our case, the efficient estimator of the decision weights uses the ranking information. The other estimator should be consistent, even if the null hypothesis is false. In our application, this is the estimator that uses the first-choice data only.

```
. hausman Choice Ranking
```

	Coefficients (b) Choice	(B) Ranking	(b-B) Difference	sqrt(diag(V_b-V_B)) S.E.
age	-.1048959	-.0984926	-.0064033	.1842657
edufit	.4558387	.7658064	-.3099676	.8613846
grades	3.443851	3.064534	.3793169	1.870551
workexp	2.545648	1.386427	1.159221	1.059878
boardexp	1.765176	.6944377	1.070739	1.04722

```
                b = consistent under Ho and Ha; obtained from rologit
     B = inconsistent under Ha, efficient under Ho; obtained from rologit

Test:  Ho:  difference in coefficients not systematic

           chi2(5) = (b-B)'[(V_b-V_B)^(-1)](b-B)
                   =         3.05
         Prob>chi2 =       0.6918
```

We do not find evidence for misspecification. We have to be cautious, though, because Hausman-type tests are often not powerful, and the number of observations in our example is very small, which makes the quality of the method of the null distribution by a chi-squared test rather uncertain.

On reversals of rankings

The rank-ordered logit model has a property that you may find unexpected and even unfortunate. Compare two analyses with the rank-ordered logit model, one in which alternatives are ranked from "most attractive" to "least attractive", the other a reversed analysis in which these alternatives are ranked from "most unattractive" to "least unattractive". By unattractiveness, you probably mean just the opposite of attractiveness, and you expect that the weights of the attributes in predicting "attractiveness" to be minus the weights in predicting "unattractiveness". This is, however, *not* true for the rank-ordered logit model. The assumed distribution of the random residual takes the form $F(\epsilon) = 1 - \exp\{\exp(-\epsilon)\}$. This distribution is right-skewed. Therefore, slightly different models result from adding and subtracting the random residual, corresponding with high-to-low and low-to-high rankings. Thus the estimated coefficients will differ between the two specifications, though usually not in an important way. You may observe the difference by specifying the `reverse` option of `rologit`. Reversing the rank order makes rankings that are incomplete at the bottom become incomplete at the top. Only the first kind of incompleteness is supported by `rologit`. Thus, for this comparison, we exclude the alternatives that are not ranked, omitting the information that ranked alternatives are preferred over excluded ones.

```
. rologit pref grades edufit workexp boardexp if job==1 & pref!=0, group(caseid)
```

(*output omitted*)

```
. estimates store Original
. rologit pref grades edufit workexp boardexp if job==1 & pref!=0, group(caseid)
> reverse
```

(*output omitted*)

```
. estimates store Reversed
```

```
. estimates table Original Reversed, stats(aic bic)
```

Variable	Original	Reversed
grades	2.0032332	-1.0955335
edufit	-.13111006	-.05710681
workexp	1.2805373	-1.2096383
boardexp	.46213212	-.27200317
aic	96.750452	99.665642
bic	104.23526	107.15045

Thus, although the weights of the attributes for reversed rankings are indeed mostly of opposite signs, the magnitudes of the weights and their standard errors differ. Which one is more appropriate? We have no advice to offer here. The specific science of the problem will determine what is appropriate, though we would be surprised indeed if this helps here. Formal testing does not help much either, as the models for the original and reversed rankings are not nested. The model-selection indices, such as the AIC and BIC, however, suggest that you stick to the rank-ordered logit model applied to the original ranking rather than to the reversed ranking.

Stored results

rologit stores the following in e():

Scalars

e(N)	number of observations
e(ll_0)	log likelihood of the null model ("all rankings are equiprobable")
e(ll)	log likelihood
e(df_m)	model degrees of freedom
e(chi2)	χ^2
e(p)	significance
e(r2_p)	pseudo-R^2
e(N_g)	number of groups
e(g_min)	minimum group size
e(g_avg)	average group size
e(g_max)	maximum group size
e(code_inc)	value for incomplete preferences
e(N_clust)	number of clusters
e(rank)	rank of e(V)

Macros

e(cmd)	rologit
e(cmdline)	command as typed
e(depvar)	name of dependent variable
e(group)	name of group() variable
e(wtype)	weight type
e(wexp)	weight expression

Matrices

e(b)	coefficient vector
e(V)	variance–covariance matrix of the estimators
e(V_modelbased)	model-based variance

Functions

e(sample)	marks estimation sample

Methods and formulas

Allison and Christakis (1994) demonstrate that maximum likelihood estimates for the rank-ordered logit model can be obtained as the maximum partial-likelihood estimates of an appropriately specified Cox regression model for waiting time ([ST] **stcox**). In this analogy, a higher value for an alternative is formally equivalent to a higher hazard rate of failure. rologit uses stcox to fit the rank-ordered logit model based on such a specification of the data in Cox terms. A higher stated preference is represented by a shorter waiting time until failure. Incomplete rankings are dealt with via censoring. Moreover, decision situations (subjects) are to be treated as strata. Finally, as proposed by Allison and Christakis, ties in rankings are handled by the marginal-likelihood method, specifying that all strict preference orderings consistent with the stated weak preference ordering are equally likely.

The marginal-likelihood estimator is available in `stcox` via the `exactm` option. The methods of the marginal likelihood due to Breslow and Efron are also appropriate for the analysis of rank-ordered logit models. Because in most applications the number of ranked alternatives by one subject will be fairly small (at most, say, 20), the number of ties is small as well, and so you rarely will need to turn to methods to restrict computer time. Because the marginal-likelihood estimator in `stcox` does not support the cluster adjustment or `pweights`, you should use the Efron method in such cases.

This command supports the clustered version of the Huber/White/sandwich estimator of the variance using `vce(robust)` and `vce(cluster` *clustvar*`)`. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*. Specifying `vce(robust)` is equivalent to specifying `vce(cluster` *groupvar*`)`, where *groupvar* is the identifier variable that links the alternatives.

Acknowledgment

The `rologit` command was written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands.

Title

rologit postestimation — Postestimation tools for rologit

Description Syntax for predict Menu for predict Options for predict
Remarks and examples Also see

Description

The following postestimation commands are available after `rologit`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estimates`	cataloging estimation results
`hausman`	Hausman's specification test
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`linktest`	link test for model specification
`lrtest`	likelihood-ratio test
`margins`[1]	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] The default prediction statistic `pr` cannot be correctly handled by `margins`; however, `margins` can be used after `rologit` with the `predict(xb)` option.

Syntax for predict

`predict` [*type*] *newvar* [*if*] [*in*] [`,` *statistic* `nooffset`]

statistic	Description
Main	
`pr`	probability that alternatives are ranked first; the default
`xb`	linear prediction
`stdp`	standard error of the linear prediction

These statistics are available both in and out of sample; type `predict ... if esample() ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`pr`, the default, calculates the probability that alternatives are ranked first.

`xb` calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`nooffset` is relevant only if you specified `offset(`*varname*`)` for `rologit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $\mathbf{x}_j\mathbf{b}$ rather than as $\mathbf{x}_j\mathbf{b} + \text{offset}_j$.

Remarks and examples

See *Comparing respondents* and *Clustered choice data* in [R] **rologit** for examples of the use of `testparm`, an alternative to the `test` command.

See *Comparison of rologit and clogit* and *On reversals of rankings* in [R] **rologit** for examples of the use of `estimates`.

See *Comparison of rologit and clogit* in [R] **rologit** for an example of the use of `hausman`.

Title

rreg — Robust regression

Syntax | Menu | Description | Options
Remarks and examples | Stored results | Methods and formulas | Acknowledgment
References | Also see

Syntax

`rreg` *depvar* [*indepvars*] [*if*] [*in*] [, *options*]

options	Description
Model	
`tune(#)`	use # as the biweight tuning constant; default is `tune(7)`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`genwt(`*newvar*`)`	create *newvar* containing the weights assigned to each observation
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Optimization	
optimization_options	control the optimization process; seldom used
`graph`	graph weights during convergence
`coeflegend`	display legend instead of statistics

indepvars may contain factor variables; see [U] **11.4.3 Factor variables**.

depvar and *indepvars* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

`by`, `mfp`, `mi estimate`, `rolling`, and `statsby` are allowed; see [U] **11.1.10 Prefix commands**.

`coeflegend` does not appear in the dialog box.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Linear models and related > Other > Robust regression

Description

`rreg` performs one version of robust regression of *depvar* on *indepvars*.

Also see *Robust standard errors* in [R] **regress** for standard regression with robust variance estimates and [R] **qreg** for quantile (including median or least-absolute-residual) regression.

Options

Model

tune(#) is the biweight tuning constant. The default is 7, meaning seven times the median absolute deviation (MAD) from the median residual; see *Methods and formulas*. Lower tuning constants downweight outliers rapidly but may lead to unstable estimates (less than 6 is not recommended). Higher tuning constants produce milder downweighting.

Reporting

level(#); see [R] **estimation options**.

genwt(*newvar*) creates the new variable *newvar* containing the weights assigned to each observation.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(*style*), cformat(%*fmt*), pformat(%*fmt*), sformat(%*fmt*), and nolstretch; see [R] **estimation options**.

Optimization

optimization_options: iterate(#), tolerance(#), [no]log. iterate() specifies the maximum number of iterations; iterations stop when the maximum change in weights drops below tolerance(); and log/nolog specifies whether to show the iteration log. These options are seldom used.

graph allows you to graphically watch the convergence of the iterative technique. The weights obtained from the most recent round of estimation are graphed against the weights obtained from the previous round.

The following option is available with rreg but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

rreg first performs an initial screening based on Cook's distance > 1 to eliminate gross outliers before calculating starting values and then performs Huber iterations followed by biweight iterations, as suggested by Li (1985).

▷ Example 1

We wish to examine the relationship between mileage rating, weight, and location of manufacture for the 74 cars in our automobile data. As a point of comparison, we begin by fitting an ordinary regression:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress mpg weight foreign
      Source |       SS       df       MS              Number of obs =      74
-------------+------------------------------           F(  2,    71) =   69.75
       Model |  1619.2877      2  809.643849            Prob > F      =  0.0000
    Residual |  824.171761     71   11.608053           R-squared     =  0.6627
-------------+------------------------------           Adj R-squared =  0.6532
       Total |  2443.45946     73  33.4720474           Root MSE      =  3.4071

------------------------------------------------------------------------------
         mpg |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
      weight |  -.0065879   .0006371   -10.34   0.000    -.0078583   -.0053175
     foreign |  -1.650029   1.075994    -1.53   0.130      -3.7955    .4954422
       _cons |    41.6797   2.165547    19.25   0.000     37.36172    45.99768
------------------------------------------------------------------------------
```

We now compare this with the results from `rreg`:

```
. rreg mpg weight foreign
   Huber iteration 1:  maximum difference in weights = .80280176
   Huber iteration 2:  maximum difference in weights = .2915438
   Huber iteration 3:  maximum difference in weights = .08911171
   Huber iteration 4:  maximum difference in weights = .02697328
Biweight iteration 5:  maximum difference in weights = .29186818
Biweight iteration 6:  maximum difference in weights = .11988101
Biweight iteration 7:  maximum difference in weights = .03315872
Biweight iteration 8:  maximum difference in weights = .00721325
Robust regression                               Number of obs =      74
                                                F(  2,    71) =  168.32
                                                Prob > F      =  0.0000

------------------------------------------------------------------------------
         mpg |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
      weight |  -.0063976   .0003718   -17.21   0.000     -.007139   -.0056562
     foreign |  -3.182639    .627964    -5.07   0.000    -4.434763   -1.930514
       _cons |   40.64022   1.263841    32.16   0.000      38.1202    43.16025
------------------------------------------------------------------------------
```

Note the large change in the `foreign` coefficient.

◁

❑ Technical note

It would have been better if we had fit the previous robust regression by typing `rreg mpg weight foreign, genwt(w)`. The new variable, `w`, would then contain the estimated weights. Let's pretend that we did this:

```
. rreg mpg weight foreign, genwt(w)
  (output omitted)
. summarize w, detail
                    Robust Regression Weight
-------------------------------------------------------------
      Percentiles      Smallest
 1%           0              0
 5%     .0442957              0
10%     .4674935              0       Obs                  74
25%     .8894815       .0442957       Sum of Wgt.          74

50%     .9690193                      Mean           .8509966
                       Largest       Std. Dev.      .2746451
75%     .9949395       .9996715
90%     .9989245       .9996953       Variance       .0754299
95%     .9996715       .9997343       Skewness      -2.287952
99%     .9998585       .9998585       Kurtosis       6.874605
```

We discover that 3 observations in our data were dropped altogether (they have weight 0). We could further explore our data:

```
. sort w
. list make mpg weight w if w <.467, sep(0)
```

	make	mpg	weight	w
1.	VW Diesel	41	2,040	0
2.	Subaru	35	2,050	0
3.	Datsun 210	35	2,020	0
4.	Plym. Arrow	28	3,260	.04429567
5.	Cad. Seville	21	4,290	.08241943
6.	Toyota Corolla	31	2,200	.10443129
7.	Olds 98	21	4,060	.28141296

Being familiar with the automobile data, we immediately spotted two things: the VW is the only diesel car in our data, and the weight recorded for the Plymouth Arrow is incorrect.

❑

▷ Example 2

If we specify no explanatory variables, `rreg` produces a robust estimate of the mean:

```
. rreg mpg
   Huber iteration 1:  maximum difference in weights = .64471879
   Huber iteration 2:  maximum difference in weights = .05098336
   Huber iteration 3:  maximum difference in weights = .0099887
Biweight iteration 4:  maximum difference in weights = .25197391
Biweight iteration 5:  maximum difference in weights = .00358606
Robust regression                                     Number of obs =      74
                                                      F(  0,    73) =    0.00
                                                      Prob > F      =       .
------------------------------------------------------------------------------
         mpg |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
       _cons |    20.68825    .641813    32.23   0.000     19.40912    21.96738
------------------------------------------------------------------------------
```

The estimate is given by the coefficient on _cons. The mean is 20.69 with an estimated standard error of 0.6418. The 95% confidence interval is [19.4, 22.0]. By comparison, ci (see [R] **ci**) gives us the standard calculation:

```
. ci mpg
    Variable |        Obs        Mean    Std. Err.       [95% Conf. Interval]
-------------+---------------------------------------------------------------
         mpg |         74     21.2973    .6725511        19.9569    22.63769
```

e(properties)	b V
e(predict)	program used to implement predict
e(marginsok)	predictions allowed by margins
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(V)	variance–covariance matrix of the estimators

Functions

e(sample)	marks estimation sample

Methods and formulas

See Berk (1990), Goodall (1983), and Rousseeuw and Leroy (1987) for a general description of the issues and methods. Hamilton (1991a, 1992) provides a more detailed description of rreg and some Monte Carlo evaluations.

rreg begins by fitting the regression (see [R] **regress**), calculating Cook's D (see [R] **predict** and [R] **regress postestimation**), and excluding any observation for which $D > 1$.

Thereafter rreg works iteratively: it performs a regression, calculates case weights from absolute residuals, and regresses again using those weights. Iterations stop when the maximum change in weights drops below tolerance(). Weights derive from one of two weight functions, Huber weights

and biweights. Huber weights (Huber 1964) are used until convergence, and then, from that result, biweights are used until convergence. The biweight was proposed by Beaton and Tukey (1974, 151–152) after the Princeton robustness study (Andrews et al. 1972) had compared various estimators. Both weighting functions are used because Huber weights have problems dealing with severe outliers, whereas biweights sometimes fail to converge or have multiple solutions. The initial Huber weighting should improve the behavior of the biweight estimator.

In Huber weighting, cases with small residuals receive weights of 1; cases with larger residuals receive gradually smaller weights. Let $e_i = y_i - \mathbf{X}_i\mathbf{b}$ represent the ith-case residual. The ith scaled residual $u_i = e_i/s$ is calculated, where $s = M/0.6745$ is the residual scale estimate and $M = \text{med}(|e_i - \text{med}(e_i)|)$ is the median absolute deviation from the median residual. Huber estimation obtains case weights:

$$w_i = \begin{cases} 1 & \text{if } |u_i| \le c_h \\ c_h/|u_i| & \text{otherwise} \end{cases}$$

`rreg` defines $c_h = 1.345$, so downweighting begins with cases whose absolute residual exceeds $(1.345/0.6745)M \approx 2M$.

With biweights, all cases with nonzero residuals receive some downweighting, according to the smoothly decreasing biweight function

$$w_i = \begin{cases} \{1 - (u_i/c_b)^2\}^2 & \text{if } |u_i| \le c_b \\ 0 & \text{otherwise} \end{cases}$$

where $c_b = 4.685 \times$ `tune()`$/7$. Thus when `tune()` $= 7$, cases with absolute residuals of $(4.685/0.6745)M \approx 7M$ or more are assigned 0 weight and thus are effectively dropped. Goodall (1983, 377) suggests using a value between 6 and 9, inclusive, for `tune()` in the biweight case and states that performance is good between 6 and 12, inclusive.

The tuning constants $c_h = 1.345$ and $c_b = 4.685$ (assuming `tune()` is set at the default 7) give `rreg` about 95% of the efficiency of OLS when applied to data with normally distributed errors (Hamilton 1991b). Lower tuning constants downweight outliers more drastically (but give up Gaussian efficiency); higher tuning constants make the estimator more like OLS.

Standard errors are calculated using the pseudovalues approach described in Street, Carroll, and Ruppert (1988).

Acknowledgment

The current version of `rreg` is due to the work of Lawrence Hamilton of the Department of Sociology at the University of New Hampshire.

Title

rreg postestimation — Postestimation tools for rreg

Description Syntax for predict Menu for predict Options for predict Also see

Description

The following postestimation commands are available after `rreg`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `mi` estimation results.

Syntax for predict

`predict` [*type*] *newvar* [*if*] [*in*] [, *statistic*]

statistic	Description
Main	
`xb`	linear prediction; the default
`stdp`	standard error of the linear prediction
`residuals`	residuals
`hat`	diagonal elements of the hat matrix

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`residuals` calculates the residuals.

`hat` calculates the diagonal elements of the hat matrix. You must have run the `rreg` command with the `genwt()` option.

Syntax

```
runtest varname [in] [, options]
```

options	Description
`continuity`	continuity correction
`drop`	ignore values equal to the threshold
`split`	randomly split values equal to the threshold as above or below the threshold; default is to count as below
`mean`	use mean as threshold; default is median
`threshold(#)`	assign arbitrary threshold; default is median

Menu

Statistics > Nonparametric analysis > Tests of hypotheses > Test for random order

Description

`runtest` tests whether the observations of *varname* are serially independent—that is, whether they occur in a random order—by counting how many runs there are above and below a threshold. By default, the median is used as the threshold. A small number of runs indicates positive serial correlation; a large number indicates negative serial correlation.

Options

`continuity` specifies a continuity correction that may be helpful in small samples. If there are fewer than 10 observations either above or below the threshold, however, the tables in Swed and Eisenhart (1943) provide more reliable critical values. By default, no continuity correction is used.

`drop` directs `runtest` to ignore any values of *varname* that are equal to the threshold value when counting runs and tabulating observations. By default, `runtest` counts a value as being above the threshold when it is strictly above the threshold and as being below the threshold when it is less than or equal to the threshold.

`split` directs `runtest` to randomly split values of *varname* that are equal to the threshold. In other words, when *varname* is equal to threshold, a "coin" is flipped. If it comes up heads, the value is counted as above the threshold. If it comes up tails, the value is counted as below the threshold.

`mean` directs `runtest` to tabulate runs above and below the mean rather than the median.

`threshold(#)` specifies an arbitrary threshold to use in counting runs. For example, if *varname* has already been coded as a 0/1 variable, the median generally will not be a meaningful separating value.

Remarks and examples

`runtest` performs a nonparametric test of the hypothesis that the observations of *varname* occur in a random order by counting how many runs there are above and below a threshold. If *varname* is positively serially correlated, it will tend to remain above or below its median for several observations in a row; that is, there will be relatively few runs. If, on the other hand, *varname* is negatively serially correlated, observations above the median will tend to be followed by observations below the median and vice versa; that is, there will be relatively many runs.

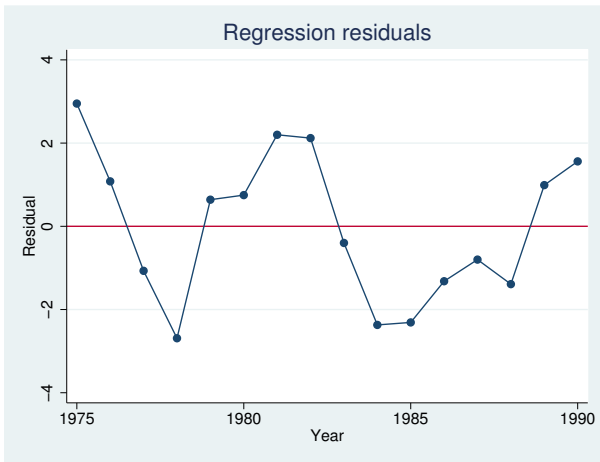
By default, `runtest` uses the median for the threshold, and this is not necessarily the best choice. If `mean` is specified, the mean is used instead of the median. If `threshold(#)` is specified, # is used. Because `runtest` divides the data into two states—above and below the threshold—it is appropriate for data that are already binary; for example, win or lose, live or die, rich or poor, etc. Such variables are often coded as 0 for one state and 1 for the other. Here you should specify `threshold(0)` because, by default, `runtest` separates the observations into those that are greater than the threshold and those that are less than *or equal* to the threshold.

As with most nonparametric procedures, the treatment of ties complicates the test. Observations equal to the threshold value are ties and can be treated in one of three ways. By default, they are treated as if they were below the threshold. If `drop` is specified, they are omitted from the calculation and the total number of observations is adjusted. If `split` is specified, each is randomly assigned to the above- and below-threshold groups. The random assignment is different each time the procedure is run unless you specify the random-number seed; see [R] **set seed**.

▷ Example 1

We can use `runtest` to check regression residuals for serial correlation.

```
. use http://www.stata-press.com/data/r13/run1
. scatter resid year, connect(l) yline(0) title(Regression residuals)
```



The graph gives the impression that these residuals are positively correlated. Excursions above or below zero—the natural threshold for regression residuals—tend to last for several observations. `runtest` can evaluate the statistical significance of this impression.

```
. runtest resid, thresh(0)
 N(resid <= 0) = 8
 N(resid >  0) = 8
           obs = 16
      N(runs) = 5
            z  = -2.07
     Prob>|z| = .04
```

There are five runs in these 16 observations. Using the normal approximation to the true distribution of the number of runs, the five runs in this series are fewer than would be expected if the residuals were serially independent. The p-value is 0.04, indicating a two-sided significant result at the 5% level. If the alternative hypothesis is positive serial correlation, rather than any deviation from randomness, then the one-sided p-value is $0.04/2 = 0.015$. With so few observations, however, the normal approximation may be inaccurate. (Tables compiled by Swed and Eisenhart list five runs as the 5% critical value for a one-sided test.)

`runtest` is a nonparametric test. It ignores the magnitudes of the observations and notes only whether the values are above or below the threshold. We can demonstrate this feature by reducing the information about the regression residuals in this example to a 0/1 variable that indicates only whether a residual is positive or negative.

```
. generate byte sign = resid>0
. runtest sign, thresh(0)
 N(sign <= 0) = 8
 N(sign >  0) = 8
          obs = 16
     N(runs) = 5
           z  = -2.07
    Prob>|z| = .04
```

As expected, `runtest` produces the same answer as before.

◁

❑ Technical note

The run test can also be used to test the null hypothesis that two samples are drawn from the same underlying distribution. The run test is sensitive to differences in the shapes, as well as the locations, of the empirical distributions.

Suppose, for example, that two different additives are added to the oil in 10 different cars during an oil change. The cars are run until a viscosity test determines that another oil change is needed, and the number of miles traveled between oil changes is recorded. The data are

```
. use http://www.stata-press.com/data/r13/additive, clear
. list
```

	additive	miles
1.	1	4024
2.	1	4756
3.	1	7993
4.	1	5025
5.	1	4188
6.	2	3007
7.	2	1988
8.	2	1051
9.	2	4478
10.	2	4232

To test whether the additives generate different distributions of miles between oil changes, we sort the data by `miles` and then use `runtest` to see whether the marker for each additive occurs in random order:

```
. sort miles
. runtest additive, thresh(1)
 N(additive <= 1) = 5
 N(additive >  1) = 5
              obs = 10
         N(runs) = 4
               z  = -1.34
        Prob>|z| = .18
```

Here the additives do not produce statistically different results.

❑

❑ Technical note

A test that is related to the run test is the runs up-and-down test. In the latter test, the data are classified not by whether they lie above or below a threshold but by whether they are steadily increasing or decreasing. Thus an unbroken string of increases in the variable of interest is counted as one run, as is an unbroken string of decreases. According to Madansky (1988), the run test is superior to the runs up-and-down test for detecting trends in the data, but the runs up-and-down test is superior for detecting autocorrelation.

`runtest` can be used to perform a runs up-and-down test. Using the regression residuals from the example above, we can perform a `runtest` on their first differences:

```
. use http://www.stata-press.com/data/r13/run1
. generate resid_D = resid - resid[_n-1]
(1 missing value generated)
. runtest resid_D, thresh(0)
 N(resid_D <= 0) = 7
 N(resid_D >  0) = 8
              obs = 15
         N(runs) = 6
               z  = -1.33
        Prob>|z| = .18
```

Edgington (1961) has compiled a table of the small sample distribution of the runs up-and-down statistic, and this table is reprinted in Madansky (1988). For large samples, the z statistic reported by `runtest` is incorrect for the runs up-and-down test. Let N be the number of observations (15 here), and let r be the number of runs (6). The expected number of runs in the runs up-and-down test is

$$\mu_r = \frac{2N-1}{3}$$

the variance is

$$\sigma_r^2 = \frac{16N-29}{90}$$

and the correct z statistic is

$$\widehat{z} = \frac{r-\mu_r}{\sigma_r}$$

❑

❑ Technical note

`runtest` will tolerate missing values at the beginning or end of a series, as occurred in the technical note above (generating first differences resulted in a missing value for the first observation). `runtest`, however, will issue an error message if there are any missing observations in the interior of the series (in the portion covered by the `in` *range* modifier). To perform the test anyway, simply `drop` the missing observations before using `runtest`.

❑

Stored results

`runtest` stores the following in `r()`:

Scalars

`r(N)`	number of observations	`r(p)`	p-value of z
`r(N_below)`	number below the threshold	`r(z)`	z statistic
`r(N_above)`	number above the threshold	`r(n_runs)`	number of runs
`r(mean)`	expected number of runs	`r(Var)`	variance of the number of runs

Methods and formulas

`runtest` begins by calculating the number of observations below the threshold, n_0; the number of observations above the threshold, n_1; the total number of observations, $N = n_0 + n_1$; and the number of runs, r. These statistics are always reported, so the exact tables of critical values in Swed and Eisenhart (1943) may be consulted if necessary.

The expected number of runs under the null is

$$\mu_r = \frac{2n_0n_1}{N} + 1$$

the variance is

$$\sigma_r^2 = \frac{2n_0n_1\left(2n_0n_1 - N\right)}{N^2\left(N-1\right)}$$

and the normal approximation test statistic is

$$\widehat{z} = \frac{r - \mu_r}{\sigma_r}$$

Acknowledgment

`runtest` was written by Sean Becketti, a past editor of the *Stata Technical Bulletin* and author of the Stata Press book *Introduction to Time Series Using Stata*.

indepvars may contain factor variables; see [U] **11.4.3 Factor variables**.

bootstrap, by, fp, jackknife, nestreg, rolling, statsby, stepwise, and svy are allowed; see [U] **11.1.10 Prefix commands**.

Weights are not allowed with the bootstrap prefix; see [R] **bootstrap**.

vce() and weights are not allowed with the svy prefix; see [SVY] **svy**.

fweights, iweights, and pweights are allowed; see [U] **11.1.6 weight**.

coeflegend does not appear in the dialog box.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Binary outcomes > Skewed logit regression

Description

scobit fits a maximum-likelihood skewed logit model.

See [R] **logistic** for a list of related estimation commands.

Options

Model

noconstant, offset(*varname*), constraints(*constraints*), collinear; see [R] **estimation options**.

asis forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] **probit**.

SE/Robust

vce(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster *clustvar*), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] ***vce_option***.

Reporting

level(#); see [R] **estimation options**.

or reports the estimated coefficients transformed to odds ratios, that is, e^b rather than b. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. or may be specified at estimation or when replaying previously estimated results.

nocnsreport; see [R] **estimation options**.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(*style*), cformat(%*fmt*), pformat(%*fmt*), sformat(%*fmt*), and nolstretch; see [R] **estimation options**.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] **maximize**. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

The following option is available with scobit but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

Remarks are presented under the following headings:

Skewed logistic model
Robust standard errors

Skewed logistic model

`scobit` fits maximum likelihood models with dichotomous dependent variables coded as 0/1 (or, more precisely, coded as 0 and not 0).

▷ Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a model explaining whether a car is foreign based on its mileage. Here is an overview of our data:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. describe
Contains data from http://www.stata-press.com/data/r13/auto.dta
  obs:            74                          1978 Automobile Data
 vars:             4                          13 Apr 2013 17:45
 size:         1,702                          (_dta has notes)
-------------------------------------------------------------------------------
              storage   display    value
variable name   type    format     label      variable label
-------------------------------------------------------------------------------

mpg             int     %8.0g                 Mileage (mpg)
weight          int     %8.0gc                Weight (lbs.)
foreign         byte    %8.0g      origin     Car type
-------------------------------------------------------------------------------
Sorted by:  foreign
     Note:  dataset has changed since last saved
. inspect foreign
foreign:  Car type                              Number of Observations
------------------                                        ------------------------------
                                                 Total   Integers   Nonintegers
  #                          Negative              -          -          -
  #                          Zero                 52         52          -
  #                          Positive             22         22          -
  #                                               ---        ---        ---
  #   #                      Total                74         74          -
  #   #                      Missing               -
------------------------------------------------  ---
0                        1                        74
   (2 unique values)
      foreign is labeled and all values are documented in the label.
```

The variable `foreign` takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

$$\Pr(\texttt{foreign} = 1) = F(\beta_0 + \beta_1 \texttt{mpg})$$

where $F(z) = 1 - 1/\{1 + \exp(z)\}^{\alpha}$.

To fit this model, we type

```
. scobit foreign mpg
Fitting logistic model:
Iteration 0:   log likelihood =  -45.03321
Iteration 1:   log likelihood = -39.380959
Iteration 2:   log likelihood = -39.288802
Iteration 3:   log likelihood =  -39.28864
Iteration 4:   log likelihood =  -39.28864
Fitting full model:
Iteration 0:   log likelihood =  -39.28864
Iteration 1:   log likelihood = -39.286393
Iteration 2:   log likelihood = -39.284415
Iteration 3:   log likelihood = -39.284234
Iteration 4:   log likelihood = -39.284197
Iteration 5:   log likelihood = -39.284196
Skewed logistic regression                      Number of obs     =         74
                                                Zero outcomes     =         52
Log likelihood =  -39.2842                      Nonzero outcomes  =         22
------------------------------------------------------------------------------
     foreign |      Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
         mpg |   .1813879   .2407362     0.75   0.451    -.2904463    .6532222
       _cons |  -4.274883   1.399305    -3.06   0.002    -7.017471   -1.532295
-------------+----------------------------------------------------------------
    /lnalpha |  -.4450405   3.879885    -0.11   0.909    -8.049476    7.159395
-------------+----------------------------------------------------------------
       alpha |   .6407983   2.486224                      .0003193    1286.133
------------------------------------------------------------------------------
Likelihood-ratio test of alpha=1:   chi2(1) =     0.01    Prob > chi2 = 0.9249
Note: likelihood-ratio tests are recommended for inference with scobit models.
```

We find that cars yielding better gas mileage are less likely to be foreign. The likelihood-ratio test at the bottom of the output indicates that the model is not significantly different from a logit model. Therefore, we should use the more parsimonious model.

◁

❑ Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if the dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If the dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

Formally, when we type `scobit` y x, Stata fits the model

$$\Pr(y_j \neq 0 \mid \mathbf{x}_j) = 1 - 1\Big/\Big\{1 + \exp(\mathbf{x}_j\boldsymbol{\beta})\Big\}^{\alpha}$$

❑

Robust standard errors

If you specify the vce(robust) option, scobit reports robust standard errors as described in [U] 20.21 Obtaining robust variance estimates. For the model of foreign on mpg, the robust calculation increases the standard error of the coefficient on mpg by around 25%:

```
. scobit foreign mpg, vce(robust) nolog
Skewed logistic regression                      Number of obs     =         74
                                                Zero outcomes     =         52
Log pseudolikelihood =  -39.2842                Nonzero outcomes  =         22
```

foreign	Coef.	Robust Std. Err.	z	P>|z|	[95% Conf.	Interval]
mpg	.1813879	.3028487	0.60	0.549	-.4121847	.7749606
_cons	-4.274883	1.335521	-3.20	0.001	-6.892455	-1.657311
/lnalpha	-.4450405	4.71561	-0.09	0.925	-9.687466	8.797385
alpha	.6407983	3.021755			.0000621	6616.919

Without vce(robust), the standard error for the coefficient on mpg was reported to be 0.241, with a resulting confidence interval of $[-0.29, 0.65]$.

Specifying the vce(cluster *clustvar*) option relaxes the independence assumption required by the skewed logit estimator to being just independence between clusters. To demonstrate this, we will switch to a different dataset.

▷ Example 2

We are studying the unionization of women in the United States and have a dataset with 26,200 observations on 4,434 women between 1970 and 1988. For our purposes, we will use the variables age (the women were 14–26 in 1968 and the data thus span the age range of 16–46), grade (years of schooling completed, ranging from 0 to 18), not_smsa (28% of the person-time was spent living outside an SMSA—standard metropolitan statistical area), south (41% of the person-time was in the South), and year. Each of these variables is included in the regression as a covariate along with the interaction between south and year. This interaction, along with the south and year variables, is specified in the scobit command using factor-variables notation, south##c.year. We also have variable union. Overall, 22% of the person-time is marked as time under union membership and 44% of these women have belonged to a union.

We fit the following model, ignoring that women are observed an average of 5.9 times each in these data:

```
. use http://www.stata-press.com/data/r13/union, clear
(NLS Women 14-24 in 1968)
. scobit union age grade not_smsa south##c.year, nrtol(1e-3)
```

(*output omitted*)

```
Skewed logistic regression                      Number of obs     =      26200
                                                Zero outcomes     =      20389
Log likelihood = -13540.61                      Nonzero outcomes  =       5811
```

union	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]

```
Likelihood-ratio test of alpha=1:   chi2(1) =     3.76   Prob > chi2 = 0.0524
Note: likelihood-ratio tests are recommended for inference with scobit models.
```

The reported standard errors in this model are probably meaningless. Women are observed repeatedly, so the observations are not independent. Looking at the coefficients, we find a large southern effect against unionization and a different time trend for the south. The `vce(cluster` *clustvar*`)` option provides a way to fit this model and obtains correct standard errors:

```
. scobit union age grade not_smsa south##c.year, vce(cluster id) nrtol(1e-3)
```

(*output omitted*)

```

`scobit, vce(cluster` *clustvar*`)` is robust to assumptions about within-cluster correlation. That is, it inefficiently sums within cluster for the standard error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation (as do the `xtgee` population-averaged models; see [XT] **xtgee**).

◁

❑ Technical note

The scobit model can be difficult to fit because of the functional form. Often it requires many iterations, or the optimizer prints out warning and informative messages during the optimization. For example, without the `nrtol(1e-3)` option, the model using the `union` dataset will not converge. See [R] **maximize** for details about the optimizer.

❑

❑ Technical note

The main reason for using `scobit` rather that `logit` is that the effects of the regressors on the probability of success are not constrained to be the largest when the probability is 0.5. Rather, the independent variables might show their largest impact when the probability of success is 0.3 or 0.6. This added flexibility results because the scobit function, unlike the logit function, can be skewed and is not constrained to be mirror symmetric about the 0.5 probability of success.

As Nagler (1994) pointed out, the point of maximum impact is constrained under the scobit model to fall within the interval $(0, 1 - e^{(-1)})$ or approximately (0, 0.63). Achen (2002) notes that if we believe the maximum impact to be outside that range, we can instead estimate the "power logit" model by simply reversing the 0s and 1s of our outcome variable and estimating a scobit model on failure, rather than success. We would need to reverse the signs of the coefficients if we wanted to interpret them in terms of impact on success, or we could leave them as they are and interpret them in terms of impact on failure. The important thing to remember is that the scobit model, unlike the logit model, is not invariant to the choice of which result is assigned to success.

❑

Stored results

scobit stores the following in e():

Scalars

e(N)	number of observations
e(k)	number of parameters
e(k_eq)	number of equations in e(b)
e(k_aux)	number of auxiliary parameters
e(k_dv)	number of dependent variables
e(ll)	log likelihood
e(ll_c)	log likelihood, comparison model
e(N_f)	number of failures (zero outcomes)
e(N_s)	number of successes (nonzero outcomes)
e(alpha)	alpha
e(N_clust)	number of clusters
e(chi2)	χ^2
e(chi2_c)	χ^2 for comparison test
e(p)	significance
e(rank)	rank of e(V)
e(ic)	number of iterations
e(rc)	return code
e(converged)	1 if converged, 0 otherwise

Macros

e(cmd)	scobit
e(cmdline)	command as typed
e(depvar)	name of dependent variable
e(wtype)	weight type
e(wexp)	weight expression
e(title)	title in estimation output
e(clustvar)	name of cluster variable
e(offset)	linear offset variable
e(chi2type)	Wald or LR; type of model χ^2 test
e(chi2_ct)	Wald or LR; type of model χ^2 test corresponding to e(chi2_c)
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(opt)	type of optimization
e(which)	max or min; whether optimizer is to perform maximization or minimization
e(ml_method)	type of ml method
e(user)	name of likelihood-evaluator program
e(technique)	maximization technique
e(properties)	b V
e(predict)	program used to implement predict
e(footnote)	program used to implement the footnote display
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(Cns)	constraints matrix
e(ilog)	iteration log (up to 20 iterations)
e(gradient)	gradient vector
e(V)	variance–covariance matrix of the estimators
e(V_modelbased)	model-based variance

Functions

e(sample)	marks estimation sample

Methods and formulas

Skewed logit analysis is an alternative to logit that relaxes the assumption that individuals with initial probability of 0.5 are most sensitive to changes in independent variables.

The log-likelihood function for skewed logit is

$$\ln L = \sum_{j \in S} w_j \ln F(\mathbf{x}_j\mathbf{b}) + \sum_{j \notin S} w_j \ln\{1 - F(\mathbf{x}_j\mathbf{b})\}$$

where S is the set of all observations j such that $y_j \neq 0$, $F(z) = 1 - 1/\{1 + \exp(z)\}^{\alpha}$, and w_j denotes the optional weights. $\ln L$ is maximized as described in [R] **maximize**.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`scobit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **variance estimation**.

Title

scobit postestimation — Postestimation tools for scobit

Description Syntax for predict Menu for predict Options for predict
Remarks and examples Also see

Description

The following postestimation commands are available after `scobit`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]

predict [type] {stub* | newvar_reg newvar_lnalpha} [if] [in], scores
```

statistic	Description
Main	
pr	probability of a positive outcome; the default
xb	$\mathbf{x}_j\mathbf{b}$, linear prediction
stdp	standard error of the linear prediction

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`pr`, the default, calculates the probability of a positive outcome.

`xb` calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`nooffset` is relevant only if you specified `offset(`*varname*`)` for `scobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $\mathbf{x}_j\mathbf{b}$ rather than as $\mathbf{x}_j\mathbf{b} + \text{offset}_j$.

`scores` calculates equation-level score variables.

The first new variable will contain $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

The second new variable will contain $\partial \ln L/\partial \ln\alpha$.

Remarks and examples

Once you have fit a model, you can obtain the predicted probabilities by using the `predict` command for both the estimation sample and other samples; see **[U] 20 Estimation and postestimation commands** and [R] **predict**. Here we will make only a few additional comments.

`predict` without arguments calculates the predicted probability of a positive outcome. With the `xb` option, it calculates the linear combination $\mathbf{x}_j\mathbf{b}$, where $\mathbf{x}_j$ are the independent variables in the jth observation and $\mathbf{b}$ is the estimated parameter vector.

With the `stdp` option, `predict` calculates the standard error of the prediction, which is *not* adjusted for replicated covariate patterns in the data.

Example 1

In example 1 of [R] **scobit**, we fit the model `scobit foreign mpg`. To obtain predicted probabilities, we type

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. scobit foreign mpg
  (output omitted)
. predict p
(option pr assumed; Pr(foreign))
. summarize foreign p
```

Variable	Obs	Mean	Std. Dev.	Min	Max
foreign	74	.2972973	.4601885	0	1
p	74	.2974049	.182352	.0714664	.871624

Syntax

One-sample variance-comparison test

```
sdtest varname == # [ if ] [ in ] [ , level(#) ]
```

Two-sample variance-comparison test using groups

```
sdtest varname [ if ] [ in ] , by(groupvar) [ level(#) ]
```

Two-sample variance-comparison test using variables

```
sdtest varname1 == varname2 [ if ] [ in ] [ , level(#) ]
```

Immediate form of one-sample variance-comparison test

```
sdtesti #obs { #mean | . } #sd #val [ , level(#) ]
```

Immediate form of two-sample variance-comparison test

```
sdtesti #obs,1 { #mean,1 | . } #sd,1 #obs,2 { #mean,2 | . } #sd,2 [ , level(#) ]
```

Robust tests for equality of variances

```
robvar varname [ if ] [ in ] , by(groupvar)
```

`by` is allowed with `sdtest` and `robvar`; see [D] **by**.

sdtesti

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Variance-comparison test calculator

robvar

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Robust equal-variance test

Description

`sdtest` performs tests on the equality of standard deviations (variances). In the first form, `sdtest` tests that the standard deviation of *varname* is #. In the second form, `sdtest` performs the same test, using the standard deviations of the two groups defined by *groupvar*. In the third form, `sdtest` tests that $varname_1$ and $varname_2$ have the same standard deviation.

`sdtesti` is the immediate form of `sdtest`; see **[U] 19 Immediate commands**.

Both the traditional F test for the homogeneity of variances and Bartlett's generalization of this test to K samples are sensitive to the assumption that the data are drawn from an underlying Gaussian distribution. See, for example, the cautionary results discussed by Markowski and Markowski (1990). Levene (1960) proposed a test statistic for equality of variance that was found to be robust under nonnormality. Then Brown and Forsythe (1974) proposed alternative formulations of Levene's test statistic that use more robust estimators of central tendency in place of the mean. These reformulations were demonstrated to be more robust than Levene's test when dealing with skewed populations.

`robvar` reports Levene's robust test statistic (W_0) for the equality of variances between the groups defined by *groupvar* and the two statistics proposed by Brown and Forsythe that replace the mean in Levene's formula with alternative location estimators. The first alternative (W_{50}) replaces the mean with the median. The second alternative replaces the mean with the 10% trimmed mean (W_{10}).

Options

`level(#)` specifies the confidence level, as a percentage, for confidence intervals of the means. The default is `level(95)` or as set by `set level`; see **[U] 20.7 Specifying the width of confidence intervals**.

`by(`*groupvar*`)` specifies the *groupvar* that defines the groups to be compared. For `sdtest`, there should be two groups, but for `robvar` there may be more than two groups. Do not confuse the `by()` option with the `by` prefix; both may be specified.

Remarks and examples

Remarks are presented under the following headings:

Basic form
Immediate form
Robust test

Basic form

`sdtest` performs two different statistical tests: one testing equality of variances and the other testing that the standard deviation is equal to a known constant. Which test it performs is determined by whether you type a variable name or a number to the right of the equal sign.

▷ Example 1: One-sample test of variance

We have a sample of 74 automobiles. For each automobile, we know the mileage rating. We wish to test whether the overall standard deviation is 5 mpg:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. sdtest mpg == 5
One-sample test of variance
```

Variable	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
mpg	74	21.2973	.6725511	5.785503	19.9569	22.63769

```
    sd = sd(mpg)                                     c = chi2 =  97.7384
Ho: sd = 5                                 degrees of freedom =       73

     Ha: sd < 5                 Ha: sd != 5                 Ha: sd > 5
  Pr(C < c) = 0.9717         2*Pr(C > c) = 0.0565          Pr(C > c) = 0.0283
```

Example 2: Variance ratio test

We are testing the effectiveness of a new fuel additive. We run an experiment on 12 cars, running each without and with the additive. The data can be found in [R] **ttest**. The results for each car are stored in the variables `mpg1` and `mpg2`:

```
. use http://www.stata-press.com/data/r13/fuel
. sdtest mpg1==mpg2
Variance ratio test
```

Variable	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
mpg1	12	21	.7881701	2.730301	19.26525	22.73475
mpg2	12	22.75	.9384465	3.250874	20.68449	24.81551
combined	24	21.875	.6264476	3.068954	20.57909	23.17091

```
    ratio = sd(mpg1) / sd(mpg2)                          f =   0.7054
Ho: ratio = 1                              degrees of freedom =   11, 11

    Ha: ratio < 1               Ha: ratio != 1                 Ha: ratio > 1
  Pr(F < f) = 0.2862         2*Pr(F < f) = 0.5725           Pr(F > f) = 0.7138
```

We cannot reject the hypothesis that the standard deviations are the same.

In [R] **ttest**, we draw an important distinction between paired and unpaired data, which, in this example, means whether there are 12 cars in a before-and-after experiment or 24 different cars. For `sdtest`, on the other hand, there is no distinction. If the data had been unpaired and stored as described in [R] **ttest**, we could have typed `sdtest mpg, by(treated)`, and the results would have been the same.

Immediate form

Example 3: sdtesti

Immediate commands are used not with data, but with reported summary statistics. For instance, to test whether a variable on which we have 75 observations and a reported standard deviation of 6.5 comes from a population with underlying standard deviation 6, we would type

```
. sdtesti 75 . 6.5 6
One-sample test of variance
```

	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf. Interval]	
x	75	.	.7505553	6.5	.	.

```
    sd = sd(x)                                     c = chi2 =  86.8472
Ho: sd = 6                                 degrees of freedom =       74

     Ha: sd < 6                  Ha: sd != 6                 Ha: sd > 6
  Pr(C < c) = 0.8542         2*Pr(C > c) = 0.2916         Pr(C > c) = 0.1458
```

The mean plays no role in the calculation, so it may be omitted.

To test whether the variable comes from a population with the same standard deviation as another for which we have a calculated standard deviation of 7.5 over 65 observations, we would type

```
. sdtesti 75 . 6.5 65 . 7.5
Variance ratio test
```

	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf. Interval]	
x	75	.	.7505553	6.5	.	.
y	65	.	.9302605	7.5	.	.
combined	140	.	.	.	.	.

```
    ratio = sd(x) / sd(y)                          f =   0.7511
Ho: ratio = 1                              degrees of freedom =   74, 64

    Ha: ratio < 1               Ha: ratio != 1                 Ha: ratio > 1
  Pr(F < f) = 0.1172         2*Pr(F < f) = 0.2344         Pr(F > f) = 0.8828
```

◁

Robust test

▷ Example 4: robvar

We wish to test whether the standard deviation of the length of stay for patients hospitalized for a given medical procedure differs by gender. Our data consist of observations on the length of hospital stay for 1778 patients: 884 males and 894 females. Length of stay, `lengthstay`, is highly skewed (skewness coefficient = 4.912591) and thus violates Bartlett's normality assumption. Therefore, we use `robvar` to compare the variances.

```
. use http://www.stata-press.com/data/r13/stay
. robvar lengthstay, by(sex)
```

sex	Summary of Length of stay in days Mean	Std. Dev.	Freq.
male	9.0874434	9.7884747	884
female	8.800671	9.1081478	894
Total	8.9432508	9.4509466	1778

```
W0  =  0.55505315   df(1, 1776)     Pr > F = 0.45635888
W50 =  0.42714734   df(1, 1776)     Pr > F = 0.51347664
W10 =  0.44577674   df(1, 1776)     Pr > F = 0.50443411
```

For these data, we cannot reject the null hypothesis that the variances are equal. However, Bartlett's test yields a significance probability of 0.0319 because of the pronounced skewness of the data. ◁

❑ Technical note

`robvar` implements both the conventional Levene's test centered at the mean and a median-centered test. In a simulation study, Conover, Johnson, and Johnson (1981) compare the properties of the two tests and recommend using the median test for asymmetric data, although for small sample sizes the test is somewhat conservative. See Carroll and Schneider (1985) for an explanation of why both mean- and median-centered tests have approximately the same level for symmetric distributions, but for asymmetric distributions the median test is closer to the correct level. ❑

Stored results

`sdtest` and `sdtesti` store the following in `r()`:

Scalars

`r(N)`	number of observations
`r(p_l)`	lower one-sided p-value
`r(p_u)`	upper one-sided p-value
`r(p)`	two-sided p-value
`r(F)`	F statistic
`r(sd)`	standard deviation
`r(sd_1)`	standard deviation for first variable
`r(sd_2)`	standard deviation for second variable
`r(df)`	degrees of freedom
`r(df_1)`	numerator degrees of freedom
`r(df_2)`	denominator degrees of freedom
`r(chi2)`	χ^2

`robvar` stores the following in `r()`:

Scalars

`r(N)`	number of observations
`r(w50)`	Brown and Forsythe's F statistic (median)
`r(p_w50)`	Brown and Forsythe's p-value
`r(w0)`	Levene's F statistic
`r(p_w0)`	Levene's p-value
`r(w10)`	Brown and Forsythe's F statistic (trimmed mean)
`r(p_w10)`	Brown and Forsythe's p-value (trimmed mean)
`r(df_1)`	numerator degrees of freedom
`r(df_2)`	denominator degrees of freedom

Methods and formulas

See Armitage et al. (2002, 149–153) or Bland (2000, 171–172) for an introduction and explanation of the calculation of these tests.

The test for $\sigma = \sigma_0$ is given by

$$\chi^2 = \frac{(n-1)s^2}{\sigma_0^2}$$

which is distributed as χ^2 with $n-1$ degrees of freedom.

The test for $\sigma_x^2 = \sigma_y^2$ is given by

$$F = \frac{s_x^2}{s_y^2}$$

which is distributed as F with $n_x - 1$ and $n_y - 1$ degrees of freedom.

Let X_{ij} be the jth observation of X for the ith group. Let $Z_{ij} = |X_{ij} - \overline{X}_i|$, where $\overline{X}_i$ is the mean of X in the ith group. Levene's test statistic is

$$W_0 = \frac{\sum_i n_i(\overline{Z}_i - \overline{Z})^2/(g-1)}{\sum_i \sum_j (Z_{ij} - \overline{Z}_i)^2 / \sum_i (n_i - 1)}$$

where n_i is the number of observations in group i and g is the number of groups. W_{50} is obtained by replacing $\overline{X}_i$ with the ith group median of X_{ij}, whereas W_{10} is obtained by replacing $\overline{X}_i$ with the 10% trimmed mean for group i.

Syntax

```
search word [word ...] [, search_options]

set searchdefault {all|local|net} [, permanently]
```

search_options	Description
`all`	search across both the local keyword database and the `net` material; the default
`local`	search using Stata's keyword database
`net`	search across materials available via Stata's `net` command
`author`	search by author's name
`entry`	search by entry ID
`exact`	search across both the local keyword database and the `net` materials; prevents matching on abbreviations
`faq`	search the FAQs posted to the Stata website
`historical`	search entries that are of historical interest only
`or`	list an entry if *any* of the words typed after `search` are associated with the entry
`manual`	search the entries in the *Stata Documentation*
`sj`	search the entries in the *Stata Journal* and the STB

Menu

Help > Search...

Description

`search` searches a keyword database and the Internet for Stata materials related to your query.

Capitalization of the words following `search` is irrelevant, as is the inclusion or exclusion of special characters such as commas and hyphens.

`set searchdefault` affects the default behavior of the `search` command. `all` is the default.

`search, all` is the best way to search for information on a topic across all sources, including the system help, the FAQs at the Stata website, the *Stata Journal*, and all Stata-related Internet sources including user-written additions. From the results, you can click to go to a source or to install additions.

Options for search

`all`, the default (unless changed by `set searchdefault`), specifies that the search be performed across both the local keyword database and the `net` materials. The results of a search performed with `all` and no other options will be displayed in the Viewer window.

`local` specifies that the search be performed using only Stata's keyword database. The results of a search performed with `local` and no other options will be displayed in the Viewer window.

`net` specifies that the search be performed across the materials available via Stata's `net` command. Using `search` *word* [*word* ...]`, net` is equivalent to typing `net search` *word* [*word* ...] (without options); see [R] **net search**. The results of a search performed with `net` and no other options will be displayed in the Viewer window.

`author` specifies that the search be performed on the basis of author's name rather than keywords. A search with the `author` option is performed on the local keyword database only, and the results are displayed in the Results window.

`entry` specifies that the search be performed on the basis of entry IDs rather than keywords. A search with the `entry` option is performed on the local keyword database only, and the results are displayed in the Results window.

`exact` prevents matching on abbreviations. A search with the `exact` option is performed across both the local keyword database and the `net` materials, and the results are displayed in the Results window.

`faq` limits the search to the FAQs posted on the Stata website: http://www.stata.com. A search with the `faq` option is performed on the local keyword database only, and the results are displayed in the Results window.

`historical` adds to the search entries that are of historical interest only. By default, such entries are not listed. Past entries are classified as historical if they discuss a feature that later became an official part of Stata. Updates to historical entries will always be found, even if `historical` is not specified. A search with the `historical` option is performed on the local keyword database only, and the results are displayed in the Results window.

`or` specifies that an entry be listed if any of the words typed after `search` are associated with the entry. The default is to list the entry only if all the words specified are associated with the entry. A search with the `or` option is performed on the local keyword database only, and the results are displayed in the Results window.

`manual` limits the search to entries in the *Stata Documentation*; that is, the search is limited to the *User's Guide* and all the reference manuals. A search with the `manual` option is performed on the local keyword database only, and the results are displayed in the Results window.

`sj` limits the search to entries in the *Stata Journal* and its predecessor, the *Stata Technical Bulletin*; see [R] **sj**. A search with the `sj` option is performed on the local keyword database only, and the results are displayed in the Results window.

Option for set searchdefault

`permanently` specifies that, in addition to making the change right now, the `searchdefault` setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Internet searches
Author searches
Entry ID searches
Return codes

Introduction

See **[U] 4 Stata's help and search facilities** for a tutorial introduction to `search`. `search` is one of Stata's most useful commands. To understand the advanced features of `search`, you need to know how it works.

`search` has a database—files—containing the titles, etc., of every entry in the *User's Guide*, the *Base Reference Manual*, the *Data Management Reference Manual*, the *Graphics Reference Manual*, the *Longitudinal-Data/Panel-Data Reference Manual*, the *Multilevel Mixed-Effects Reference Manual*, the *Multiple-Imputation Reference Manual*, the *Multivariate Statistics Reference Manual*, the *Power and Sample-Size Reference Manual*, the *Programming Reference Manual*, the *Structural Equation Modeling Reference Manual*, the *Survey Data Reference Manual*, the *Survival Analysis and Epidemiological Tables Reference Manual*, the *Treatment-Effects Reference Manual*, the *Time-Series Reference Manual*, the *Mata Reference Manual*, undocumented help files, NetCourses, Stata Press books, FAQs posted on the Stata website, videos posted on the Stata YouTube channel, selected articles on StataCorp's official blog, selected user-written FAQs and examples, and the articles in the *Stata Journal* and the *Stata Technical Bulletin*. In these files is a list of words, called keywords, associated with each entry.

When you type `search` *xyz*, `search` reads the database and compares the list of keywords with *xyz*. If it finds *xyz* in the list or a keyword that allows an abbreviation of *xyz*, it displays the entry.

When you type `search` *xyz abc*, `search` does the same thing but displays an entry only if it contains both keywords. The order does not matter, so you can `search linear regression` or `search regression linear`.

Obviously, how many entries `search` finds depends on how the search database was constructed. We have included a plethora of keywords under the theory that, for a given request, it is better to list too much rather than risk listing nothing at all. Still, you are in the position of guessing the keywords. Do you look up normality test, normality tests, or tests of normality? Well, normality test would be best, but all would work. In general, use the singular, and strike the unnecessary words. For guidelines for specifying keywords, see **[U] 4.6 More on search**.

`set searchdefault` allows you to specify where `search` searches. `set searchdefault all`, the default, indicates that both the keyword database and the Internet are to be searched. `set searchdefault local` restricts `search` to using only Stata's keyword database. `set searchdefault net` restricts `search` to searching only the Internet.

Internet searches

`search` with the `net` option searches the Internet for user-written additions to Stata, including, but not limited to, user-written additions published in the *Stata Journal* (SJ) and the *Stata Technical Bulletin* (STB). `search` *keywords*`, net` performs the same search as the command `net search` (with no options); see **[R] net search**.

```

(end of search)
```

Author searches

`search` ordinarily compares the words following `search` with the keywords for the entry. If you specify the `author` option, however, it compares the words with the author's name. In the search database, we have filled in author names for all SJ and STB inserts.

For instance, in [R] **kdensity** in this manual you will discover that Isaías H. Salgado-Ugarte wrote the first version of Stata's `kdensity` command and published it in the STB. Assume that you read his original insert and found the discussion useful. You might now wonder what else he has written in the SJ or STB. To find out, you type

```
. search Salgado-Ugarte, author
  (output omitted)
```

Names like Salgado-Ugarte are confusing to many people. `search` does not require you to specify the entire name; what you type is compared with each "word" of the name and, if any part matches, the entry is listed. The hyphen is a special character, and you can omit it. Thus you can obtain the same list by looking up Salgado, Ugarte, or Salgado Ugarte without the hyphen.

Actually, to find all entries written by Salgado-Ugarte, you need to type

```
. search Salgado-Ugarte, author historical
  (output omitted)
```

Prior inserts in the SJ or STB that provide a feature that later was superseded by a built-in feature of Stata are marked as historical in the search database and, by default, are not listed. The `historical` option ensures that all entries are listed.

Entry ID searches

If you specify the `entry` option, `search` compares what you have typed with the entry ID. The entry ID is not the title—it is the reference listed to the left of the title that tells you where to look. For instance, in

```
[R]     regress  . . . . . . . . . . . . . . . . . . . . . . . Linear regression
        (help regress)
```

[R] **regress** is the entry ID. This is a reference, of course, to this manual. In

```
FAQ     . . . . . . . . . . .  Analysis of multiple failure-time survival data
        . . . . . . . . . . . . . . . . . . . . . . . . . . . M. Cleves and I. Canette
        07/09   How do I analyze multiple failure-time data using Stata?
                http://www.stata.com/support/faqs/statistics/multiple-failure-
                type-data/
```

"FAQ" is the entry ID. In

```
SJ-7-1  st0118  . . A survey on survey stat.: What is and can be done in Stata
        . . . . . . . . . . . . . . . . . . . . . . . . F. Kreuter and R. Valliant
        Q1/07  SJ7(1):1--21                                        (no commands)
        discusses survey issues in analyzing complex survey
        data and describes some of Stata's capabilities for
        such analyses
```

"SJ-7-1" is the entry ID.

`search` with the `entry` option searches these entry IDs.

Thus you could generate a table of contents for the *User's Guide* by typing

```
. search [U], entry
```
(*output omitted*)

You could generate a table of contents for *Stata Journal*, Volume 1, Issue 1, by typing

```
. search sj-1-1, entry
```
(*output omitted*)

To generate a table of contents for the 26th issue of the STB, you would type

```
. search STB-26, entry historical
```
(*output omitted*)

The `historical` option here is possibly important. STB-26 was published in July 1995, and perhaps some of its inserts have already been marked historical.

You could obtain a list of all inserts associated with sg53 by typing

```
. search sg53, entry historical
```
(*output omitted*)

Again we include the `historical` option in case any of the relevant inserts have been marked historical.

Return codes

In addition to indexing the entries in the *User's Guide* and all the *Reference* manuals, `search` also can be used to search return codes.

To see information on return code 131, type

```
. search rc 131
[P]     error . . . . . . . . . . . . . . . . . . . . . . . .  Return code 131
        not possible with test;
        You requested a test of a hypothesis that is nonlinear in the
        variables.  test tests only linear hypotheses.  Use testnl.
```

If you want a list of all Stata return codes, type

```
. search error, entry
```
(*output omitted*)

Acknowledgment

We thank Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* for his contributions to the `search` command.

Title

serrbar — Graph standard error bar chart

Syntax | Menu | Description | Options
Remarks and examples | Acknowledgment | Also see

Syntax

`serrbar` *mvar svar xvar* [*if*] [*in*] [, *options*]

options	Description
Main	
`scale(#)`	scale length of graph bars; default is `scale(1)`
Error bars	
rcap_options	affect rendition of capped spikes
Plotted points	
`mvopts(`*scatter_options*`)`	affect rendition of plotted points
Add plots	
`addplot(`*plot*`)`	add other plots to generated graph
Y axis, X axis, Titles, Legend, Overall	
twoway_options	any options other than `by()` documented in [G-3] ***twoway_options***

Menu

Statistics > Other > Quality control > Standard error bar chart

Description

`serrbar` graphs *mvar* ± `scale()` × *svar* against *xvar*. Usually, but not necessarily, *mvar* and *svar* will contain means and standard errors or standard deviations of some variable so that a standard error bar chart is produced.

Options

Main

`scale(#)` controls the length of the bars. The upper and lower limits of the bars will be *mvar* + `scale()` × *svar* and *mvar* − `scale()` × *svar*. The default is `scale(1)`.

Error bars

rcap_options affect the rendition of the plotted error bars (the capped spikes). See [G-2] **graph twoway rcap**.

Plotted points

`mvopts(`*scatter_options*`)` affects the rendition of the plotted points (*mvar* versus *xvar*). See [G-2] **graph twoway scatter**.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph; see [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] ***twoway_options***, excluding `by()`. These include options for titling the graph (see [G-3] ***title_options***) and for saving the graph to disk (see [G-3] ***saving_option***).

Remarks and examples

▷ Example 1

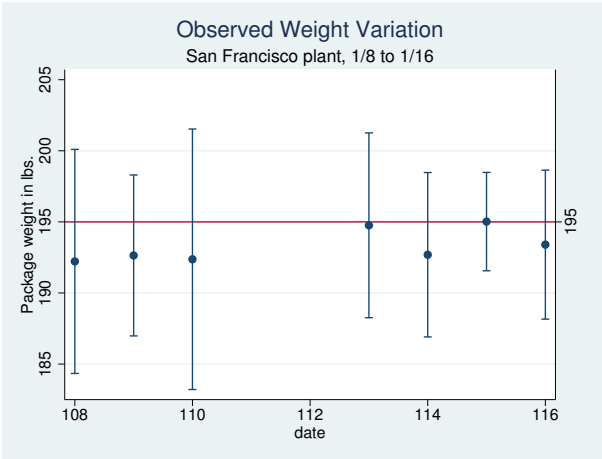
In quality-control applications, the three most commonly used variables with this command are the process mean, process standard deviation, and time. For instance, we have data on the average weights and standard deviations from an assembly line in San Francisco for the period January 8 to January 16. Our data are

```
. use http://www.stata-press.com/data/r13/assembly
. list, sep(0) divider
```

	date	mean	std
1.	108	192.22	3.94
2.	109	192.64	2.83
3.	110	192.37	4.58
4.	113	194.76	3.25
5.	114	192.69	2.89
6.	115	195.02	1.73
7.	116	193.40	2.62

We type `serrbar mean std date, scale(2)` but, after seeing the result, decide to make it fancier:

```
. serrbar mean std date, scale(2) title("Observed Weight Variation")
> sub("San Francisco plant, 1/8 to 1/16") yline(195) yaxis(1 2)
> ylab(195, axis(2)) ytitle("", axis(2))
```



Acknowledgment

serrbar was written by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal*.

Title

set — Overview of system parameters

Syntax Description Remarks and examples Also see

Syntax

```
set [ setcommand ... ]
```

`set` typed without arguments is equivalent to `query` typed without arguments.

Description

This entry provides a reference to Stata's `set` commands. For many entries, more thorough information is provided elsewhere; see the Reference field in each entry below for the location of this information.

To reset system parameters to factory defaults, see [R] **set_defaults**.

Remarks and examples

`set adosize`
Syntax: `set adosize # [ , permanently ]`
Default: 1,000
Description: sets the maximum amount of memory that automatically loaded do-files may consume. $10 \leq \# \leq 10000$.
Reference: [P] **sysdir**

`set autotabgraphs` (Windows only)
Syntax: `set autotabgraphs {on|off} [ , permanently ]`
Default: `off`
Description: determines whether graphs are created as tabs within one window or as separate windows.

`set cformat`
Syntax: `set cformat [fmt] [ , permanently ]`
Description: specifies the output format of coefficients, standard errors, and confidence limits in coefficient tables. *fmt* is a numerical format; see [D] **format**.
Reference: [R] **set cformat**

`set charset` (Mac only)
Syntax: `set charset {mac|latin1} [ , permanently ]`
Default: `mac`
Description: sets the character set used by Stata for Mac for rendering of ASCII text.

`set checksum`
Syntax: `set checksum {on|off} [, permanently]`
Default: `off`
Description: determines whether files should be prevented from being downloaded from the Internet if checksums do not match.
Reference: [D] **checksum**

`set coeftabresults`
Syntax: `set coeftabresults {on|off}`
Default: `on`
Description: determines whether coefficient table results are stored in `r()`.
There is no `permanently` option because `permanently` is implied.

`set conren` (Unix console only)
Syntax 1: `set conren`
Syntax 2: `set conren clear`
Syntax 3: `set conren [sf | bf | it] {result | [txt | text] | input | error | link | hilite} [char[char...]]`
Syntax 4: `set conren {ulon | uloff} [char [char ...]]`
Syntax 5: `set conren reset [char [char ...]]`
Description: can possibly make the output on your screen appear prettier.
`set conren` displays a list of the currently defined display codes.
`set conren clear` clears all codes.
`set conren` followed by a font type (`bf`, `sf`, or `it`) and display context (`result`, `error`, `link`, or `hilite`) and then followed by a series of space-separated characters sets the code for the specified font type and display context. If the font type is omitted, the code is set to the same specified code for all three font types.
`set conren ulon` and `set conren uloff` set the codes for turning on and off underlining.
`set conren reset` sets the code that will turn off all display and underlining codes.
Reference: [GSU] **conren**

`set copycolor` (Mac and Windows only)
Syntax: `set copycolor {automatic|asis|gs1|gs2|gs3} [, permanently]`
Default: `automatic`
Description: determines how colors are handled when graphs are copied to the Clipboard.
Reference: [G-2] **set printcolor**

`set dockable` (Windows only)
Syntax: `set dockable {on|off} [, permanently]`
Default: `on`
Description: determines whether to enable the use of dockable window characteristics, including the ability to dock or tab a window into another window.

set dockingguides (Windows only)
Syntax: set dockingguides {on | off} [, permanently]
Default: on
Description: determines whether to enable the use of dockable guides when repositioning a dockable window.

set doublebuffer (Windows only)
Syntax: set doublebuffer {on | off} [, permanently]
Default: on
Description: enables or disables double buffering of the Results, Viewer, and Data Editor windows. Double buffering prevents the windows from flickering when redrawn or resized. Users who encounter performance problems such as the Results window outputting very slowly should disable double buffering.

set dp
Syntax: set dp {comma | period} [, permanently]
Default: period
Description: determines whether a period or a comma is to be used as the decimal point.
Reference: [D] **format**

set emptycells
Syntax: set emptycells {keep | drop} [, permanently]
Default: keep
Description: sets what to do with empty cells in interactions.
Reference: [R] **set emptycells**

set eolchar (Mac only)
Syntax: set eolchar {mac | unix} [, permanently]
Default: unix
Description: sets the default end-of-line delimiter for text files created in Stata.

set fastscroll (Unix and Windows only)
Syntax: set fastscroll {on | off} [, permanently]
Default: on
Description: sets the scrolling method for new output in the Results window. Setting fastscroll to on is faster but can be jumpy. Setting fastscroll to off is slower but smoother.

set floatwindows (Windows only)
Syntax: set floatwindows {on | off}
Default: off
Description: determines whether to enable floating window behavior for dialog boxes and dockable window. The term "float" in this context means that a window will always float over the main Stata window; these windows cannot be placed behind the main Stata window. There is no permanently option because permanently is implied.

set fvlabel
Syntax: set fvlabel { on | off } [, permanently]
Description: specifies whether to display factor-variable value labels in coefficient tables.
Reference: [R] set showbaselevels

set fvwrap
Syntax: set fvwrap # [, permanently]
Description: specifies that long value labels wrap # lines in coefficient tables.
Reference: [R] set showbaselevels

set fvwrapon
Syntax: set fvwrapon { word | width } [, permanently]
Description: specifies whether value labels that wrap will break at word bounderies or break based on available space.
Reference: [R] set showbaselevels

set graphics
Syntax: set graphics {on | off}
Default: on; default is off for console Stata
Description: determines whether graphs are displayed on your monitor.
Reference: [G-2] set graphics

set haverdir
Syntax: set haverdir "*path*" [, permanently]
Description: specifies the directory where the Haver databases are stored.
Reference: [D] import haver

set httpproxy
Syntax: set httpproxy {on | off} [, init]
Default: off
Description: turns on/off the use of a proxy server. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyauth
Syntax: set httpproxyauth {on | off}
Default: off
Description: determines whether authorization is required for the proxy server. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyhost
Syntax: set httpproxyhost ["]*name*["]
Description: sets the name of a host to be used as a proxy server. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyport
Syntax: set httpproxyport #
Default: 8080 if Stata cannot autodetect the proper setting for your computer.
Description: sets the port number for a proxy server. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxypw
Syntax: set httpproxypw ["]password["]
Description: sets the appropriate password. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyuser
Syntax: set httpproxyuser ["]name["]
Description: sets the appropriate user ID. There is no permanently option because permanently is implied.
Reference: [R] netio

set include_bitmap (Mac only)
Syntax: set include_bitmap {on | off} [, permanently]
Default: on
Description: sets the output behavior when copying an image to the Clipboard.

set level
Syntax: set level # [, permanently]
Default: 95
Description: sets the default confidence level for confidence intervals for all commands that report confidence intervals. 10.00 ≤ # ≤ 99.99, and # can have at most two digits after the decimal point.
Reference: [R] level

set linegap
Syntax: set linegap #
Default: 1
Description: sets the space between lines, in pixels, in the Results window. There is no permanently option because permanently is implied.

set linesize
Syntax: set linesize #
Default: 1 less than the full width of the screen
Description: sets the line width, in characters, for both the screen and the log file.
Reference: [R] log

set locksplitters (Windows only)
Syntax: set locksplitters {on | off} [, permanently]
Default: off
Description: determines whether splitters should be locked so that docked windows cannot be resized.

set logtype
Syntax: set logtype {text | smcl} [, permanently]
Default: smcl
Description: sets the default log filetype.
Reference: [R] log

set lstretch
Syntax: set lstretch {on | off} [, permanently]
Description: specifies whether to automatically widen the coefficient table up to the width of the Results window to accommodate longer variable names.

set matacache, set matafavor, set matalibs, set matalnum, set matamofirst, set mataoptimize, and set matastrict; see [M-3] mata set.

set matsize
Syntax: set matsize # [, permanently]
Default: 400 for Stata/MP, Stata/SE, and Stata/IC; 40 for Small Stata
Description: sets the maximum number of variables that can be included in any estimation command. This setting cannot be changed in Small Stata.
$10 \leq \# \leq 11000$ for Stata/MP and Stata/SE; $10 \leq \# \leq 800$ for Stata/IC.
Reference: [R] matsize

set max_memory
Syntax: set max_memory #[b | k | m | g] [, permanently]
Default: . (all the memory the operating system will supply)
Description: specifies the maximum amount of memory Stata can use to store your data.
$2 \times \text{segmentsize} \leq \# \leq .$
Reference: [D] memory

set maxdb
Syntax: set maxdb # [, permanently]
Default: 50
Description: sets the maximum number of dialog boxes whose contents are remembered from one invocation to the next during a session. $5 \leq \# \leq 1000$
Reference: [R] db

set maxiter
Syntax: set maxiter # [, permanently]
Default: 16000
Description: sets the default maximum number of iterations for estimation commands.
$0 \leq \# \leq 16000$
Reference: [R] maximize

set maxvar
Syntax: set maxvar # [, permanently]
Default: 5000 for Stata/MP and Stata/SE, 2048 for Stata/IC, and 99 for Small Stata
Description: sets the maximum number of variables. This can be changed only in Stata/MP and Stata/SE. 2048 ≤ # ≤ 32767
Reference: [D] **memory**

set min_memory
Syntax: set min_memory #[b|k|m|g] [, permanently]
Default: 0
Description: specifies an amount of memory Stata will not fall below. This setting affects efficiency, not the size of datasets you can analyze. 0 ≤ # ≤ max_memory
Reference: [D] **memory**

set more
Syntax: set more {on|off} [, permanently]
Default: on
Description: pauses when —more— is displayed, continuing only when the user presses a key.
Reference: [R] **more**

set niceness
Syntax: set niceness # [, permanently]
Default: 5
Description: affects how soon Stata gives back unused segments to the operating system. 0 ≤ # ≤ 10
Reference: [D] **memory**

set notifyuser (Mac only)
Syntax: set notifyuser {on|off} [, permanently]
Default: on
Description: sets the default Notification Manager behavior in Stata.

set obs
Syntax: set obs #
Default: current number of observations
Description: changes the number of observations in the current dataset. # must be at least as large as the current number of observations. If there are variables in memory, the values of all new observations are set to *missing*.
Reference: [D] **obs**

set odbcmgr (Unix only)
Syntax: set odbcmgr {iodbc|unixodbc} [, permanently]
Default: iodbc
Description: determines whether iODBC or unixODBC is your ODBC driver manager.
Reference: [D] **odbc**

set output
Syntax: set output {proc | inform | error}
Default: proc
Description: specifies the output to be displayed. proc means display all output; inform suppresses procedure output but displays informative messages and error messages; error suppresses all output except error messages. set output is seldom used.
Reference: [P] quietly

set pagesize
Syntax: set pagesize #
Default: 2 less than the physical number of lines on the screen
Description: sets the number of lines between —more— messages.
Reference: [R] more

set pformat
Syntax: set pformat [fmt] [, permanently]
Description: specifies the output format of p-values in coefficient tables. fmt is a numerical format; see [D] format.
Reference: [R] set cformat

set pinnable (Windows only)
Syntax: set pinnable {on | off} [, permanently]
Default: on
Description: determines whether to enable the use of pinnable window characteristics for certain windows in Stata.

set playsnd (Mac only)
Syntax: set playsnd {on | off} [, permanently]
Default: on
Description: sets the sound behavior for the Notification Manager behavior in Stata.

set printcolor
Syntax: set printcolor {automatic | asis | gs1 | gs2 | gs3} [, permanently]
Default: automatic
Description: determines how colors are handled when graphs are printed.
Reference: [G-2] set printcolor

set processors
Syntax: set processors #
Description: sets the number of processors or cores that Stata/MP will use. The default is the number of processors available on the computer, or the number of processors allowed by Stata/MP's license, whichever is less.

set reventries
Syntax: set reventries # [, permanently]
Default: 5000
Description: sets the number of scrollback lines available in the Review window. $5 \leq \# \leq 32000$.

set revkeyboard (Mac only)
Syntax: set revkeyboard {on | off} [, permanently]
Default: on
Description: sets the keyboard navigation behavior for the Review window. on indicates that you can use the keyboard to navigate and enter items from the Review window into the Command window. off indicates that all keyboard input be directed at the Command window; items can be entered from the Review window only by using the mouse.

set rmsg
Syntax: set rmsg {on | off} [, permanently]
Default: off
Description: indicates whether a return message telling the execution time is to be displayed at the completion of each command.
Reference: [P] **rmsg**

set scheme
Syntax: set scheme *schemename* [, permanently]
Default: s2color
Description: determines the overall look for graphs.
Reference: [G-2] **set scheme**

set scrollbufsize
Syntax: set scrollbufsize #
Default: 200000
Description: sets the scrollback buffer size, in bytes, for the Results window; may be set between 10,000 and 2,000,000.

set searchdefault
Syntax: set searchdefault {local | net | all} [, permanently]
Default: local
Description: sets the default behavior of the search command. set searchdefault local restricts search to use only Stata's keyword database. set searchdefault net restricts search to searching only the Internet. set searchdefault all indicates that both the keyword database and the Internet are to be searched.
Reference: [R] **search**

set seed
Syntax: set seed {# | *code*}
Default: 123456789
Description: specifies initial value of the random-number seed used by the runiform() function.
Reference: [R] **set seed**

set segmentsize
Syntax: set segmentsize #[b | k | m | g] [, permanently]
Default: 32m for 64-bit machines; 16m for 32-bit machines
Description: Stata allocates memory for data in units of segmentsize. This setting changes the amount of memory in a single segment.
1m $\leq$ # $\leq$ 32g for 64-bit machines; 1m $\leq$ # $\leq$ 1g for 32-bit machines
Reference: [D] **memory**

set sformat
Syntax: set sformat [*fmt*] [, permanently]
Description: specifies the output format of test statistics in coefficient tables.
fmt is a numerical format; see [D] **format**.
Reference: [R] **set cformat**

set showbaselevels
Syntax: set showbaselevels {on | off | all} [, permanently]
Description: specifies whether to display base levels of factor variables and their interactions in coefficient tables.
Reference: [R] **set showbaselevels**

set showemptycells
Syntax: set showemptycells {on | off} [, permanently]
Description: specifies whether to display empty cells in coefficient tables.
Reference: [R] **set showbaselevels**

set showomitted
Syntax: set showomitted {on | off} [, permanently]
Description: specifies whether to display omitted coefficients in coefficient tables.
Reference: [R] **set showbaselevels**

set smoothfonts (Mac only)
Syntax: set smoothfonts {on | off}
Default: on
Description: determines whether to use font smoothing (antialiased text) in the Results, Viewer, and Data Editor windows.

set timeout1
Syntax: set timeout1 *#seconds* [, permanently]
Default: 30
Description: sets the number of seconds Stata will wait for a remote host to respond to an initial contact before giving up. In general, users should not modify this value unless instructed to do so by Stata Technical Services.
Reference: [R] **netio**

set timeout2
Syntax: set timeout2 *#seconds* [, permanently]
Default: 180
Description: sets the number of seconds Stata will keep trying to get information from a remote host after initial contact before giving up. In general, users should not modify this value unless instructed to do so by Stata Technical Services.
Reference: [R] **netio**

set trace
Syntax: set trace {on | off}
Default: off
Description: determines whether to trace the execution of programs for debugging.
Reference: [P] **trace**

set tracedepth
Syntax: set tracedepth #
Default: 32000 (equivalent to ∞)
Description: if trace is set on, traces execution of programs and nested programs up to tracedepth. For example, if tracedepth is 2, the current program and any subroutine called would be traced, but subroutines of subroutines would not be traced.
Reference: [P] trace

set traceexpand
Syntax: set traceexpand {on | off} [, permanently]
Default: on
Description: if trace is set on, shows lines both before and after macro expansion. If traceexpand is set off, only the line before macro expansion is shown.
Reference: [P] trace

set tracehilite
Syntax: set tracehilite "*pattern*" [, word]
Default: ""
Description: highlights *pattern* in the trace output.
Reference: [P] trace

set traceindent
Syntax: set traceindent {on | off} [, permanently]
Default: on
Description: if trace is set on, indents displayed lines according to their nesting level. The lines of the main program are not indented. Two spaces of indentation are used for each level of nested subroutine.
Reference: [P] trace

set tracenumber
Syntax: set tracenumber {on | off} [, permanently]
Default: off
Description: if trace is set on, shows the nesting level numerically in front of the line. Lines of the main program are preceded by 01, lines of subroutines called by the main program are preceded by 02, etc.
Reference: [P] trace

set tracesep
Syntax: set tracesep {on | off} [, permanently]
Default: on
Description: if trace is set on, displays a horizontal separator line that displays the name of the subroutine whenever a subroutine is called or exits.
Reference: [P] trace

set type
Syntax: set type {float | double} [, permanently]
Default: float
Description: specifies the default storage type assigned to new variables.
Reference: [D] generate

set update_interval (Mac and Windows only)
Syntax: set update_interval #
Default: 7
Description: sets the number of days to elapse before performing the next automatic update query.
Reference: [R] update

set update_prompt (Mac and Windows only)
Syntax: set update_prompt {on | off}
Default: on
Description: determines wheter a dialog is to be displayed before performing an automatic update query. There is no permanently option because permanently is implied.
Reference: [R] update

set update_query (Mac and Windows only)
Syntax: set update_query {on | off}
Default: on
Description: determines whether update query is to be automatically performed when Stata is launched. There is no permanently option because permanently is implied.
Reference: [R] update

set varabbrev
Syntax: set varabbrev {on | off} [, permanently]
Default: on
Description: indicates whether Stata should allow variable abbreviations.
Reference: [P] varabbrev

set varkeyboard (Mac only)
Syntax: set varkeyboard {on | off} [, permanently]
Default: on
Description: sets the keyboard navigation behavior for the Variables window. on indicates that you can use the keyboard to navigate and enter items from the Variables window into the Command window. off indicates that all keyboard input be directed at the Command window; items can be entered from the Variables window only by using the mouse.

Title

set cformat — Format settings for coefficient tables

Syntax Description Option Remarks and examples Also see

Syntax

```
set cformat [fmt] [, permanently]

set pformat [fmt] [, permanently]

set sformat [fmt] [, permanently]
```

where *fmt* is a numerical format.

Description

`set cformat` specifies the output format of coefficients, standard errors, and confidence limits in coefficient tables.

`set pformat` specifies the output format of p-values in coefficient tables.

`set sformat` specifies the output format of test statistics in coefficient tables.

Option

`permanently` specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

The formatting of the numbers in the coefficient table can be controlled by using the `set cformat`, `set pformat`, and `set sformat` commands or by using the `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, and `sformat(%`*fmt*`)` options at the time of estimation or on replay of the estimation command. See [R] **estimation options**.

The maximum format widths for `set cformat`, `set pformat`, and `set sformat` in coefficient tables are 9, 5, and 8, respectively.

▷ Example 1

We use `auto.dta` to illustrate.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress mpg weight displacement
```

Source	SS	df	MS

Title

set_defaults — Reset system parameters to original Stata defaults

Syntax Description Option Remarks and examples Also see

Syntax

```
set_defaults { category | _all } [ , permanently ]
```

where *category* is one of memory | output | interface | graphics | efficiency |

network | update | trace | mata | other

Description

`set_defaults` resets settings made by `set` to the original default settings that were shipped with Stata.

`set_defaults _all` resets all the categories, whereas `set defaults` *category* resets only the settings for the specified category.

Option

`permanently` specifies that, in addition to making the change right now, the settings be remembered and become the default settings when you invoke Stata.

Remarks and examples

▷ Example 1

To assist us in debugging a new command, we modified some of the `trace` settings. To return them to their original values, we type

```
. set_defaults trace
-> set trace off
-> set tracedepth 32000
-> set traceexpand on
-> set tracesep on
-> set traceindent on
-> set tracenumber off
-> set tracehilite ""
(preferences reset)
```

◁

Title

set emptycells — Set what to do with empty cells in interactions

Syntax Description Option Remarks and examples Also see

Syntax

```
set emptycells {keep|drop} [, permanently]
```

Description

`set emptycells` allows you to control how Stata handles interaction terms with empty cells. Stata can keep empty cells or drop them. The default is to keep empty cells.

Option

`permanently` specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

By default, Stata keeps empty cells so they can be reported in the coefficient table. For example, type

```
. use http://www.stata-press.com/data/r13/auto
. regress mpg rep78#foreign, baselevels
```

and you will see a regression of `mpg` on 10 indicator variables because `rep78` takes on 5 values and `foreign` takes on 2 values in the `auto` dataset. Two of those cells will be reported as empty because the data contain no observations of foreign cars with a `rep78` value of 1 or 2.

Many real datasets contain a large number of empty cells, and this could cause the "matsize too small" error, r(908). In that case, type

```
. set emptycells drop
```

to get Stata to drop empty cells from the list of coefficients. If you commonly fit models with empty cells, you can permanently set Stata to drop empty cells by typing the following:

```
. set emptycells drop, permanently
```

Also see

[R] **set** — Overview of system parameters

Title

set seed — Specify initial value of random-number seed

Syntax Description Remarks and examples Also see

Syntax

```
set seed #
```

```
set seed statecode
```

where

is any number between 0 and $2^{31} - 1$ (2,147,483,647), and

statecode is a random-number state previously obtained from `creturn` value `c(seed)`.

Description

`set seed #` specifies the initial value of the random-number seed used by the random-number functions, such as `runiform()` and `rnormal()`.

`set seed` *statecode* resets the state of the random-number functions to the value specified, which is a state previously obtained from `creturn` value `c(seed)`.

Remarks and examples

Remarks are presented under the following headings:

Examples
Setting the seed
How to choose a seed
Do not set the seed too often
Preserving and restoring the random-number generator state

Examples

1. Specify initial value of random-number seed

   ```
   . set seed 339487731
   ```

2. Create variable `u` containing uniformly distributed pseudorandom numbers on the interval $[0, 1)$

   ```
   . generate u = runiform()
   ```

3. Create variable `z` containing normally distributed random numbers with mean 0 and standard deviation 1

   ```
   . generate z = rnormal()
   ```

4. Obtain state of pseudorandom-number generator and store it in a local macro named `state`

   ```
   . local state = c(seed)
   ```

5. Restore pseudorandom-number generator state to that previously stored in local macro named `state`

   ```
   . set seed `state'
   ```

Setting the seed

Stata's random-number generation functions, such as `runiform()` and `rnormal()`, do not really produce random numbers. These functions are deterministic algorithms that produce numbers that can pass for random. `runiform()` produces numbers that can pass for independent draws from a rectangular distribution over $[0, 1)$; `rnormal()` produces numbers that can pass for independent draws from $N(0, 1)$. Stata's random-number functions are formally called pseudorandom-number functions.

The sequences these functions produce are determined by the seed, which is just a number and which is set to 123456789 every time Stata is launched. This means that `runiform()` produces the same sequence each time you start Stata. The first time you use `runiform()` after Stata is launched, `runiform()` returns 0.136984078446403146. The second time you use it, `runiform()` returns 0.643220667960122228. The third time you use it, ...

To obtain different sequences, you must specify different seeds using the `set seed` command. You might specify the seed 472195:

```
. set seed 472195
```

If you were now to use `runiform()`, the first call would return 0.247166610788553953, the second call would return 0.593119932804256678, and so on. Whenever you `set seed 472195`, `runiform()` will return those numbers the first two times you use it.

Thus you set the seed to obtain different pseudorandom sequences from the pseudorandom-number functions.

If you record the seed you set, pseudorandom results such as results from a simulation or imputed values from `mi impute` can be reproduced later. Whatever you do after setting the seed, if you set the seed to the same value and repeat what you did, you will obtain the same results.

How to choose a seed

Your best choice for the seed is an element chosen randomly from the set $\{0, 1, \ldots, 2{,}147{,}483{,}647\}$. We recommend that, but that is difficult to achieve because finding easy-to-access, truly random sources is difficult.

One person we know uses digits from the serial numbers from dollar bills he finds in his wallet. Of course, the numbers he obtains are not really random, but they are good enough, and they are probably a good deal more random than the seeds most people choose. Some people use dates and times, although we recommend against that because, over the day, it just gets later and later, and that is a pattern. Others try to make up a random number, figuring if they include enough digits, the result just has to be random. This is a variation on the five-second rule for dropped food, and we admit to using both of these rules.

It does not really matter how you set the seed, as long as there is no obvious pattern in the seeds that you set and as long as you do not set the seed too often during a session.

Nonetheless, here are two methods that we have seen used but you should not use:

1. The first time you set the seed, you set the number 1. The next time, you set 2, and then 3, and so on. Variations on this included setting 1001, 1002, 1003, ..., or setting 1001, 2001, 3001, and so on.

   Do not follow any of these procedures. The seeds you set must not exhibit a pattern.

2. To set the seed, you obtain a pseudorandom number from `runiform()` and then use the digits from that to form the seed.

   This is a bad idea because the pseudorandom-number generator can converge to a cycle. If you obtained the pseudorandom-number generator unrelated to those in Stata, this would work well, but then you would have to find a rule to set the first generator's seed. In any case, the pseudorandom-number generators in Stata are all closely related, and so you must not follow this procedure.

Choosing seeds that do not exhibit a pattern is of great importance. That the seeds satisfy the other properties of randomness is minor by comparison.

Do not set the seed too often

We cannot emphasize this enough: Do not set the seed too often.

To see why this is such a bad idea, consider the limiting case: You set the seed, draw one pseudorandom number, reset the seed, draw again, and so continue. The pseudorandom numbers you obtain will be nothing more than the seeds you run through a mathematical function. The results you obtain will not pass for random unless the seeds you choose pass for random. If you already had such numbers, why are you even bothering to use the pseudorandom-number generator?

The definition of too often is more than once per problem.

If you are running a simulation of 10,000 replications, set the seed at the start of the simulation and do not reset it until the 10,000th replication is finished. The pseudorandom-number generators provided by Stata have long periods. The longer you go between setting the seed, the more random-like are the numbers produced.

It is sometimes useful later to be able to reproduce in isolation any one of the replications, and so you might be tempted to set the seed to a known value for each of the replications. We negatively mentioned setting the seed to 1, 2, . . . , and it is in exactly such situations that we have seen this done. The advantage, however, is that you could reproduce the fifth replication merely by setting the seed to 5 and then repeating whatever it is that is to be replicated. If this is your goal, you do not need to reset the seed. You can record the state of the random-number generator, save the state with your replication results, and then use the recorded states later to reproduce whichever of the replications that you wish. This will be discussed in *Preserving and restoring the random-number generator state*.

There is another reason you might be tempted to set the seed more than once per problem. It sometimes happens that you run a simulation, let's say for 5,000 replications, and then you decide you should have run it for 10,000 replications. Instead of running all 10,000 replications afresh, you decide to save time by running another 5,000 replications and then combining those results with your previous 5,000 results. That is okay. We at StataCorp do this kind of thing. If you do this, it is important that you set the seed especially well, particularly if you repeat this process to add yet another 5,000 replications. It is also important that in each run there be a large enough number of replications, which is say thousands of them.

Even so, do not do this: You want 500,000 replications. To obtain them, you run in batches of 1,000, setting the seed 500 times. Unless you have a truly random source for the seeds, it is unlikely you can produce a patternless sequence of 500 seeds. The fact that you ran 1,000 replications in between choosing the seeds does not mitigate the requirement that there be no pattern to the seeds you set.

In all cases, the best solution is to set the seed only once and then use the method we suggest in the next section.

Preserving and restoring the random-number generator state

In the previous section, we discussed the case in which you might be tempted to set the seed more frequently than otherwise necessary, either to save time or to be able to rerun any one of the replications. In such cases, there is an alternative to setting a new seed: recording the state of the pseudorandom-number generator and then restoring the state later should the need arise.

The state of the random-number generator is a string that looks like this:

```
Xb5804563c43f462544a474abacbdd93d00021fb3
```

You can obtain the state from `c(seed)`:

```
. display c(seed)
Xb5804563c43f462544a474abacbdd93d00021fb3
```

The name `c(seed)` is unfortunate because it suggests that Xb5804563c43f462544a474abacbdd93d00021fb3 is nothing more than a seed such as 1073741823 in a different guise. It is not. A better name for `c(seed)` would have been `c(rng_state)`. The state string specifies an entry point into the sequence produced by the pseudorandom-number generator. Let us explain.

The best way to use a pseudorandom-number generator would be to choose a seed once, draw random numbers until you use up the generator, and then get a new generator and choose a new key. Pseudorandom-number generators have a period, after which they repeat the original sequence. That is what we mean by using up a generator. The period of the pseudorandom-number generator that Stata is currently using is over 2^{123}. Stata uses the KISS generator. It is difficult to imagine that you could ever use up KISS.

The string reported by `c(seed)` reports an encoded form of the information necessary for Stata to reestablish exactly where it is located in the pseudorandom-number generator's sequence.

We are not seriously suggesting you choose only one seed over your entire lifetime, but let's look at how you might do that. Sometime after birth, when you needed your first random number, you would set your seed,

```
. set seed 1073741823
```

On that day, you would draw, say, 10,000 pseudorandom numbers, perhaps to impute some missing values. Being done for the day, you type

```
. display c(seed)
X15b512f3b2143ab434f1c92f4e7058e400023bc3
```

The next day, after launching Stata, you type

```
. set seed X15b512f3b2143ab434f1c92f4e7058e400023bc3
```

When you type `set seed` followed by a state string rather than a number, instead of setting the seed, Stata reestablishes the previous state. Thus the next time you draw a pseudorandom number, Stata will produce the 10,001st result after setting seed 1073741823. Let's assume that you draw 100,000 numbers this day. Done for the day, you display `c(seed)`.

```
. display c(seed)
X5d13d693a72ad0602b093cc4f61e07a500020381
```

On the third day, after setting the seed to the string above, you will be in a position to draw the 110,001st pseudorandom number.

In this way, you would eat your way though the 2^{123} random numbers, but you would be unlikely ever to make it to the end. Assuming you did this every day for 100 years, to arrive at the end of the sequence you would need to consume 2.9e+32 pseudorandom numbers per day.

We do not expect you to set the seed just once in your life, but using the state string makes it easy to set the seed just once for a problem.

When we do simulations at StataCorp, we record `c(seed)` for each replication. Just like everybody else, we record results from replications as observations in datasets; we just happen to have an extra variable in the dataset, namely, a string variable named `state`. That string is filled in observation by observation from the then-current values of `c(seed)`, which is a function and so can be used in any context that a function can be used in Stata.

Anytime we want to reproduce a particular replication, we thus have the information we need to reset the pseudorandom-number generator, and having it in the dataset is convenient because we had to go there anyway to determine which replication we wanted to reproduce.

In addition to recording each of the state strings for each replication, we record the closing value of `c(seed)` as a note, which is easy enough to do:

```
. note: closing state ‘c(seed)’
```

If we want to add more replications later, we have a state string that we can use to continue from where we left off.

Title

set showbaselevels — Display settings for coefficient tables

Syntax Description Option Remarks and examples Also see

Syntax

```
set showbaselevels {on|off|all} [, permanently]

set showemptycells {on|off} [, permanently]

set showomitted {on|off} [, permanently]

set fvlabel {on|off} [, permanently]

set fvwrap # [, permanently]

set fvwrapon {word|width} [, permanently]
```

Description

`set showbaselevels` specifies whether to display base levels of factor variables and their interactions in coefficient tables. `set showbaselevels on` specifies that base levels be reported for factor variables and for interactions whose bases cannot be inferred from their component factor variables. `set showbaselevels all` specifies that all base levels of factor variables and interactions be reported.

`set showemptycells` specifies whether to display empty cells in coefficient tables.

`set showomitted` specifies whether to display omitted coefficients in coefficient tables.

`set fvlabel` specifies whether to display factor-variable value labels in coefficient tables. `set fvlabel on`, the default, specifies that the labels be displayed. `set fvlabel off` specifies that the levels of factor variables rather than the labels be displayed.

`set fvwrap` # specifies that long value labels wrap # lines in the coefficient table. The default is `set fvwrap 1`, which means that long value labels will be abbreviated to fit on one line.

`set fvwrapon` specifies whether value labels that wrap will break at word boundaries or break based on available space. `set fvwrapon word`, the default, specifies that value labels break at word boundaries. `set fvwrapon width` specifies that value labels break based on available space.

Option

`permanently` specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

▷ Example 1

We illustrate the first three `set` commands using `cholesterol2.dta`.

```
. use http://www.stata-press.com/data/r13/cholesterol2
(Artificial cholesterol data, empty cells)
. generate x = race
. regress chol race##agegrp x
note: 2.race#2.agegrp identifies no observations in the sample
note: x omitted because of collinearity
```

signrank

Statistics > Nonparametric analysis > Tests of hypotheses > Wilcoxon matched-pairs signed-rank test

signtest

Statistics > Nonparametric analysis > Tests of hypotheses > Test equality of matched pairs

Description

`signrank` tests the equality of matched pairs of observations by using the Wilcoxon matched-pairs signed-ranks test (Wilcoxon 1945). The null hypothesis is that both distributions are the same.

`signtest` also tests the equality of matched pairs of observations (Arbuthnott [1710], but better explained by Snedecor and Cochran [1989]) by calculating the differences between *varname* and the expression. The null hypothesis is that the median of the differences is zero; no further assumptions are made about the distributions. This, in turn, is equivalent to the hypothesis that the true proportion of positive (negative) signs is one-half.

For equality tests on unmatched data, see [R] **ranksum**.

Remarks and examples

▷ Example 1: signrank

We are testing the effectiveness of a new fuel additive. We run an experiment with 12 cars. We first run each car without the fuel treatment and measure the mileage. We then add the fuel treatment and repeat the experiment. The results of the experiment are

Without treatment	With treatment	Without treatment	With treatment
20	24	18	17
23	25	24	28
21	21	20	24
25	22	24	27
18	23	23	21
17	18	19	23

We create two variables called `mpg1` and `mpg2`, representing mileage without and with the treatment, respectively. We can test the null hypothesis that the treatment had no effect by typing

```
. use http://www.stata-press.com/data/r13/fuel
. signrank mpg1=mpg2
Wilcoxon signed-rank test

        sign |      obs    sum ranks    expected
-------------+---------------------------------
    positive |        3         13.5        38.5
    negative |        8         63.5        38.5
        zero |        1            1           1
-------------+---------------------------------
         all |       12           78          78

unadjusted variance      162.50
adjustment for ties       -1.62
adjustment for zeros      -0.25
                        --------
adjusted variance        160.62

Ho: mpg1 = mpg2
             z =  -1.973
    Prob > |z| =   0.0485
```

The output indicates that we can reject the null hypothesis at any level above 4.85%. ◁

▷ Example 2: signtest

`signtest` tests that the median of the differences is zero, making no further assumptions, whereas `signrank` assumed that the distributions are equal as well. Using the data above, we type

```
. signtest mpg1=mpg2
Sign test

        sign |    observed    expected
-------------+--------------------------
    positive |           3         5.5
    negative |           8         5.5
        zero |           1           1
-------------+--------------------------
         all |          12          12

One-sided tests:
  Ho: median of mpg1 - mpg2 = 0 vs.
  Ha: median of mpg1 - mpg2 > 0
      Pr(#positive >= 3) =
         Binomial(n = 11, x >= 3, p = 0.5) =  0.9673

  Ho: median of mpg1 - mpg2 = 0 vs.
  Ha: median of mpg1 - mpg2 < 0
      Pr(#negative >= 8) =
         Binomial(n = 11, x >= 8, p = 0.5) =  0.1133
```

```
Two-sided test:
  Ho: median of mpg1 - mpg2 = 0 vs.
  Ha: median of mpg1 - mpg2 != 0
      Pr(#positive >= 8 or #negative >= 8) =
         min(1, 2*Binomial(n = 11, x >= 8, p = 0.5)) =  0.2266
```

The summary table indicates that there were three comparisons for which `mpg1` exceeded `mpg2`, eight comparisons for which `mpg2` exceeded `mpg1`, and one comparison for which they were the same.

The output below the summary table is based on the binomial distribution. The significance of the one-sided test, where the alternative hypothesis is that the median of `mpg2` − `mpg1` is greater than zero, is 0.1133. The significance of the two-sided test, where the alternative hypothesis is simply that the median of the differences is different from zero, is $0.2266 = 2 \times 0.1133$. ◁

Stored results

`signrank` stores the following in `r()`:

Scalars

`r(N_neg)`	number of negative comparisons	`r(sum_neg)`	sum of the negative ranks
`r(N_pos)`	number of positive comparisons	`r(z)`	z statistic
`r(N_tie)`	number of tied comparisons	`r(Var_a)`	adjusted variance
`r(sum_pos)`	sum of the positive ranks		

`signtest` stores the following in `r()`:

Scalars

`r(N_neg)`	number of negative comparisons	`r(p_2)`	two-sided probability
`r(N_pos)`	number of positive comparisons	`r(p_neg)`	one-sided probability of negative comparison
`r(N_tie)`	number of tied comparisons	`r(p_pos)`	one-sided probability of positive comparison

Methods and formulas

For a practical introduction to these techniques with an emphasis on examples rather than theory, see Bland (2000) or Sprent and Smeeton (2007). For a summary of these tests, see Snedecor and Cochran (1989).

Methods and formulas are presented under the following headings:

signrank
signtest

signrank

Both the sign test and Wilcoxon signed-rank tests test the null hypothesis that the distribution of a random variable $D = \textit{varname} - \textit{exp}$ has median zero. The sign test makes no additional assumptions, but the Wilcoxon signed-rank test makes the additional assumption that the distribution of D is symmetric. If $D = X_1 - X_2$, where X_1 and X_2 have the same distribution, then it follows that the distribution of D is symmetric about zero. Thus the Wilcoxon signed-rank test is often described as a test of the hypothesis that two distributions are the same, that is, $X_1 \sim X_2$.

Let d_j denote the difference for any matched pair of observations,

$$d_j = x_{1j} - x_{2j} = \textit{varname} - \textit{exp}$$

for $j = 1, 2, \ldots, n$.

Rank the absolute values of the differences, $|d_j|$, and assign any tied values the average rank. Consider the signs of d_j, and let

$$r_j = \text{sign}(d_j)\,\text{rank}(|d_j|)$$

be the signed ranks. The test statistic is

$$T_{\text{obs}} = \sum_{j=1}^{n} r_j = (\text{sum of ranks for } + \text{ signs}) - (\text{sum of ranks for } - \text{ signs})$$

The null hypothesis is that the distribution of d_j is symmetric about 0. Hence the likelihood is unchanged if we flip signs on the d_j, and thus the randomization datasets are the 2^n possible sign changes for the d_j. Thus the randomization distribution of our test statistic T can be computed by considering all the 2^n possible values of

$$T = \sum_{j=1}^{n} S_j r_j$$

where the r_j are the observed signed ranks (considered fixed) and S_j is either $+1$ or -1.

With this distribution, the mean and variance of T are given by

$$E(T) = 0 \qquad \text{and} \qquad \text{Var}_{\text{adj}}(T) = \sum_{j=1}^{n} r_j^2$$

The test statistic for the Wilcoxon signed-rank test is often expressed (equivalently) as the sum of the positive signed-ranks, T_+, where

$$E(T_+) = \frac{n(n+1)}{4} \qquad \text{and} \qquad \text{Var}_{\text{adj}}(T_+) = \frac{1}{4}\sum_{j=1}^{n} r_j^2$$

Zeros and ties do not affect the theory above, and the exact variance is still given by the above formula for $\text{Var}_{\text{adj}}(T_+)$. When $d_j = 0$ is observed, d_j will always be zero in each of the randomization datasets (using $\text{sign}(0) = 0$). When there are ties, you can assign averaged ranks for each group of ties and then treat them the same as the other ranks.

The "unadjusted variance" reported by `signrank` is the variance that the randomization distribution would have had if there had been no ties or zeros:

$$\text{Var}_{\text{unadj}}(T_+) = \frac{1}{4}\sum_{j=1}^{n} j^2 = \frac{n(n+1)(2n+1)}{24}$$

The adjustment for zeros is the change in the variance when the ranks for the zeros are signed to make $r_j = 0$,

$$\Delta\text{Var}_{\text{zero adj}}(T_+) = -\frac{1}{4}\sum_{j=1}^{n_0} j^2 = -\frac{n_0(n_0+1)(2n_0+1)}{24}$$

where n_0 is the number of zeros. The adjustment for ties is the change in the variance when the ranks (for nonzero observations) are replaced by averaged ranks:

$$\Delta\text{Var}_{\text{ties adj}}(T_+) = \text{Var}_{\text{adj}}(T_+) - \text{Var}_{\text{unadj}}(T_+) - \Delta\text{Var}_{\text{zero adj}}(T_+)$$

A normal approximation is used to calculate

$$z = \frac{T_+ - E(T_+)}{\sqrt{\text{Var}_{\text{adj}}(T_+)}}$$

signtest

The test statistic for the sign test is the number n_+ of differences

$$d_j = x_{1j} - x_{2j} = \textit{varname} - \textit{exp}$$

greater than zero. Assuming that the probability of a difference being equal to zero is exactly zero, then, under the null hypothesis, $n_+ \sim \text{binomial}(n, p = 1/2)$, where n is the total number of observations.

But what if some differences are zero? This question has a ready answer if you view the test from the perspective of Fisher's Principle of Randomization (Fisher 1935). Fisher's idea (stated in a modern way) was to look at a family of transformations of the observed data such that the a priori likelihood (under the null hypothesis) of the transformed data is the same as the likelihood of the observed data. The distribution of the test statistic is then produced by calculating its value for each of the transformed "randomization" datasets, assuming that each dataset is equally likely.

For the sign test, the "data" are simply the set of signs of the differences. Under the null hypothesis of the sign test, the probability that d_j is less than zero is equal to the probability that d_j is greater than zero. Thus you can transform the observed signs by flipping any number of them, and the set of signs will have the same likelihood. The 2^n possible sign changes form the family of randomization datasets. If you have no zeros, this procedure again leads to $n_+ \sim \text{binomial}(n, p = 1/2)$.

If you do have zeros, changing their signs leaves them as zeros. So, if you observe n_0 zeros, each of the 2^n sign-change datasets will also have n_0 zeros. Hence, the values of n_+ calculated over the sign-change datasets range from 0 to $n - n_0$, and the "randomization" distribution of n_+ is $\text{binomial}(n - n_0, p = 1/2)$.

The work of Arbuthnott (1710) and later eighteenth-century contributions is discussed by Hald (2003, chap. 17).

Frank Wilcoxon (1892–1965) was born in Ireland to American parents. After working in various occupations (including merchant seaman, oil-well pump attendant, and tree surgeon), he settled in chemistry, gaining degrees from Rutgers and Cornell and employment from various companies. Working mainly on the development of fungicides and insecticides, Wilcoxon became interested in statistics in 1925 and made several key contributions to nonparametric methods. After retiring from industry, he taught statistics at Florida State until his death.

Title

simulate — Monte Carlo simulations

Syntax Description Options Remarks and examples
References Also see

Syntax

```
simulate [exp_list] , reps(#) [options] : command
```

options	Description
`nodots`	suppress replication dots
`noisily`	display any output from *command*
`trace`	trace *command*
`saving(`*filename*`, ...)`	save results to *filename*
`nolegend`	suppress table legend
`verbose`	display the full table legend
`seed(#)`	set random-number seed to #

All weight types supported by *command* are allowed; see **[U] 11.1.6 weight**.

exp_list contains	`(`*name*`:` *elist*`)`
	elist
	eexp
elist contains	*newvar* `=` `(`*exp*`)`
	`(`*exp*`)`
eexp is	*specname*
	`[`*eqno*`]`*specname*
specname is	`_b`
	`_b[]`
	`_se`
	`_se[]`
eqno is	`##`
	name

exp is a standard Stata expression; see **[U] 13 Functions and expressions**.

Distinguish between `[]`, which are to be typed, and [ ], which indicate optional arguments.

Description

`simulate` eases the programming task of performing Monte Carlo–type simulations. Typing

```
. simulate exp_list, reps(#): command
```

runs *command* for # replications and collects the results in *exp_list*.

command defines the command that performs one simulation. Most Stata commands and user-written programs can be used with `simulate`, as long as they follow standard Stata syntax; see [U] **11 Language syntax**. The `by` prefix may not be part of *command*.

exp_list specifies the expression to be calculated from the execution of *command*. If no expressions are given, *exp_list* assumes a default, depending upon whether *command* changes results in `e()` or `r()`. If *command* changes results in `e()`, the default is `_b`. If *command* changes results in `r()` (but not `e()`), the default is all the scalars posted to `r()`. It is an error not to specify an expression in *exp_list* otherwise.

Options

`reps(#)` is required—it specifies the number of replications to be performed.

`nodots` suppresses display of the replication dots. By default, one dot character is displayed for each successful replication. A red 'x' is displayed if *command* returns an error or if one of the values in *exp_list* is missing.

`noisily` requests that any output from *command* be displayed. This option implies the `nodots` option.

`trace` causes a trace of the execution of *command* to be displayed. This option implies the `noisily` option.

`saving(`*filename*`[ , `*suboptions*`])` creates a Stata data file (`.dta` file) consisting of (for each statistic in *exp_list*) a variable containing the simulated values.

`double` specifies that the results for each replication be saved as `double`s, meaning 8-byte reals. By default, they are saved as `float`s, meaning 4-byte reals.

`every(#)` specifies that results be written to disk every #th replication. `every()` should be specified only in conjunction with `saving()` when *command* takes a long time for each replication. This will allow recovery of partial results should some other software crash your computer. See [P] **postfile**.

`replace` specifies that *filename* be overwritten if it exists.

`nolegend` suppresses display of the table legend. The table legend identifies the rows of the table with the expressions they represent.

`verbose` requests that the full table legend be displayed. By default, coefficients and standard errors are not displayed.

`seed(#)` sets the random-number seed. Specifying this option is equivalent to typing the following command before calling `simulate`:

```
. set seed #
```

Remarks and examples

For an introduction to Monte Carlo methods, see Cameron and Trivedi (2010, chap. 4). White (2010) provides a command for analyzing results of simulation studies.

▷ Example 1: Simulating basic summary statistics

We have a dataset containing means and variances of 100-observation samples from a lognormal distribution (as a first step in evaluating, say, the coverage of a 95%, t-based confidence interval). Then we perform the experiment 1,000 times.

The following command definition will generate 100 independent observations from a lognormal distribution and compute the summary statistics for this sample.

```
program lnsim, rclass
        version 13
        drop _all
        set obs 100
        gen z = exp(rnormal())
        summarize z
        return scalar mean = r(mean)
        return scalar Var  = r(Var)
end
```

We can save 1,000 simulated means and variances from `lnsim` by typing

```
. set seed 1234
. simulate mean=r(mean) var=r(Var), reps(1000) nodots: lnsim
      command:  lnsim
         mean:  r(mean)
          var:  r(Var)
. describe *
              storage   display    value
variable name   type    format     label      variable label
------------------------------------------------------------------------------
mean            float   %9.0g                 r(mean)
var             float   %9.0g                 r(Var)
. summarize
    Variable |       Obs        Mean    Std. Dev.       Min        Max
-------------+--------------------------------------------------------
        mean |      1000    1.638466     .214371   1.095099   2.887392
         var |      1000     4.63856    6.428406      .8626   175.3746
```

◁

❑ Technical note

Before executing our `lnsim` simulator, we can verify that it works by executing it interactively.

```
. set seed 1234
. lnsim
obs was 0, now 100
    Variable |       Obs        Mean    Std. Dev.       Min        Max
-------------+--------------------------------------------------------
           z |       100    1.597757    1.734328   .0625807   12.71548
. return list
scalars:
               r(Var) =  3.007893773683719
              r(mean) =  1.59775722913444
```

❑

▷ Example 2: Simulating a regression model

Consider a more complicated problem. Let's experiment with fitting $y_j = a + bx_j + u_j$ when the true model has $a = 1$, $b = 2$, $u_j = z_j + cx_j$, and when z_j is $N(0, 1)$. We will save the parameter estimates and standard errors and experiment with varying c. x_j will be fixed across experiments but will originally be generated as $N(0, 1)$. We begin by interactively making the true data:

```
. drop _all
. set obs 100
obs was 0, now 100
. set seed 54321
. gen x = rnormal()
. gen true_y = 1+2*x
. save truth
file truth.dta saved
```

Our program is

```
program hetero1
        version 13
        args c
        use truth, clear
        gen y = true_y + (rnormal() + `c'*x)
        regress y x
end
```

Note the use of `` `c' `` in our statement for generating `y`. `c` is a local macro generated from `args c` and thus refers to the first argument supplied to `hetero1`. If we want $c = 3$ for our experiment, we type

```
. simulate _b _se, reps(10000): hetero1 3
  (output omitted)
```

Our program `hetero1` could, however, be more efficient because it rereads the file `truth` once every replication. It would be better if we could read the data just once. In fact, if we read in the data right before running `simulate`, we really should not have to reread for each subsequent replication. A faster version reads

```
program hetero2
        version 13
        args c
        capture drop y
        gen y = true_y + (rnormal() + `c'*x)
        regress y x
end
```

Requiring that the current dataset has the variables `true_y` and `x` may become inconvenient. Another improvement would be to require that the user supply variable names, such as in

```
program hetero3
        version 13
        args truey x c
        capture drop y
        gen y = `truey' + (rnormal() + `c'*`x')
        regress y x
end
```

Thus we can type

```
. simulate _b _se, reps(10000): hetero3 true_y x 3
  (output omitted)
```

◁

▷ Example 3: Simulating a ratio of statistics

Now let's consider the problem of simulating the ratio of two medians. Suppose that each sample of size n_i comes from a normal population with a mean μ_i and standard deviation σ_i, where $i = 1, 2$. We write the program below and save it as a text file called `myratio.ado` (see **[U] 17 Ado-files**). Our program is an `rclass` command that requires six arguments as input, identified by the local macros `n1`, `mu1`, `sigma1`, `n2`, `mu2`, and `sigma2`, which correspond to n_1, μ_1, σ_1, n_2, μ_2, and σ_2, respectively. With these arguments, `myratio` will generate the data for the two samples, use `summarize` to compute the two medians and store the ratio of the medians in `r(ratio)`.

```
program myratio, rclass
        version 13
        args n1 mu1 sigma1 n2 mu2 sigma2
        // generate the data
        drop _all
        local N = `n1'+`n2'
        set obs `N'
        tempvar y
        generate `y' = rnormal()
        replace `y' = cond(_n<=`n1',`mu1'+`y'*`sigma1',`mu2'+`y'*`sigma2')
        // calculate the medians
        tempname m1
        summarize `y' if _n<=`n1', detail
        scalar `m1' = r(p50)
        summarize `y' if _n>`n1', detail
        // store the results
        return scalar ratio = `m1' / r(p50)
end
```

The result of running our simulation is

```
. set seed 19192
. simulate ratio=r(ratio), reps(1000) nodots: myratio 5 3 1 10 3 2
      command:  myratio 5 3 1 10 3 2
        ratio:  r(ratio)

. summarize
    Variable |        Obs        Mean    Std. Dev.       Min        Max

❑ Technical note

Stata lets us do simulations of simulations and simulations of bootstraps. Stata's `bootstrap` command (see [R] **bootstrap**) works much like `simulate`, except that it feeds the user-written program a bootstrap sample. Say that we want to evaluate the bootstrap estimator of the standard error of the median when applied to lognormally distributed data. We want to perform a simulation, resulting in a dataset of medians and bootstrap estimated standard errors.

As background, `summarize` (see [R] **summarize**) calculates summary statistics, leaving the mean in `r(mean)` and the standard deviation in `r(sd)`. `summarize` with the `detail` option also calculates summary statistics, but more of them, and leaves the median in `r(p50)`.

Thus our plan is to perform simulations by randomly drawing a dataset: we calculate the median of our random sample, we use `bootstrap` to obtain a dataset of medians calculated from bootstrap samples of our random sample, the standard deviation of those medians is our estimate of the standard error, and the summary statistics are stored in the results of `summarize`.

Our simulator is

```
program define bsse, rclass
        version 13
        drop _all
        set obs 100
        gen x = rnormal()
        tempfile bsfile
        bootstrap midp=r(p50), rep(100) saving('bsfile'): summarize x, detail
        use 'bsfile', clear
        summarize midp
        return scalar mean = r(mean)
        return scalar sd   = r(sd)
end
```

We can obtain final results, running our simulation 1,000 times, by typing

```
. set seed 48901
. simulate med=r(mean) bs_se=r(sd), reps(1000): bsse
      command:  bsse
          med:  r(mean)
        bs_se:  r(sd)
Simulations (1000)
----+--- 1 ---+--- 2 ---+--- 3 ---+--- 4 ---+--- 5
..................................................   50
..................................................   100
..................................................   150
..................................................   200

..................................................  1000
. summarize
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
         med |       1000   -.0008696    .1210451  -.3132536   .4058724
       bs_se |       1000     .126236     .029646   .0326791   .2596813
```

This is a case where the simulation dots (drawn by default, unless the `nodots` option is specified) will give us an idea of how long this simulation will take to finish as it runs. ❑

sj — Stata Journal and STB installation instructions

Description Remarks and examples Also see

Description

The *Stata Journal* (SJ) is a quarterly journal containing articles about statistics, data analysis, teaching methods, and effective use of Stata's language. The SJ publishes reviewed papers together with shorter notes and comments, regular columns, tips, book reviews, and other material of interest to researchers applying statistics in a variety of disciplines. You can read all about the *Stata Journal* at http://www.stata-journal.com.

The *Stata Journal* is a printed and electronic journal with corresponding software. If you want the journal, you must subscribe, but the software is available for no charge from our website at http://www.stata-journal.com. PDF copies of SJ articles that are older than three years are available for download for no charge at http://www.stata-journal.com/archives.html. More recent articles may be individually purchased.

The predecessor to the *Stata Journal* was the *Stata Technical Bulletin* (STB). The STB was also a printed and electronic journal with corresponding software. PDF copies of all STB journals are available for download for no charge at http://www.stata-press.com/journals/stbj.html. The STB software is available for no charge from our website at http://www.stata.com.

Below are instructions for installing the *Stata Journal* and the *Stata Technical Bulletin* software from our website.

Remarks and examples

Remarks are presented under the following headings:

Installing the Stata Journal software
Obtaining from the Internet by pointing and clicking
Obtaining from the Internet via command mode
Installing the STB software
Obtaining from the Internet by pointing and clicking
Obtaining from the Internet via command mode

Installing the Stata Journal software

Each issue of the *Stata Journal* is labeled Volume #, Number #. Volume 1 refers to the first year of publication, Volume 2 to the second, and so on. Issues are numbered 1, 2, 3, and 4 within each year. The first issue of the *Journal* was published in the fourth quarter of 2001, and that issue is numbered Volume 1, Number 1. For installation purposes, we refer to this issue as `sj1-1`.

The articles, columns, notes, and comments that make up the *Stata Journal* are assigned a letter-and-number code, called an insert tag, such as st0001, an0034, or ds0011. The letters represent a category: st is the statistics category, an is the announcements category, etc. The numbers are assigned sequentially, so st0001 is the first article in the statistics category.

Sometimes inserts are subsequently updated, either to fix bugs or to add new features. A number such as st0001_1 indicates that this article, column, note, or comment is an update to the original st0001 article. Updates are complete; that is, installing st0001_1 provides all the features of the original article and more.

The *Stata Journal* software may be obtained by pointing and clicking or by using command mode.

The sections below detail how to install an insert. In all cases, pretend that you wish to install insert st0274 from `sj12-4`.

Obtaining from the Internet by pointing and clicking

1. Select **Help > SJ and User-written Programs**.
2. Click on *Stata Journal*.
3. Click on *sj12-4*.
4. Click on *st0274*.
5. Click on *(click here to install)*.

Obtaining from the Internet via command mode

Type the following:

```
. net from http://www.stata-journal.com/software
. net cd sj12-4
. net describe st0274
. net install st0274
```

The above could be shortened to

```
. net from http://www.stata-journal.com/software/sj12-4
. net describe st0274
. net install st0274
```

Alternatively, you could type

```
. net sj 12-4
. net describe st0274
. net install st0274
```

but going about it the long way is more entertaining, at least the first time.

Installing the STB software

Each issue of the STB is numbered. STB-1 refers to the first issue (published May 1991), STB-2 refers to the second (published July 1991), and so on.

An issue of the STB consists of inserts—articles—and these are assigned letter-and-number combinations, such as sg84, dm80, sbe26.1, etc. The letters represent a category; for example, sg is the general statistics category and dm the data management category. The numbers are assigned sequentially, so sbe39 is the 39th insert in the biostatistics and epidemiology series.

Insert sbe39, it turns out, provides a method of accounting for publication bias in meta-analysis; it adds a new command called `metatrim` to Stata. If you installed sbe39, you would have that command and its help file. Insert sbe39 was published in STB-57 (September 2000). Obtaining `metatrim` simply requires going to STB-57 and getting sbe39.

Sometimes inserts were subsequently updated, either to fix bugs or to add new features. sbe39 was updated: the first update is sbe39.1 and the second is sbe39.2. You could install insert sbe39.2, and it would not matter whether you had previously installed sbe39.1. Updates are complete: installing sbe39.2 provides all the features of the original insert and more.

For computer naming purposes, insert sbe39.2 is referred to as `sbe39_2`. When referred to in normal text, however, the insert is still called sbe39.2 because that looks nicer.

Inserts are easily available from the Internet. Inserts may be obtained by pointing and clicking or by using command mode.

The sections below detail how to install an insert. In all cases, pretend that you wish to install insert sbe39.2 from STB-61.

Obtaining from the Internet by pointing and clicking

1. Select **Help > SJ and User-written Programs**.
2. Click on *STB*.
3. Click on *stb61*.
4. Click on *sbe39_2*.
5. Click on *(click here to install)*.

Obtaining from the Internet via command mode

Type the following:

```
. net from http://www.stata.com
. net cd stb
. net cd stb61
. net describe sbe39_2
. net install sbe39_2
```

The above could be shortened to

```
. net from http://www.stata.com/stb/stb61
. net describe sbe39_2
. net install sbe39_2
```

but going about it the long way is more entertaining, at least the first time.

Title

sktest — Skewness and kurtosis test for normality

Syntax | Menu | Description | Option
Remarks and examples | Stored results | Methods and formulas | Acknowledgments
References | Also see

Syntax

```
sktest varlist [if] [in] [weight] [, noadjust]
```

`aweights` and `fweights` are allowed; see **[U] 11.1.6 weight**.

Menu

Statistics > Summaries, tables, and tests > Distributional plots and tests > Skewness and kurtosis normality test

Description

For each variable in *varlist*, `sktest` presents a test for normality based on skewness and another based on kurtosis and then combines the two tests into an overall test statistic. `sktest` requires a minimum of 8 observations to make its calculations. See [MV] **mvtest normality** for multivariate tests of normality.

Option

Main

`noadjust` suppresses the empirical adjustment made by Royston (1991c) to the overall χ^2 and its significance level and presents the unaltered test as described by D'Agostino, Belanger, and D'Agostino (1990).

Remarks and examples

Also see [R] **swilk** for the Shapiro–Wilk and Shapiro–Francia tests for normality. Those tests are, in general, preferred for nonaggregated data (Gould and Rogers 1991; Gould 1992; Royston 1991c). Moreover, a normal quantile plot should be used with any test for normality; see [R] **diagnostic plots** for more information.

▷ Example 1

Using our automobile dataset, we will test whether the variables `mpg` and `trunk` are normally distributed:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. sktest mpg trunk
```

Skewness/Kurtosis tests for Normality

Variable	Obs	Pr(Skewness)	Pr(Kurtosis)	joint adj chi2(2)	joint Prob>chi2
mpg	74	0.0015	0.0804	10.95	0.0042
trunk	74	0.9115	0.0445	4.19	0.1228

We can reject the hypothesis that `mpg` is normally distributed, but we cannot reject the hypothesis that `trunk` is normally distributed, at least at the 12% level. The kurtosis for `trunk` is 2.19, as can be verified by issuing the command

```
. summarize trunk, detail
```

(*output omitted*)

and the p-value of 0.0445 shown in the table above indicates that it is significantly different from the kurtosis of a normal distribution at the 5% significance level. However, on the basis of skewness alone, we cannot reject the hypothesis that `trunk` is normally distributed.

◁

❑ Technical note

`sktest` implements the test as described by D'Agostino, Belanger, and D'Agostino (1990) but with the adjustment made by Royston (1991c). In the above example, if we had specified the `noadjust` option, the χ^2 values would have been 13.13 for `mpg` and 4.05 for `trunk`. With the adjustment, the χ^2 value might show as '`.`'. This result should be interpreted as an absurdly large number; the data are most certainly not normal.

❑

Stored results

`sktest` stores the following in `r()`:

Scalars

`r(chi2)`	χ^2
`r(P_skew)`	Pr(skewness)
`r(P_kurt)`	Pr(kurtosis)
`r(P_chi2)`	Prob > chi2

Matrices

`r(N)`	matrix of observations
`r(Utest)`	matrix of test results, one row per variable

Methods and formulas

`sktest` implements the test described by D'Agostino, Belanger, and D'Agostino (1990) with the empirical correction developed by Royston (1991c).

Let g_1 denote the coefficient of skewness and b_2 denote the coefficient of kurtosis as calculated by `summarize`, and let n denote the sample size. If weights are specified, then g_1, b_2, and n denote the weighted coefficients of skewness and kurtosis and weighted sample size, respectively. See [R] **summarize** for the formulas for skewness and kurtosis.

To perform the test of skewness, we compute

$$Y = g_1 \left\{ \frac{(n+1)(n+3)}{6(n-2)} \right\}^{1/2}$$

$$\beta_2(g_1) = \frac{3(n^2+27n-70)(n+1)(n+3)}{(n-2)(n+5)(n+7)(n+9)}$$

$$W^2 = -1 + \left[2\left\{\beta_2(g_1) - 1\right\}\right]^{1/2}$$

and

$$\alpha = \left\{2/(W^2-1)\right\}^{1/2}$$

Then the distribution of the test statistic

$$Z_1 = \frac{1}{\sqrt{\ln W}} \ln\left[Y/\alpha + \left\{ (Y/\alpha)^2 + 1 \right\}^{1/2} \right]$$

is approximately standard normal under the null hypothesis that the data are distributed normally.

To perform the test of kurtosis, we compute

$$E(b_2) = \frac{3(n-1)}{n+1}$$

$$\mathrm{var}(b_2) = \frac{24n(n-2)(n-3)}{(n+1)^2(n+3)(n+5)}$$

$$X = \left\{ b_2 - E(b_2) \right\} / \sqrt{\mathrm{var}(b_2)}$$

$$\sqrt{\beta_1(b_2)} = \frac{6(n^2-5n+2)}{(n+7)(n+9)} \left\{ \frac{6(n+3)(n+5)}{n(n-2)(n-3)} \right\}^{1/2}$$

and

$$A = 6 + \frac{8}{\sqrt{\beta_1(b_2)}} \left[\frac{2}{\sqrt{\beta_1(b_2)}} + \left\{ 1 + \frac{4}{\beta_1(b_2)} \right\}^{1/2} \right]$$

Then the distribution of the test statistic

$$Z_2 = \frac{1}{\sqrt{2/(9A)}} \left[\left(1 - \frac{2}{9A}\right) - \left\{ \frac{1-2/A}{1+X\sqrt{2/(A-4)}} \right\}^{1/3} \right]$$

is approximately standard normal under the null hypothesis that the data are distributed normally.

D'Agostino, Balanger, and D'Agostino Jr.'s omnibus test of normality uses the statistic

$$K^2 = Z_1^2 + Z_2^2$$

which has approximately a χ^2 distribution with 2 degrees of freedom under the null of normality.

Royston (1991c) proposed the following adjustment to the test of normality, which `sktest` uses by default. Let $\Phi(x)$ denote the cumulative standard normal distribution function for x, and let $\Phi^{-1}(p)$ denote the inverse cumulative standard normal function [that is, $x = \Phi^{-1}\{\Phi(x)\}$]. Define the following terms:

$$
\begin{aligned}
Z_c &= -\Phi^{-1}\left\{\exp\left(-\frac{1}{2}K^2\right)\right\} \\
Z_t &= 0.55n^{0.2} - 0.21 \\
a_1 &= (-5 + 3.46\ln n)\exp(-1.37\ln n) \\
b_1 &= 1 + (0.854 - 0.148\ln n)\exp(-0.55\ln n) \\
a_2 &= a_1 - \{2.13/(1 - 2.37\ln n)\}\, Z_t \\
\text{and} \quad b_2 &= 2.13/(1 - 2.37\ln n) + b1
\end{aligned}
$$

If $Z_c < -1$ set $Z = Z_c$; else if $Z_c < Z_t$ set $Z = a_1 + b_1 Z_c$; else set $Z = a_2 + b_2 Z_c$. Define $P = 1 - \Phi(Z)$. Then $K^2 = -2\ln P$ is approximately distributed χ^2 with 2 degrees of freedom.

The relative merits of the skewness and kurtosis test versus the Shapiro–Wilk and Shapiro–Francia tests have been a subject of debate. The interested reader is directed to the articles in the *Stata Technical Bulletin*. Our recommendation is to use the Shapiro–Francia test whenever possible, that is, whenever dealing with nonaggregated or ungrouped data (Gould and Rogers 1991; Gould 1992); see [R] **swilk**. If normality is rejected, use `sktest` to determine the source of the problem.

As both D'Agostino, Belanger, and D'Agostino (1990) and Royston (1991d) mention, researchers should also examine the normal quantile plot to determine normality rather than blindly relying on a few test statistics. See the `qnorm` command documented in [R] **diagnostic plots** for more information on normal quantile plots.

`sktest` is similar in spirit to the Jarque–Bera (1987) test of normality. The Jarque–Bera test statistic is also calculated from the sample skewness and kurtosis, though it is based on asymptotic standard errors with no corrections for sample size. In effect, `sktest` offers two adjustments for sample size, that of Royston (1991c) and that of D'Agostino, Belanger, and D'Agostino (1990).

Acknowledgments

`sktest` has benefited greatly by the comments and work of Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*. At this point, the program should be viewed as due as much to Royston as to us, except, of course, for any errors. We are also indebted to Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* for his helpful comments.

Syntax

```
slogit depvar [indepvars] [if] [in] [weight] [, options]
```

options	Description
Model	
`dimension(#)`	dimension of the model; default is `dimension(1)`
`baseoutcome(# | lbl)`	set the base outcome to # or *lbl*; default is the last outcome
`constraints(numlist)`	apply specified linear constraints
`collinear`	keep collinear variables
`nocorner`	do not generate the corner constraints
SE/Robust	
`vce(vcetype)`	*vcetype* may be `oim`, `robust`, `cluster` *clustvar*, `opg`, `bootstrap`, or `jackknife`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`nocnsreport`	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
`initialize(inityp e)`	method of initializing scale parameters; *initype* can be `constant`, `random`, or `svd`; see *Options* for details
`nonormalize`	do not normalize the numeric variables
`coeflegend`	display legend instead of statistics

indepvars may contain factor variables; see **[U] 11.4.3 Factor variables**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see **[R] bootstrap**.

`vce()` and weights are not allowed with the `svy` prefix; see **[SVY] svy**.

`fweights`, `iweights`, and `pweights` are allowed; see **[U] 11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Categorical outcomes > Stereotype logistic regression

Description

`slogit` fits maximum-likelihood stereotype logistic regression models as developed by Anderson (1984). Like multinomial logistic and ordered logistic models, stereotype logistic models are for use with categorical dependent variables. In a multinomial logistic model, the categories cannot be ranked, whereas in an ordered logistic model the categories follow a natural ranking scheme. You can view stereotype logistic models as a compromise between those two models. You can use them when you are unsure of the relevance of the ordering, as is often the case when subjects are asked to assess or judge something. You can also use them in place of multinomial logistic models when you suspect that some of the alternatives are similar. Unlike ordered logistic models, stereotype logistic models do not impose the proportional-odds assumption.

Options

Model

`dimension(#)` specifies the dimension of the model, which is the number of equations required to describe the relationship between the dependent variable and the independent variables. The maximum dimension is $\min(m-1, p)$, where m is the number of categories of the dependent variable and p is the number of independent variables in the model. The stereotype model with maximum dimension is a reparameterization of the multinomial logistic model.

`baseoutcome(#|`*lbl*`)` specifies the outcome level whose scale parameters and intercept are constrained to be zero. The base outcome may be specified as a number of a label. By default, `slogit` assumes that the outcome levels are ordered and uses the largest level of the dependent variable as the base outcome.

`constraints(`*numlist*`)`, `collinear`; see [R] **estimation options**.

By default, the linear equality constraints suggested by Anderson (1984), termed the corner constraints, are generated for you. You can add constraints to these as needed, or you can turn off the corner constraints by specifying `nocorner`. These constraints are in addition to the constraints placed on the ϕ parameters corresponding to `baseoutcome(#)`.

`nocorner` specifies that `slogit` not generate the corner constraints. If you specify `nocorner`, you must specify at least `dimension()` $\times$ `dimension()` constraints for the model to be identified.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

If specifying `vce(bootstrap)` or `vce(jackknife)`, you must also specify `baseoutcome()`.

Reporting

`level(#)`; see [R] **estimation options**.

`nocnsreport`; see [R] **estimation options**.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(*style*), cformat(%*fmt*), pformat(%*fmt*), sformat(%*fmt*), and nolstretch; see [R] **estimation options**.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] **maximize**. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

initialize(constant | random | svd) specifies how initial estimates are computed. The default, initialize(constant), is to set the scale parameters to the constant $\min(1/2, 1/d)$, where d is the dimension specified in dimension().

initialize(random) requests that uniformly distributed random numbers between 0 and 1 be used as initial values for the scale parameters. If you specify this option, you should also use set seed to ensure that you can replicate your results; see [R] **set seed**.

initialize(svd) requests that a singular value decomposition (SVD) be performed on the matrix of regression estimates from mlogit to reduce its rank to the dimension specified in dimension(). slogit uses the reduced-rank components of the SVD as initial estimates for the scale and regression coefficients. For details, see *Methods and formulas*.

nonormalize specifies that the numeric variables not be normalized. Normalization of the numeric variables improves numerical stability but consumes more memory in generating temporary double-precision variables. Variables that are of type byte are not normalized, and if initial estimates are specified using the from() option, normalization of variables is not performed. See *Methods and formulas* for more information.

The following option is available with slogit but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

Remarks are presented under the following headings:

Introduction
One-dimensional model
Higher-dimension models

Introduction

Stereotype logistic models are often used when subjects are requested to assess or judge something. For example, consider a survey in which consumers may be asked to rate the quality of a product on a scale from 1 to 5, with 1 indicating poor quality and 5 indicating excellent quality. If the categories are monotonically related to an underlying latent variable, the ordered logistic model is appropriate. However, suppose that consumers assess quality not just along one dimension, but rather weigh two or three latent factors. Stereotype logistic regression allows you to specify multiple equations to capture the effects of those latent variables, which you then parameterize in terms of observable characteristics. Unlike with multinomial logit, the number of equations you specify could be less than $m - 1$, where m is the number of categories of the dependent variable.

Stereotype logistic models are also used when categories may be indistinguishable. Suppose that a consumer must choose among A, B, C, or D. Multinomial logistic modeling assumes that the four choices are distinct in the sense that a consumer choosing one of the goods can distinguish its characteristics from the others. If goods A and B are in fact similar, consumers may be randomly picking between the two. One alternative is to combine the two categories and fit a three-category multinomial logistic model. A more flexible alternative is to use a stereotype logistic model.

In the multinomial logistic model, you estimate $m-1$ parameter vectors $\widetilde{\boldsymbol{\beta}}_k$, $k = 1, \ldots, m-1$, where m is the number of categories of the dependent variable. The stereotype logistic model is a restriction on the multinomial model in the sense that there are d parameter vectors, where d is between one and $\min(m-1, p)$, and p is the number of regressors. The relationship between the stereotype model's coefficients $\boldsymbol{\beta}_j$, $j = 1, \ldots, d$, and the multinomial model's coefficients is $\widetilde{\boldsymbol{\beta}}_k = -\sum_{j=1}^{d} \phi_{jk}\boldsymbol{\beta}_j$. The ϕs are scale parameters to be estimated along with the $\boldsymbol{\beta}_j$s.

Given a row vector of covariates $\mathbf{x}$, let $\eta_k = \theta_k - \sum_{j=1}^{d} \phi_{jk}\mathbf{x}\boldsymbol{\beta}_j$. The probability of observing outcome k is

$$\Pr(Y_i = k) = \begin{cases} \dfrac{\exp(\eta_k)}{1 + \sum_{l=1}^{m-1} \exp(\eta_l)} & k < m \\ \dfrac{1}{1 + \sum_{l=1}^{m-1} \exp(\eta_l)} & k = m \end{cases}$$

This model includes a set of θ parameters so that each equation has an unrestricted constant term. If $d = m-1$, the stereotype model is just a reparameterization of the multinomial logistic model. To identify the ϕs and the $\boldsymbol{\beta}$s, you must place at least d^2 restrictions on the parameters. By default, `slogit` uses the "corner constraints" $\phi_{jj} = 1$ and $\phi_{jk} = 0$ for $j \neq k$, $k \leq d$, and $j \leq d$.

For a discussion of the stereotype logistic model, see Lunt (2005).

One-dimensional model

▷ Example 1

We have 2 years of repair rating data on the make, price, mileage rating, and gear ratio of 104 foreign and 44 domestic automobiles (with 13 missing values on repair rating). We wish to fit a stereotype logistic model to discriminate between the levels of repair rating using mileage, price, gear ratio, and origin of the manufacturer. Here is an overview of our data:

```
. use http://www.stata-press.com/data/r13/auto2yr
(Automobile Models)
. tabulate repair
```

Repair rating	Freq.	Percent	Cum.
Poor	5	3.70	3.70
Fair	19	14.07	17.78
Average	57	42.22	60.00
Good	38	28.15	88.15
Excellent	16	11.85	100.00
Total	135	100.00	

The variable `repair` can take five values, 1, ..., 5, which represent the subjective rating of the car model's repair record as *Poor*, *Fair*, *Average*, *Good*, and *Excellent*.

We wish to fit the one-dimensional stereotype logistic model

$$\eta_k = \theta_k - \phi_k \left(\beta_1 \texttt{foreign} + \beta_2 \texttt{mpg} + \beta_3 \texttt{price} + \beta_4 \texttt{gratio}\right)$$

for $k < 5$ and $\eta_5 = 0$. To fit this model, we type

```
. slogit repair foreign mpg price gratio
Iteration 0:   log likelihood = -173.78178  (not concave)
Iteration 1:   log likelihood = -164.77316
Iteration 2:   log likelihood =  -161.7069
Iteration 3:   log likelihood = -159.76138
Iteration 4:   log likelihood = -159.34327
Iteration 5:   log likelihood = -159.25914
Iteration 6:   log likelihood = -159.25691
Iteration 7:   log likelihood = -159.25691
Stereotype logistic regression                  Number of obs   =        135
                                                Wald chi2(4)    =       9.33
Log likelihood = -159.25691                     Prob > chi2     =     0.0535
 ( 1)  [phi1_1]_cons = 1
```

```
(repair=Excellent is the base outcome)
```

The coefficient associated with the first scale parameter, ϕ_{11}, is 1, and its standard error and other statistics are missing. This is the corner constraint applied to the one-dimensional model; in the header, this constraint is listed as `[phi1_1]_cons = 1`. Also, the ϕ and θ parameters that are associated with the base outcome are identified. Keep in mind, though, that there are no coefficient estimates for `[phi1_5]_cons` or `[theta5]_cons` in the `ereturn` matrix `e(b)`. The Wald statistic is for a test of the joint significance of the regression coefficients on `foreign`, `mpg`, `price`, and `gratio`.

The one-dimensional stereotype model restricts the multinomial logistic regression coefficients $\widetilde{\boldsymbol{\beta}}_k$, $k = 1, \ldots, m-1$ to be parallel; that is, $\widetilde{\boldsymbol{\beta}}_k = -\phi_k \boldsymbol{\beta}$. As Lunt (2001) discusses, in the one-dimensional stereotype model, one linear combination $\mathbf{x}_i\boldsymbol{\beta}$ best discriminates the outcomes of the dependent variable, and the scale parameters ϕ_k measure the distance between the outcome levels and the linear predictor. If $\phi_1 \geq \phi_2 \geq \cdots \phi_{m-1} \geq \phi_m \equiv 0$, the model suggests that the subjective assessment of the dependent variable is indeed ordered. Here the maximum likelihood estimates of the ϕs are not monotonic, as would be assumed in an ordered logit model.

We test that $\phi_1 = \phi_2$ by typing

```
. test [phi1_2]_cons = [phi1_1]_cons
 ( 1)  - [phi1_1]_cons + [phi1_2]_cons = 0
           chi2(  1) =    0.55
         Prob > chi2 =    0.4576
```

Because the two parameters are not statistically different, we decide to add a constraint to force $\phi_1 = \phi_2$:

```
. constraint define 1 [phi1_2]_cons = [phi1_1]_cons
. slogit repair foreign mpg price gratio, constraint(1) nolog
Stereotype logistic regression                  Number of obs   =        135
                                                Wald chi2(4)    =      21.28
Log likelihood = -159.65769                     Prob > chi2     =     0.0003
 ( 1)  [phi1_1]_cons = 1
 ( 2)  - [phi1_1]_cons + [phi1_2]_cons = 0
```

repair	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]

/theta5	0	(base outcome)				

```
(repair=Excellent is the base outcome)
```

The ϕ estimates are now monotonically decreasing and the standard errors of the ϕs are small relative to the size of the estimates, so we conclude that, with the exception of outcomes *Poor* and *Fair*, the groups are distinguishable for the one-dimensional model and that the quality assessment can be ordered.

◁

Higher-dimension models

The stereotype logistic model is not limited to ordered categorical dependent variables; you can use it on nominal data to reduce the dimension of the regressions. Recall that a multinomial model fit to a categorical dependent variable with m levels will have $m - 1$ sets of regression coefficients. However, a model with fewer dimensions may fit the data equally well, suggesting that some of the categories are indistinguishable.

Example 2

As discussed in [R] **mlogit**, we have data on the type of health insurance available to 616 psychologically depressed subjects in the United States (Tarlov et al. 1989; Wells et al. 1989). Patients may have either an indemnity (fee-for-service) plan or a prepaid plan, such as an HMO, or may be uninsured. Demographic variables include age, gender, race, and site.

First, we fit the saturated, two-dimensional model that is equivalent to a multinomial logistic model. We choose the base outcome to be 1 (indemnity insurance) because that is the default for `mlogit`.

```
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. slogit insure age male nonwhite i.site, dim(2) base(1)
Iteration 0:   log likelihood = -534.36165
Iteration 1:   log likelihood = -534.36165
Stereotype logistic regression                  Number of obs   =        615
                                                Wald chi2(10)   =      38.17
Log likelihood = -534.36165                     Prob > chi2     =     0.0000
 ( 1)  [phi1_2]_cons = 1
 ( 2)  [phi1_3]_cons = 0
 ( 3)  [phi2_2]_cons = 0
 ( 4)  [phi2_3]_cons = 1
```

Uninsure						
age	-.0077961	.0114418	-0.68	0.496	-.0302217	.0146294
male	.4518496	.3674867	1.23	0.219	-.268411	1.17211
nonwhite	.2170589	.4256361	0.51	0.610	-.6171725	1.05129
site						
2	-1.211563	.4705127	-2.57	0.010	-2.133751	-.2893747
3	-.2078123	.3662926	-0.57	0.570	-.9257327	.510108
_cons	-1.286943	.5923219	-2.17	0.030	-2.447872	-.1260134

Apart from having opposite signs, the coefficients from the stereotype logistic model are identical to those from the multinomial logit model. Recall the definition of η_k given in the *Remarks and examples*, particularly the minus sign in front of the summation. One other difference in the output is that the constant estimates labeled `/theta` in the `slogit` output are the constants labeled `_cons` in the `mlogit` output.

Next we examine the one-dimensional model.

```

We have reduced a two-dimensional multinomial model to one dimension, reducing the number of estimated parameters by four and decreasing the model likelihood by ≈ 5.4.

`slogit` does not report a model likelihood-ratio test. The test of $d = 1$ (a one-dimensional model) versus $d = 0$ (the null model) does not have an asymptotic χ^2 distribution because the unconstrained ϕ parameters (`/phi1_3` in this example) cannot be identified if $\boldsymbol{\beta} = \mathbf{0}$. More generally, this problem precludes testing any hierarchical model of dimension d versus $d-1$. Of course, the likelihood-ratio test of a full-dimension model versus $d = 0$ is valid because the full model is just multinomial logistic, and all the ϕ parameters are fixed at 0 or 1.

◁

❑ Technical note

The stereotype model is a special case of the reduced-rank vector generalized linear model discussed by Yee and Hastie (2003). If we define $\eta_{ik} = \theta_k - \sum_{j=1}^{d} \phi_{jk}\mathbf{x}_i\boldsymbol{\beta}_j$, for $k = 1, \ldots, m-1$, we can write the expression in matrix notation as

$$\boldsymbol{\eta}_i = \boldsymbol{\theta} + \boldsymbol{\Phi}\left(\mathbf{x}_i\mathbf{B}\right)'$$

where $\boldsymbol{\Phi}$ is a $(m-1) \times d$ matrix containing the ϕ_{jk} parameters and $\mathbf{B}$ is a $p \times d$ matrix with columns containing the $\boldsymbol{\beta}_j$ parameters, $j = 1, \ldots, d$. The factorization $\boldsymbol{\Phi}\mathbf{B}'$ is not unique because $\boldsymbol{\Phi}\mathbf{B}' = \boldsymbol{\Phi}\mathbf{M}\mathbf{M}^{-1}\mathbf{B}'$ for any nonsingular $d \times d$ matrix $\mathbf{M}$. To avoid this identifiability problem, we choose $\mathbf{M} = \boldsymbol{\Phi}_1^{-1}$, where

$$\boldsymbol{\Phi} = \begin{pmatrix} \boldsymbol{\Phi}_1 \\ \boldsymbol{\Phi}_2 \end{pmatrix}$$

and $\boldsymbol{\Phi}_1$ is $d \times d$ of rank d so that

$$\boldsymbol{\Phi}\mathbf{M} = \begin{pmatrix} \mathbf{I}_d \\ \boldsymbol{\Phi}_2\boldsymbol{\Phi}_1^{-1} \end{pmatrix}$$

and $\mathbf{I}_d$ is a $d \times d$ identity matrix. Thus the corner constraints used by `slogit` are $\phi_{jj} \equiv 1$ and $\phi_{jk} \equiv 0$ for $j \neq k$ and $k, j \leq d$.

Methods and formulas

`slogit` obtains the maximum likelihood estimates for the stereotype logistic model by using `ml`; see [R] **ml**. Each set of regression estimates, one set of $\boldsymbol{\beta}_j$s for each dimension, constitutes one `ml model` equation. The $d \times (m-1)$ ϕs and the $(m-1)$ θs are `ml` ancillary parameters.

Without loss of generality, let the base outcome level be the mth level of the dependent variable. Define the row vector $\boldsymbol{\phi}_k = (\phi_{1k}, \ldots, \phi_{dk})$ for $k = 1, \ldots, m-1$, and define the $p \times d$ matrix $\mathbf{B} = (\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_d)$. For observation i, the log odds of outcome level k relative to level m, $k = 1, \ldots, m-1$ is the index

$$\begin{aligned}\ln\left\{\frac{\Pr(Y_i = k)}{\Pr(Y_i = m)}\right\} = \eta_{ik} &= \theta_k - \boldsymbol{\phi}_k (\mathbf{x}_i \mathbf{B})' \\ &= \theta_k - \boldsymbol{\phi}_k \boldsymbol{\nu}_i'\end{aligned}$$

The row vector $\boldsymbol{\nu}_i$ can be interpreted as a latent variable reducing the p-dimensional vector of covariates to a more interpretable $d < p$ dimension.

The probability of the ith observation having outcome level k is then

$$\Pr(Y_i = k) = p_{ik} = \begin{cases} \dfrac{e^{\eta_{ik}}}{1 + \sum_{j=1}^{m-1} e^{\eta_{ij}}}, \text{ if } \quad k < m \\ \dfrac{1}{1 + \sum_{j=1}^{m-1} e^{\eta_{ij}}}, \text{ if } \quad k = m \end{cases}$$

from which the log-likelihood function is computed as

$$L = \sum_{i=1}^{n} w_i \sum_{k=1}^{m} I_k(y_i) \ln(p_{ik}) \tag{1}$$

Here w_i is the weight for observation i and

$$I_k(y_i) = \begin{cases} 1, \text{ if observation } y_i \text{ has outcome } k \\ 0, \text{ otherwise} \end{cases}$$

Numeric variables are normalized for numerical stability during optimization where a new double-precision variable $\widetilde{x}_j$ is created from variable x_j, $j = 1, \ldots, p$, such that $\widetilde{x}_j = (x_j - \bar{x}_j)/s_j$. This feature is turned off if you specify `nonormalize`, or if you use the `from()` option for initial estimates. Normalization is not performed on byte variables, including the indicator variables generated by [R] **xi**. The linear equality constraints for regression parameters, if specified, must be scaled also. Assume that a constraint is applied to the regression parameter associated with variable j and dimension i, β_{ji}, and the corresponding element of the constraint matrix (see [P] **makecns**) is divided by s_j.

After convergence, the parameter estimates for variable j and dimension i—$\widetilde{\beta}_{ji}$, say—are transformed back to their original scale, $\beta_{ji} = \widetilde{\beta}_{ji}/s_j$. For the intercepts, you compute

$$\theta_k = \widetilde{\theta}_k + \sum_{i=1}^{d} \phi_{ik} \sum_{j=1}^{p} \frac{\widetilde{\beta}_{ji} \bar{x}_j}{s_j}$$

Initial values are computed using estimates obtained using `mlogit` to fit a multinomial logistic model. Let the $p \times (m-1)$ matrix $\widetilde{\mathbf{B}}$ contain the multinomial logistic regression parameters less the $m-1$ intercepts. Each ϕ is initialized with constant values $\min(1/2, 1/d)$, the `initialize(constant)` option (the default), or, with uniform random numbers, the `initialize(random)` option. Constraints are then applied to the starting values so that the structure of the $(m-1) \times d$ matrix $\mathbf{\Phi}$ is

$$\mathbf{\Phi} = \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_{m-1} \end{pmatrix} = \begin{pmatrix} \mathbf{I}_d \\ \widetilde{\mathbf{\Phi}} \end{pmatrix}$$

where $\mathbf{I}_d$ is a $d \times d$ identity matrix. Assume that only the corner constraints are used, but any constraints you place on the scale parameters are also applied to the initial scale estimates, so the structure of $\mathbf{\Phi}$ will change accordingly. The ϕ parameters are invariant to the scale of the covariates, so initial estimates in $[\,0, 1\,]$ are reasonable. The constraints guarantee that the rank of $\mathbf{\Phi}$ is at least d, so the initial estimates for the stereotype regression parameters are obtained from $\mathbf{B} = \widetilde{\mathbf{B}}\mathbf{\Phi}(\mathbf{\Phi}'\mathbf{\Phi})^{-1}$.

One other approach for initial estimates is provided: `initialize(svd)`. It starts with the `mlogit` estimates and computes $\widetilde{\mathbf{B}}' = \mathbf{UDV}'$, where $\mathbf{U}_{m-1 \times p}$ and $\mathbf{V}_{p \times p}$ are orthonormal matrices and $\mathbf{D}_{p \times p}$ is a diagonal matrix containing the singular values of $\widetilde{\mathbf{B}}$. The estimates for $\mathbf{\Phi}$ and $\mathbf{B}$ are the first d columns of $\mathbf{U}$ and $\mathbf{VD}$, respectively (Yee and Hastie 2003).

The score for regression coefficients is

$$\mathbf{u}_i(\boldsymbol{\beta}_j) = \frac{\partial L_{ik}}{\partial \boldsymbol{\beta}_j} = \mathbf{x}_i \left(\sum_{l=1}^{m-1} \phi_{jl} p_{il} - \phi_{jk} \right)$$

the score for the scale parameters is

$$u_i(\phi_{jl}) = \frac{\partial L_{ik}}{\partial \phi_{jl}} = \begin{cases} \mathbf{x}_i \boldsymbol{\beta}_j (p_{ik} - 1), & \text{if } l = k \\ \mathbf{x}_i \boldsymbol{\beta}_j p_{il}, & \text{if } l \neq k \end{cases}$$

for $l = 1, \ldots, m-1$; and the score for the intercepts is

$$u_i(\theta_l) = \frac{\partial L_{ik}}{\partial \theta_l} = \begin{cases} 1 - p_{ik}, & \text{if } l = k \\ -p_{il}, & \text{if } l \neq k \end{cases}$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`slogit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **variance estimation**.

Title

slogit postestimation — Postestimation tools for slogit

Description | Syntax for predict | Menu for predict | Options for predict
Remarks and examples | Methods and formulas | Also see

Description

The following postestimation commands are available after `slogit`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[1]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predicted probabilities, estimated index and its approximate standard error
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] {stub* | newvar | newvarlist} [if] [in] [, statistic outcome(outcome)]

predict [type] {stub* | newvarlist} [if] [in], scores
```

statistic	Description
Main	
pr	probability of one or all of the dependent variable outcomes; the default
xb	index for the kth outcome
stdp	standard error of the index for the kth outcome

If you do not specify `outcome()`, `pr` (with one new variable specified), `xb`, and `stdp` assume `outcome(#1)`.

You specify one or k new variables with `pr`, where k is the number of outcomes.

You specify one new variable with `xb` and `stdp`.

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`pr`, the default, calculates the probability of each of the categories of the dependent variable or the probability of the level specified in `outcome(`*outcome*`)`. If you specify the `outcome(`*outcome*`)` option, you need to specify only one new variable; otherwise, you must specify a new variable for each category of the dependent variable.

`xb` calculates the index, $\theta_k - \sum_{j=1}^{d} \phi_{\mathrm{jk}} \mathbf{x}_i \boldsymbol{\beta}_j$, for outcome level $k \neq$ `e(i_base)` and dimension $d =$ `e(k_dim)`. It returns a vector of zeros if $k =$ `e(i_base)`. A synonym for `xb` is `index`. If `outcome()` is not specified, `outcome(#1)` is assumed.

`stdp` calculates the standard error of the index. A synonym for `stdp` is `seindex`. If `outcome()` is not specified, `outcome(#1)` is assumed.

`outcome(`*outcome*`)` specifies the outcome for which the statistic is to be calculated. `equation()` is a synonym for `outcome()`: it does not matter which you use. `outcome()` or `equation()` can be specified using

`#1`, `#2`, ..., where `#1` means the first category of the dependent variable, `#2` means the second category, etc.;

the values of the dependent variable; or

the value labels of the dependent variable if they exist.

`scores` calculates the equation-level score variables. For models with d dimensions and m levels, $d + (d+1)(m-1)$ new variables are created. Assume $j = 1, \ldots, d$ and $k = 1, \ldots, m$ in the following.

The first d new variables will contain $\partial \ln L / \partial(\mathbf{x}\boldsymbol{\beta}_j)$.

The next $d(m-1)$ new variables will contain $\partial \ln L/\partial \phi_{jk}$.

The last $m-1$ new variables will contain $\partial \ln L/\partial \theta_k$.

Remarks and examples

Once you have fit a stereotype logistic model, you can obtain the predicted probabilities by using the `predict` command for both the estimation sample and other samples; see [U] **20 Estimation and postestimation commands** and [R] **predict**.

`predict` without arguments (or with the `pr` option) calculates the predicted probability of each outcome of the dependent variable. You must therefore give a new variable name for each of the outcomes. To compute the estimated probability of one outcome, you use the `outcome(`*outcome*`)` option where *outcome* is the level encoding the outcome. If the dependent variable's levels are labeled, the outcomes can also be identified by the label values (see [D] **label**).

The `xb` option in conjunction with `outcome(`*outcome*`)` specifies that the index be computed for the outcome encoded by level *outcome*. Its approximate standard error is computed if the `stdp` option is specified. Only one of the `pr`, `xb`, or `stdp` options can be specified with a call to `predict`.

▷ Example 1

In example 2 of [R] **slogit**, we fit the one-dimensional stereotype model, where the *depvar* is `insure` with levels $k=1$ for outcome *Indemnity*, $k=2$ for *Prepaid*, and $k=3$ for *Uninsure*. The base outcome for the model is *Indemnity*, so for $k \neq 1$ the vector of indices for the kth level is

$$\boldsymbol{\eta}_k = \theta_k - \phi_k\left(\beta_1\texttt{age} + \beta_2\texttt{male} + \beta_3\texttt{nonwhite} + \beta_4\texttt{2.site} + \beta_5\texttt{3.site}\right)$$

We estimate the group probabilities by calling `predict` after `slogit`.

```
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. slogit insure age male nonwhite i.site, dim(1) base(1) nolog
  (output omitted)
. predict pIndemnity pPrepaid pUninsure, p
. list pIndemnity pPrepaid pUninsure insure in 1/10
```

	pIndem~y	pPrepaid	pUnins~e	insure
1.	.5419344	.3754875	.0825782	Indemnity
2.	.4359638	.496328	.0677081	Prepaid
3.	.5111583	.4105107	.0783309	Indemnity
4.	.3941132	.5442234	.0616633	Prepaid
5.	.4655651	.4625064	.0719285	.
6.	.4401779	.4915102	.0683118	Prepaid
7.	.4632122	.4651931	.0715948	Prepaid
8.	.3772302	.5635696	.0592002	.
9.	.4867758	.4383018	.0749225	Uninsure
10.	.5823668	.3295802	.0880531	Prepaid

Observations 5 and 8 are not used to fit the model because `insure` is missing at these points, but `predict` estimates the probabilities for these observations since none of the independent variables is missing. You can use `if e(sample)` in the call to `predict` to use only those observations that are used to fit the model.

◁

Methods and formulas

predict

Let level b be the base outcome that is used to fit the stereotype logistic regression model of dimension d. The index for observation i and level $k \neq b$ is $\eta_{ik} = \theta_k - \sum_{j=1}^{d} \phi_{jk}\mathbf{x}_i\boldsymbol{\beta}_j$. This is the log odds of outcome encoded as level k relative to that of b so that we define $\eta_{ib} \equiv 0$. The outcome probabilities for this model are defined as $\Pr(Y_i = k) = e^{\eta_{ik}} / \sum_{j=1}^{m} e^{\eta_{ij}}$. Unlike in `mlogit`, `ologit`, and `oprobit`, the index is no longer a linear function of the parameters. The standard error of index η_{ik} is thus computed using the delta method (see also [R] **predictnl**).

The equation-level score for regression coefficients is

$$\frac{\partial \ln L_{ik}}{\partial \mathbf{x}_i\boldsymbol{\beta}_j} = \left(\sum_{l=1}^{m-1} \phi_{jl} p_{il} - \phi_{jk} \right)$$

the equation-level score for the scale parameters is

$$\frac{\partial \ln L_{ik}}{\partial \phi_{jl}} = \begin{cases} \mathbf{x}_i\boldsymbol{\beta}_j(p_{ik} - 1), & \text{if } l = k \\ \mathbf{x}_i\boldsymbol{\beta}_j p_{il}, & \text{if } l \neq k \end{cases}$$

for $l = 1, \ldots, m-1$; and the equation-level score for the intercepts is

$$\frac{\partial \ln L_{ik}}{\partial \theta_l} = \begin{cases} 1 - p_{ik}, & \text{if } l = k \\ -p_{il}, & \text{if } l \neq k \end{cases}$$

Statistics > Nonparametric analysis > Robust nonlinear smoother

Description

`smooth` applies the specified resistant, nonlinear smoother to *varname* and stores the smoothed series in *newvar*.

Option

`generate(`*newvar*`)` is required; it specifies the name of the new variable that will contain the smoothed values.

Remarks and examples

Smoothing is an exploratory data-analysis technique for making the general shape of a series apparent. In this approach (Tukey 1977), the observed data series is assumed to be the sum of an underlying process that evolves smoothly (the smooth) and of an unsystematic noise component (the rough); that is,

$$\text{data} = \text{smooth} + \text{rough}$$

Smoothed values z_t are obtained by taking medians (or some other location estimate) of each point in the original data y_t and a few of the points around it. The number of points used is called the span of the smoother. Thus a span-3 smoother produces z_t by taking the median of y_{t-1}, y_t, and y_{t+1}. `smooth` provides running median smoothers of spans 1 to 9—indicated by the digit that specifies their span. Median smoothers are resistant to isolated outliers, so they provide robustness to spikes in the data. Because the median is also a nonlinear operator, such smoothers are known as robust (or resistant) nonlinear smoothers.

`smooth` also provides the Hanning linear, nonrobust smoother, indicated by the letter `H`. Hanning is a span-3 smoother with binomial weights. Repeated applications of `H`—`HH`, `HHH`, etc.— provide binomial smoothers of span 5, 7, etc. See Cox (1997, 2004) for a graphical application of this fact.

Because one smoother usually cannot adequately separate the smooth from the rough, compound smoothers—multiple smoothers applied in sequence—are used. The smoother `35H`, for instance, then smooths the data with a span-3 median smoother, smooths the result with a span-5 median smoother, and finally smooths that result with the Hanning smoother. `smooth` allows you to specify any number of smoothers in any sequence.

Three refinements can be combined with the running median and Hanning smoothers. First, the endpoints of a smooth can be given special treatment. This is specified by the `E` operator. Second, smoothing by `3`, the span-3 running median, tends to produce flat-topped hills and valleys. The splitting operator, `S`, "splits" these repeated values, applies the endpoint operator to them, and then "rejoins" the series. Finally, it is sometimes useful to repeat an odd-span median smoother or the splitting operator until the smooth no longer changes. Following a digit or an `S` with an `R` specifies this type of repetition.

Even the best smoother may fail to separate the smooth from the rough adequately. To guard against losing any systematic components of the data series, after smoothing, the smoother can be reapplied to the resulting rough, and any recovered signal can be added back to the original smooth. The `twice` operator specifies this procedure. More generally, an arbitrary smoother can be applied to the rough (using a second `smooth` command), and the recovered signal can be added back to the smooth. This more general procedure is called reroughing (Tukey 1977).

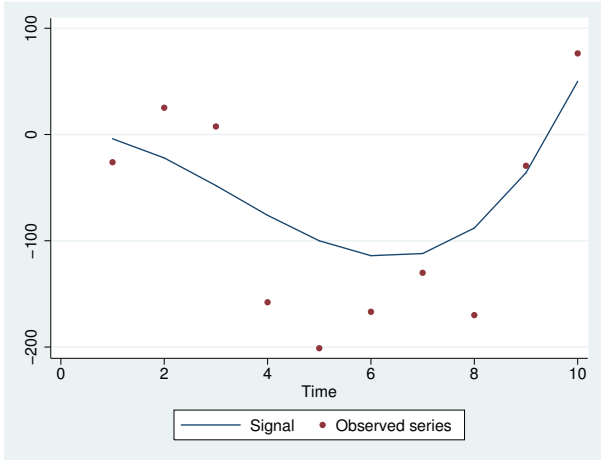
The details of each of the smoothers and operators are explained in *Methods and formulas* below.

▷ Example 1

`smooth` is designed to recover the general features of a series that has been contaminated with noise. To demonstrate this, we construct a series, add noise to it, and then `smooth` the noisy version to recover an estimate of the original data. First, we construct and display the data:

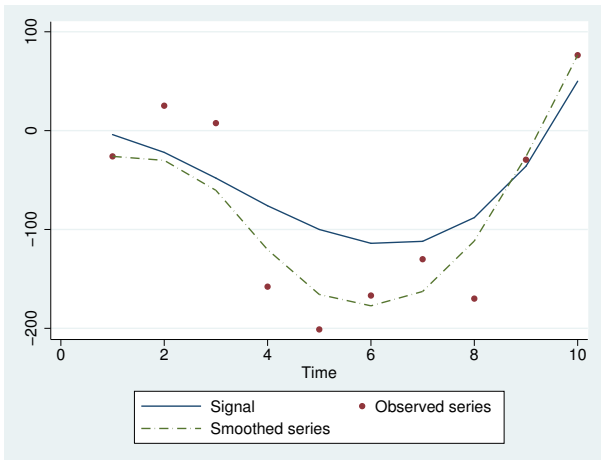
```
. drop _all
. set obs 10
. set seed 123456789
. generate time = _n
. label variable time "Time"
. generate x = _n^3 - 10*_n^2 + 5*_n
. label variable x "Signal"
. generate z = x + 50*rnormal()
. label variable z "Observed series"
```

```
. scatter x z time, c(l .) m(i o) ytitle("")
```



Now we smooth the noisy series, z, assumed to be the only data we would observe:

```
. smooth 4253eh,twice z, gen(sz)
. label variable sz "Smoothed series"
. scatter x z sz time, c(l . l) m(i o i) ytitle("") || scatter sz time,
> c(l . l) m(i o i) ytitle("") clpattern(dash_dot)
```

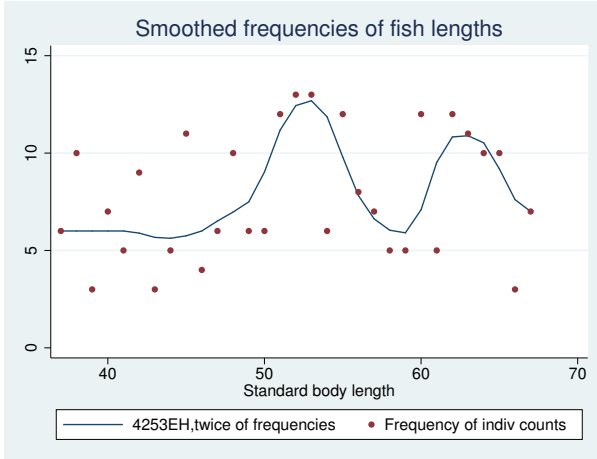


▷ Example 2

Salgado-Ugarte and Curts-García (1993) provide data on the frequencies of observed fish lengths. In this example, the series to be smoothed—the frequencies—is ordered by fish length rather than by time.

```
. use http://www.stata-press.com/data/r13/fishdata, clear
. smooth 4253eh,twice freq, gen(sfreq)
. label var sfreq "4253EH,twice of frequencies"
```

```
. scatter sfreq freq length, c(l .) m(i o)
> title("Smoothed frequencies of fish lengths") ytitle("") xlabel(#4)
```



◁

❑ Technical note

`smooth` allows missing values at the beginning and end of the series, but missing values in the middle are not allowed. Leading and trailing missing values are ignored. If you wish to ignore missing values in the middle of the series, you must `drop` the missing observations before using `smooth`. Doing so, of course, would violate `smooth`'s assumption that observations are equally spaced—each observation represents a year, a quarter, or a month (or a 1-year birth-rate category). In practice, `smooth` produces good results as long as the spaces between adjacent observations do not vary too much.

Smoothing is usually applied to time series, but any variable with a natural order can be smoothed. For example, a smoother might be applied to the birth rate recorded by the age of the mothers (birth rate for 17-year-olds, birth rate for 18-year-olds, and so on).

❑

Methods and formulas

Methods and formulas are presented under the following headings:

Running median smoothers of odd span
Running median smoothers of even span
Repeat operator
Endpoint rule
Splitting operator
Hanning smoother
Twicing

Running median smoothers of odd span

The smoother 3 defines

$$z_t = \text{median}(y_{t-1}, y_t, y_{t+1})$$

The smoother 5 defines

$$z_t = \text{median}(y_{t-2}, y_{t-1}, y_t, y_{t+1}, y_{t+2})$$

and so on. The smoother 1 defines $z_t = \text{median}(y_t)$, so it does nothing.

Endpoints are handled by using smoothers of shorter, odd span. Thus for 3,

$$\begin{aligned} z_1 &= y_1 \\ z_2 &= \text{median}(y_1, y_2, y_3) \\ &\vdots \\ z_{N-1} &= \text{median}(y_{N-2}, y_{N-1}, y_N) \\ Z_N &= y_N \end{aligned}$$

For 5,

$$\begin{aligned} z_1 &= y_1 \\ z_2 &= \text{median}(y_1, y_2, y_3) \\ z_3 &= \text{median}(y_1, y_2, y_3, y_4, y_5) \\ z_4 &= \text{median}(y_2, y_3, y_4, y_5, y_6) \\ &\vdots \\ z_{N-2} &= \text{median}(y_{N-4}, y_{N-3}, y_{N-2}, y_{N-1}, y_N) \\ z_{N-1} &= \text{median}(y_{N-2}, y_{N-1}, y_N) \\ Z_N &= y_N \end{aligned}$$

and so on.

Running median smoothers of even span

Define the median() function as returning the linearly interpolated value when given an even number of arguments. Thus the smoother 2 defines

$$z_{t+0.5} = (y_t + y_{t+1})/2$$

The smoother 4 defines $z_{t+0.5}$ as the linearly interpolated median of $(y_{t-1}, y_t, y_{t+1}, y_{t+2})$, and so on. Endpoints are always handled using smoothers of shorter, even span. Thus for 4,

$$
\begin{aligned}
z_{0.5} &= y_1 \\
z_{1.5} &= \text{median}(y_1, y_2) = (y_1 + y_2)/2 \\
z_{2.5} &= \text{median}(y_1, y_2, y_3, y_4) \\
&\vdots \\
z_{N-2.5} &= \text{median}(y_{N-4}, y_{N-3}, y_{N-2}, y_N) \\
z_{N-1.5} &= \text{median}(y_{N-2}, y_{N-1}) \\
z_{N-0.5} &= \text{median}(y_{N-1}, y_N) \\
z_{N+0.5} &= y_N
\end{aligned}
$$

As defined above, an even-span smoother increases the length of the series by 1 observation. However, the series can be recentered on the original observation numbers, and the "extra" observation can be eliminated by smoothing the series again with another even-span smoother. For instance, the smooth of `4` illustrated above could be followed by a smooth of `2` to obtain

$$
\begin{aligned}
z^*_1 &= (z_{0.5} + z_{1.5})/2 \\
z^*_2 &= (z_{1.5} + z_{2.5})/2 \\
z^*_3 &= (z_{2.5} + z_{3.5})/2 \\
&\vdots \\
z^*_{N-2} &= (z_{N-2.5} + z_{N-1.5})/2 \\
z^*_{N-1} &= (z_{N-1.5} + z_{N-0.5})/2 \\
z^*_N &= (z_{N-0.5} + z_{N+0.5})/2
\end{aligned}
$$

`smooth` keeps track of the number of even smoothers applied to the data and expands and shrinks the length of the series accordingly. To ensure that the final smooth has the same number of observations as *varname*, `smooth` requires you to specify an even number of even-span smoothers. However, the pairs of even-span smoothers need not be contiguous; for instance, `4253` and `4523` are both allowed.

Repeat operator

`R` indicates that a smoother is to be repeated until convergence, that is, until repeated applications of the smoother produce the same series. Thus `3` applies the smoother of running medians of span 3. `33` applies the smoother twice. `3R` produces the result of repeating `3` an infinite number of times. `R` should be used only with odd-span smoothers because even-span smoothers are not guaranteed to converge.

The smoother `453R2` applies a span-4 smoother, followed by a span-5 smoother, followed by repeated applications of a span-3 smoother, followed by a span-2 smoother.

Endpoint rule

The endpoint rule E modifies the values z_1 and z_N according to the following formulas:

$$z_1 = \text{median}(3z_2 - 2z_3, z_1, z_2)$$
$$z_N = \text{median}(3z_{N-2} - 2z_{N-1}, z_N, z_{N-1})$$

When the endpoint rule is not applied, endpoints are typically "copied in"; that is, $z_1 = y_1$ and $z_N = y_N$.

Splitting operator

The smoothers 3 and 3R can produce flat-topped hills and valleys. The split operator attempts to eliminate such hills and valleys by splitting the sequence, applying the endpoint rule E, rejoining the series, and then resmoothing by 3R.

The S operator may be applied only after 3, 3R, or S.

We recommend that the S operator be repeated once (SS) or until no further changes take place (SR).

Hanning smoother

H is the Hanning linear smoother:

$$z_t = (y_{t-1} + 2y_t + y_{t+1})/4$$

Endpoints are copied in: $z_1 = y_1$ and $z_N = y_N$. H should be applied only after all nonlinear smoothers.

Twicing

A smoother divides the data into a smooth and a rough:

$$\text{data} = \text{smooth} + \text{rough}$$

If the smoothing is successful, the rough should exhibit no pattern. Twicing refers to applying the smoother to the observed, calculating the rough, and then applying the smoother to the rough. The resulting "smoothed rough" is then added back to the smooth from the first step.

Acknowledgments

smooth was originally written by William Gould (1992)—at which time it was named nlsm—and was inspired by Salgado-Ugarte and Curts-García (1992). Salgado-Ugarte and Curts-García (1993) subsequently reported anomalies in nlsm's treatment of even-span median smoothers. smooth corrects these problems and incorporates other improvements but otherwise is essentially the same as originally published.

spearman

Statistics > Nonparametric analysis > Tests of hypotheses > Spearman's rank correlation

ktau

Statistics > Nonparametric analysis > Tests of hypotheses > Kendall's rank correlation

Description

`spearman` displays Spearman's rank correlation coefficients for all pairs of variables in *varlist* or, if *varlist* is not specified, for all the variables in the dataset.

`ktau` displays Kendall's rank correlation coefficients between the variables in *varlist* or, if *varlist* is not specified, for all the variables in the dataset. `ktau` is intended for use on small- and moderate-sized datasets; it requires considerable computation time for larger datasets.

Options for spearman

Main

`stats(`*spearman_list*`)` specifies the statistics to be displayed in the matrix of output. `stats(rho)` is the default. Up to three statistics may be specified; `stats(rho obs p)` would display the correlation coefficient, number of observations, and significance level. If *varlist* contains only two variables, all statistics are shown in tabular form, and `stats()`, `print()`, and `star()` have no effect unless the `matrix` option is specified.

`print(#)` specifies the significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing `spearman, print(.10)` would list only those correlation coefficients that are significant at the 10% level or lower.

`star(#)` specifies the significance level of correlation coefficients to be marked with a star. Typing `spearman, star(.05)` would "star" all correlation coefficients significant at the 5% level or lower.

`bonferroni` makes the Bonferroni adjustment to calculated significance levels. This adjustment affects printed significance levels and the `print()` and `star()` options. Thus `spearman, print(.05) bonferroni` prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

`sidak` makes the Šidák adjustment to calculated significance levels. This adjustment affects printed significance levels and the `print()` and `star()` options. Thus `spearman, print(.05) sidak` prints coefficients with Šidák-adjusted significance levels of 0.05 or less.

`pw` specifies that correlations be calculated using pairwise deletion of observations with missing values. By default, `spearman` uses casewise deletion, where observations are ignored if any of the variables in *varlist* are missing.

matrix forces spearman to display the statistics as a matrix, even if *varlist* contains only two variables. matrix is implied if more than two variables are specified.

Options for ktau

Main

stats(*ktau_list*) specifies the statistics to be displayed in the matrix of output. stats(taua) is the default. Up to six statistics may be specified; stats(taua taub score se obs p) would display the correlation coefficients τ_a, τ_b, score, standard error of score, number of observations, and significance level. If *varlist* contains only two variables, all statistics are shown in tabular form and stats(), print(), and star() have no effect unless the matrix option is specified.

print(#) specifies the significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing ktau, print(.10) would list only those correlation coefficients that are significant at the 10% level or lower.

star(#) specifies the significance level of correlation coefficients to be marked with a star. Typing ktau, star(.05) would "star" all correlation coefficients significant at the 5% level or lower.

bonferroni makes the Bonferroni adjustment to calculated significance levels. This adjustment affects printed significance levels and the print() and star() options. Thus ktau, print(.05) bonferroni prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

sidak makes the Šidák adjustment to calculated significance levels. This adjustment affects printed significance levels and the print() and star() options. Thus ktau, print(.05) sidak prints coefficients with Šidák-adjusted significance levels of 0.05 or less.

pw specifies that correlations be calculated using pairwise deletion of observations with missing values. By default, ktau uses casewise deletion, where observations are ignored if any of the variables in *varlist* are missing.

matrix forces ktau to display the statistics as a matrix, even if *varlist* contains only two variables. matrix is implied if more than two variables are specified.

Remarks and examples

▷ Example 1

We wish to calculate the correlation coefficients among marriage rate (mrgrate), divorce rate (divorce_rate), and median age (medage) in state data. We can calculate the standard Pearson correlation coefficients and significance by typing

```
.use http://www.stata-press.com/data/r13/states2
(State data)
. pwcorr mrgrate divorce_rate medage, sig
             |  mrgrate divorc~e   medage
-------------+---------------------------
     mrgrate |   1.0000
             |
             |
divorce_rate |   0.7895   1.0000
             |   0.0000
             |
      medage |   0.0011  -0.1526   1.0000
             |   0.9941   0.2900
             |
```

We can calculate Spearman's rank correlation coefficients by typing

```
. spearman mrgrate divorce_rate medage, stats(rho p)
(obs=50)
```

Key
rho
Sig. level

	mrgrate	divorc~e	medage
mrgrate	1.0000		
divorce_rate	0.6933	1.0000	
	0.0000		
medage	-0.4869	-0.2455	1.0000
	0.0003	0.0857	

The large difference in the results is caused by one observation. Nevada's marriage rate is almost 10 times higher than the state with the next-highest marriage rate. An important feature of the Spearman rank correlation coefficient is its reduced sensitivity to extreme values compared with the Pearson correlation coefficient.

We can calculate Kendall's rank correlations by typing

```
. ktau mrgrate divorce_rate medage, stats(taua taub p)
(obs=50)
```

Key
tau_a
tau_b
Sig. level

	mrgrate	divorc~e	medage
mrgrate	0.9829		
	1.0000		
divorce_rate	0.5110	0.9804	
	0.5206	1.0000	
	0.0000		
medage	-0.3486	-0.1698	0.9845
	-0.3544	-0.1728	1.0000
	0.0004	0.0828	

There are tied values for variables `mrgrate`, `divorce_rate`, and `medage`, so tied ranks are used. As a result, $\tau_a < 1$ on the diagonal (see *Methods and formulas* for the definition of τ_a).

◁

❑ Technical note

According to Conover (1999, 323), "Spearman's ρ tends to be larger than Kendall's τ in absolute value. However, as a test of significance, there is no strong reason to prefer one over the other because both will produce nearly identical results in most cases."

❑

▷ Example 2

We illustrate `spearman` and `ktau` with the auto data, which contains some missing values.

```
.use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)

. spearman mpg rep78

 Number of obs =      69
Spearman's rho =       0.3098

Test of Ho: mpg and rep78 are independent
    Prob > |t| =       0.0096
```

Because we specified two variables, `spearman` displayed the sample size, correlation, and p-value in tabular form. To obtain just the correlation coefficient displayed in matrix form, we type

```
. spearman mpg rep78, stats(rho) matrix
(obs=69)
```

	mpg	rep78
mpg	1.0000	
rep78	0.3098	1.0000

The `pw` option instructs `spearman` and `ktau` to use all nonmissing observations between a pair of variables when calculating their correlation coefficient. In the output below, some correlations are based on 74 observations, whereas others are based on 69 because 5 observations contain a missing value for `rep78`.

```
. spearman mpg price rep78, pw stats(rho obs p) star(0.01)
```

Key
rho
Number of obs
Sig. level

	mpg	price	rep78
mpg	1.0000		
	74		
price	-0.5419*	1.0000	
	74	74	
	0.0000		
rep78	0.3098*	0.1028	1.0000
	69	69	69
	0.0096	0.4008	

Finally, the bonferroni and sidak options provide adjusted significance levels:

```
. ktau mpg price rep78, stats(taua taub score se p) bonferroni
(obs=69)
```

Key
tau_a
tau_b
score
se of score
Sig. level

	mpg	price	rep78

rep78	0.2076	0.0648	0.7136
	0.2525	0.0767	1.0000
	487.0000	152.0000	1674.0000
	181.7024	182.2233	172.2161
	0.0224	1.0000	

Charles Edward Spearman (1863–1945) was a British psychologist who made contributions to correlation, factor analysis, test reliability, and psychometrics. After several years' military service, he obtained a PhD in experimental psychology at Leipzig and became a professor at University College London, where he sustained a long program of work on the interpretation of intelligence tests. Ironically, the rank correlation version bearing his name is not the formula he advocated.

Maurice George Kendall (1907–1983) was a British statistician who contributed to rank correlation, time series, multivariate analysis, among other topics, and wrote many statistical texts. Most notably, perhaps, his advanced survey of the theory of statistics went through several editions, later ones with Alan Stuart; the baton has since passed to others. Kendall was employed in turn as a government and business statistician, as a professor at the London School of Economics, as a consultant, and as director of the World Fertility Survey. He was knighted in 1974.

Stored results

`spearman` stores the following in `r()`:

Scalars

`r(N)`	number of observations (last variable pair)
`r(rho)`	ρ (last variable pair)
`r(p)`	two-sided p-value (last variable pair)

Matrices

`r(Nobs)`	number of observations
`r(Rho)`	ρ
`r(P)`	two-sided p-value

`ktau` stores the following in `r()`:

Scalars

`r(N)`	number of observations (last variable pair)
`r(tau_a)`	$\tau_{\rm a}$ (last variable pair)
`r(tau_b)`	$\tau_{\rm b}$ (last variable pair)
`r(score)`	Kendall's score (last variable pair)
`r(se_score)`	se of score (last variable pair)
`r(p)`	two-sided p-value (last variable pair)

Matrices

`r(Nobs)`	number of observations
`r(Tau_a)`	$\tau_{\rm a}$
`r(Tau_b)`	$\tau_{\rm b}$
`r(Score)`	Kendall's score
`r(Se_Score)`	standard error of score
`r(P)`	two-sided p-value

Methods and formulas

Spearman's (1904) rank correlation is calculated as Pearson's correlation computed on the ranks and average ranks (Conover 1999, 314–315). Ranks are as calculated by `egen`; see [D] **egen**. The significance is calculated using the approximation

$$p = 2 \times \texttt{ttail}(n-2, |\widehat{\rho}|\sqrt{n-2}/\sqrt{1-\widehat{\rho}^2})$$

For any two pairs of ranks (x_i, y_i) and (x_j, y_j) of one variable pair ($varname_1$, $varname_2$), $1 \leq i, j \leq n$, where n is the number of observations, define them as concordant if

$$(x_i - x_j)(y_i - y_j) > 0$$

and discordant if this product is less than zero.

Kendall's (1938; also see Kendall and Gibbons [1990] or Bland [2000], 222–225) score S is defined as $C - D$, where C (D) is the number of concordant (discordant) pairs. Let $N = n(n-1)/2$ be the total number of pairs, so $\tau_{\rm a}$ is given by

$$\tau_{\rm a} = S/N$$

and $\tau_{\rm b}$ is given by

$$\tau_{\rm b} = \frac{S}{\sqrt{N-U}\sqrt{N-V}}$$

where

$$U = \sum_{i=1}^{N_1} u_i(u_i - 1)/2$$

$$V = \sum_{j=1}^{N_2} v_j(v_j - 1)/2$$

and where N_1 is the number of sets of tied x values, u_i is the number of tied x values in the ith set, N_2 is the number of sets of tied y values, and v_j is the number of tied y values in the jth set. Under the null hypothesis of independence between *varname*$_1$ and *varname*$_2$, the variance of S is exactly (Kendall and Gibbons 1990, 66)

$$\begin{aligned}\mathrm{Var}(S) = &\frac{1}{18}\left\{n(n-1)(2n+5) - \sum_{i=1}^{N_1} u_i(u_i-1)(2u_i+5) - \sum_{j=1}^{N_2} v_j(v_j-1)(2v_j+5)\right\} \\ &+ \frac{1}{9n(n-1)(n-2)}\left\{\sum_{i=1}^{N_1} u_i(u_i-1)(u_i-2)\right\}\left\{\sum_{j=1}^{N_2} v_j(v_j-1)(v_j-2)\right\} \\ &+ \frac{1}{2n(n-1)}\left\{\sum_{i=1}^{N_1} u_i(u_i-1)\right\}\left\{\sum_{j=1}^{N_2} v_j(v_j-1)\right\}\end{aligned}$$

Using a normal approximation with a continuity correction,

$$z = \frac{|S| - 1}{\sqrt{\mathrm{Var}(S)}}$$

For the hypothesis of independence, the statistics S, τ_{a}, and τ_{b} produce equivalent tests and give the same significance.

For Kendall's τ, the normal approximation is surprisingly accurate for sample sizes as small as 8, at least for calculating p-values under the null hypothesis for continuous variables. (See Kendall and Gibbons [1990, chap. 4], who also present some tables for calculating exact p-values for $n < 10$.) For Spearman's ρ, the normal approximation requires larger samples to be valid.

Let v be the number of variables specified so that $k = v(v-1)/2$ correlation coefficients are to be estimated. If `bonferroni` is specified, the adjusted significance level is $p' = \min(1, kp)$. If `sidak` is specified, $p' = \min\left\{1, 1-(1-p)^n\right\}$. See *Methods and formulas* in [R] **oneway** for a more complete description of the logic behind these adjustments.

Early work on rank correlation is surveyed by Kruskal (1958).

Acknowledgment

The original version of `ktau` was written by Sean Becketti, a past editor of the *Stata Technical Bulletin* and author of the Stata Press book *Introduction to Time Series Using Stata*.

Graphics > Distributional graphs > Spike plot and rootogram

Description

`spikeplot` produces a frequency plot for a variable in which the frequencies are depicted as vertical lines from zero. The frequency may be a count, a fraction, or the square root of the count (Tukey's rootogram, circa 1965). The vertical lines may also originate from a baseline other than zero at the user's option.

Options

Main

`round(#)` rounds the values of *varname* to the nearest multiple of #. This action effectively specifies the bin width.

`fraction` specifies that the vertical scale be the proportion of total values (percentage) rather than the count.

`root` specifies that the vertical scale show square roots. This option may not be specified if `fraction` is specified.

Plot

spike_options affect the rendition of the plotted spikes; see [G-2] **graph twoway spike**.

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph. See [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall, By

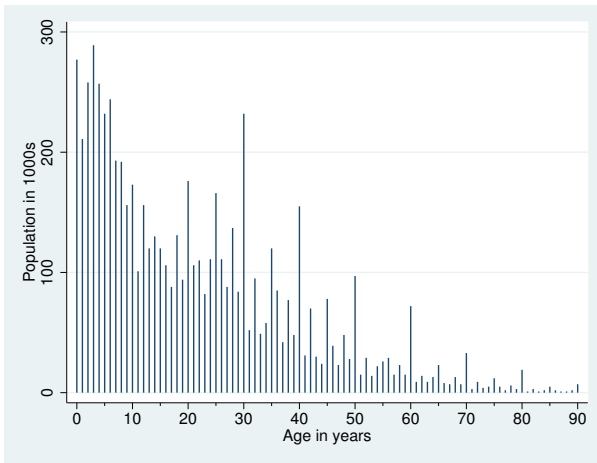
twoway_options are any of the options documented in [G-3] ***twoway_options***. These include options for titling the graph (see [G-3] ***title_options***), options for saving the graph to disk (see [G-3] ***saving_option***), and the `by()` option (see [G-3] ***by_option***).

Remarks and examples

Example 1

Cox and Brady (1997a) present an illustrative example using the age structure of the population of Ghana from the 1960 census (rounded to the nearest 1,000). The dataset has ages from 0 (less than 1 year) to 90. To view the distribution of ages, we would like to use each integer from 0 to 90 as the bins for the dataset.

```
. use http://www.stata-press.com/data/r13/ghanaage
. spikeplot age [fw=pop], ytitle("Population in 1000s") xlab(0(10)90)
> xmtick(5(10)85)
```



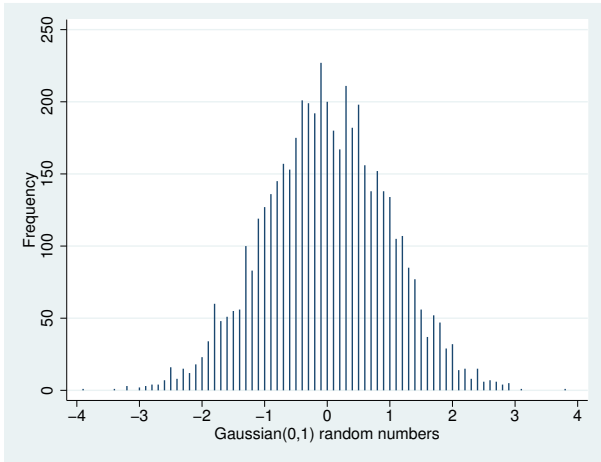
The resulting graph shows a "heaping" of ages at the multiples of 5. Also, ages ending in even numbers are more frequent than ages ending in odd numbers (except for 5). This preference for reporting ages is well known in demography and other social sciences.

Note also that we used the `ytitle()` option to override the default title of "Frequency" and that we used the `xlab()` and `xmtick()` options with *numlist*s to further customize the resulting graph. See [U] **11.1.8 numlist** for details on specifying *numlist*s.

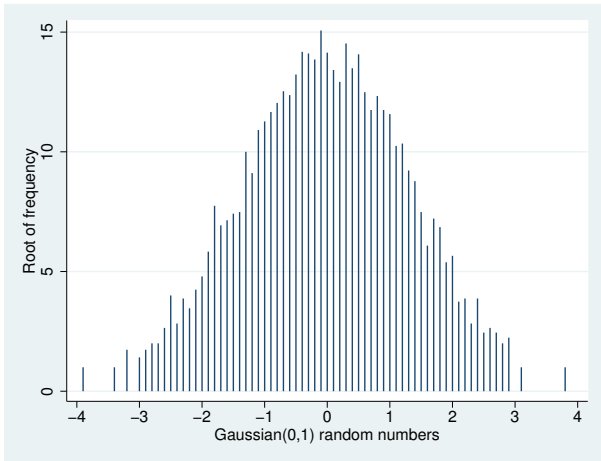
Example 2

The rootogram is a plot of the square-root transformation of the frequency counts. The square root of a normal distribution is a multiple of another normal distribution.

```
. clear
. set seed 1234567
. set obs 5000
obs was 0, now 5000
. generate normal = rnormal()
. label variable normal "Gaussian(0,1) random numbers"
. spikeplot normal, round(.10) xlab(-4(1)4)
```



```
. spikeplot normal, round(.10) xlab(-4(1)4) root
```



Interpreting a histogram in terms of normality is thus similar to interpreting the rootogram for normality.

This example also shows how the `round()` option is used to bin the values for a spike plot of a continuous variable.

▷ Example 3

`spikeplot` can also be used to produce time-series plots. *varname* should be the time variable, and weights should be specified as the values for those times. To get a plot of daily rainfalls, we type

```
. spikeplot day [w=rain] if rain, ytitle("Daily rainfall in mm")
```

The `base()` option of `graph twoway spike` may be used to set a different baseline, such as when we want to show variations relative to an average or to some other measure of level. ◁

Acknowledgments

The original version of `spikeplot` was written by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* and Anthony R. Brady of the Imperial College School of Medicine (1997a, 1997b).

Syntax

Summary of packages most recently added or updated at SSC

```
ssc new [ , saving(filename[ , replace]) type]
```

Summary of most popular packages at SSC

```
ssc hot [ , n(#) author(name)]
```

Describe a specified package at SSC

```
ssc describe {pkgname | letter} [ , saving(filename[ , replace])]
```

Install a specified package from SSC

```
ssc install pkgname [ , all replace]
```

Uninstall from your computer a previously installed package from SSC

```
ssc uninstall pkgname
```

Type a specific file stored at SSC

```
ssc type filename [ , asis]
```

Copy a specific file from SSC to your computer

```
ssc copy filename [ , plus personal replace public binary]
```

where *letter* in `ssc describe` is `a`–`z` or `_`.

Description

`ssc` works with packages (and files) from the Statistical Software Components (SSC) archive, which is often called the Boston College Archive and is provided by http://repec.org.

The SSC has become the premier Stata download site for user-written software on the web. `ssc` provides a convenient interface to the resources available there. For example, on Statalist (see http://www.statalist.org/), users will often write

> The program can be found by typing `ssc install newprogramname`.

Typing that would load everything associated with `newprogramname`, including the help files.

If you are searching for what is available, type `ssc new` and `ssc hot`, and see [R] **search**. `search` searches the SSC and other places, too. `search` provides a GUI interface from which programs can be installed, including the programs at the SSC archive.

You can uninstall particular packages by using `ssc uninstall`. For the packages that you keep, see [R] **adoupdate** for an automated way of keeping those packages up to date.

Command overview

`ssc new` summarizes the packages made available or updated recently. Output is presented in the Stata Viewer, and from there you may click to find out more about individual packages or to install them.

`ssc hot` lists the most popular packages—popular based on a moving average of the number of downloads in the past three months. By default, 10 packages are listed.

`ssc describe` *pkgname* describes, but does not install, the specified package. Use `search` to find packages; see [R] **search**. If you know the package name but do not know the exact spelling, type `ssc describe` followed by one letter, `a`–`z` or `_` (underscore), to list all the packages starting with that letter.

`ssc install` *pkgname* installs the specified package. You do not have to describe a package before installing it. (You may also install a package by using `net install`; see [R] **net**.)

`ssc uninstall` *pkgname* removes the previously installed package from your computer. It does not matter how the package was installed. (`ssc uninstall` is a synonym for `ado uninstall`, so either may be used to installed any package.)

`ssc type` *filename* types a specific file stored at SSC. `ssc cat` is a synonym for `ssc type`, which may appeal to those familiar with Unix.

`ssc copy` *filename* copies a specific file stored at SSC to your computer. By default, the file is copied to the current directory, but you can use options to change this. `ssc copy` is a rarely used alternative to `ssc install ..., all`. `ssc cp` is a synonym for `ssc copy`.

Options

Options are presented under the following headings:

Options for use with ssc new
Options for use with ssc hot
Option for use with ssc describe
Options for use with ssc install
Option for use with ssc type
Options for use with ssc copy

Options for use with ssc new

`saving(`*filename*`[ , replace ])` specifies that the "what's new" summary be saved in *filename*. If *filename* is specified without a suffix, *filename*`.smcl` is assumed. If `saving()` is not specified, `saving(ssc_results.smcl)` is assumed.

`type` specifies that the "what's new" results be displayed in the Results window rather than in the Viewer.

Options for use with ssc hot

`n(#)` specifies the number of packages to list; `n(10)` is the default. Specify `n(.)` to list all packages in order of popularity.

`author(`*name*`)` lists the 10 most popular packages by the specified author. If `n(#)` is also specified, the top # packages are listed.

Option for use with ssc describe

`saving(`*filename*[`, replace`]`)` specifies that, in addition to the descriptions being displayed on your screen, it be saved in the specified file.

If *filename* is specified without an extension, `.smcl` will be assumed, and the file will be saved as a SMCL file.

If *filename* is specified with an extension, no default extension is added. If the extension is `.log`, the file will be stored as a text file.

If `replace` is specified, *filename* is replaced if it already exists.

Options for use with ssc install

`all` specifies that any ancillary files associated with the package be downloaded to your current directory, in addition to the program and help files being installed. Ancillary files are files that do not end in `.ado` or `.sthlp` and typically contain datasets or examples of the use of the new command.

You can find out which files are associated with the package by typing `ssc describe` *pkgname* before or after installing. If you install without using the `all` option and then want the ancillary files, you can `ssc install` again.

`replace` specifies that any files being downloaded that already exist on your computer be replaced by the downloaded files. If `replace` is not specified and any files already exist, none of the files from the package is downloaded or installed.

It is better not to specify the `replace` option and wait to see if there is a problem. If there is a problem, it is usually better to uninstall the old package by using `ssc uninstall` or `ado uninstall` (which are, in fact, the same command).

Option for use with ssc type

`asis` affects how files with the suffixes `.smcl` and `.sthlp` are displayed. The default is to interpret SMCL directives the file might contain. `asis` specifies that the file be displayed in raw, uninterpreted form.

Options for use with ssc copy

`plus` specifies that the file be copied to the `PLUS` directory, the directory where user-written additions are installed. Typing `sysdir` will display the identity of the `PLUS` directory on your computer; see [P] **sysdir**.

`personal` specifies that the file be copied to your `PERSONAL` directory as reported by `sysdir`; see [P] **sysdir**.

If neither `plus` nor `personal` is specified, the default is to copy the file to the current directory.

`replace` specifies that, if the file already exists on your computer, the new file replace it.

`public` specifies that the new file be made readable by everyone; otherwise, the file will be created according to the default permission you have set with your operating system.

`binary` specifies that the file being copied is a binary file and that it is to be copied as is. The default is to assume that the file is a text file and change the end-of-line characters to those appropriate for your computer/operating system.

Remarks and examples

Users can add new features to Stata, and some users choose to make new features that they have written available to others via the web. The files that comprise a new feature are called a package, and a package usually consists of one or more ado-files and help files. The `net` command (see [R] **net**) makes it reasonably easy to install and uninstall packages regardless of where they are on the web. One site, the SSC, has become particularly popular as a repository for additions to Stata. Command `ssc` is an easier to use version of `net` designed especially for the SSC.

Many packages are available at the SSC. Packages have names, such as `oaxaca`, `estout`, or `egenmore`. At SSC, capitalization is not significant, so `Oaxaca`, `ESTOUT`, and `EGENmore` are ways of writing the same package names.

When you type

```
. ssc install oaxaca
```

the files associated with the package are downloaded and installed on your computer. Package names usually correspond to the names of the command being added to Stata, so one would expect that installing the package `oaxaca` will add command `oaxaca` to Stata on your computer, and expect that typing `help oaxaca` will provide the documentation. That is the situation here, but that is not always so. Before or after installing a package, type `ssc describe` *pkgname* to obtain the details.

▷ Example 1

`ssc new` summarizes the packages most recently made available or updated. Output is presented in the Viewer, from which you may click on a package name to find out more or install it. For example,

```
. ssc new
(contacting http://repec.org)

(Click on package name for description)

ssc describe *pkgname* describes, but does not install, the specified package. You must already know the name of the package. See [R] **search** for assistance in searching for packages. Sometimes you know the package name, but you do not know the exact spelling. Then you can type ssc describe followed by one letter, a–z or _, to list all the packages starting with that letter; even so, using search is better.

```
. ssc describe bidensity
```

package **bidensity** from http://fmwww.bc.edu/repec/bocode/b

TITLE

'BIDENSITY': module to produce and graph bivariate density estimates

DESCRIPTION/AUTHOR(S)

bidensity produces bivariate kernel density estimates and graphs the result using a twoway contourline plot, optionally overlaying a scatterplot. The default kernel is Epanechnikov; all of the kernels provided by -kdensity- are also available. Compared to Baum's -kdens2- (SSC), which was recently enhanced to produce contourline plots, -bidensity- computes the bivariate kernel densities much more efficiently through use of Mata, and provides a choice of kernel estimators. The estimated densities can be saved in a Stata dataset or accessed as Mata matrices.
KW: density estimation
KW: bivariate density
KW: contourline plots
Requires: Stata version 12.1 and moremata from SSC (q.v.)
Distribution-Date: 20130119
Author: John Luke Gallup, Portland State University
Support: email jlgallup@pdx.edu
Author: Christopher F Baum, Boston College
Support: email baum@bc.edu

INSTALLATION FILES (type **net install bidensity**)

bidensity.ado
bidensity.sthlp

(type **-ssc install bidensity-** to install)

The default setting for the `saving()` option is for the output to be saved with the `.smcl` extension. You could also save the file with a `log` extension, and in this case, the file would be stored as a text file.

```
. ssc describe b, saving(b.index)
  (output omitted)
. ssc describe bidensity, saving(bidensity.log)
  (output omitted)
```

`ssc install` *pkgname* installs the specified package. You do not have to describe a package before installing it. There are ways of installing packages other than `ssc install`, such as `net`; see [R] **net**. It does not matter how a package is installed. For instance, a package can be installed using `net` and still be uninstalled using `ssc`.

```
. ssc install bidensity
checking bidensity consistency and verifying not already installed...
installing into C:\ado\plus\...
installation complete.
```

`ssc uninstall` *pkgname* removes the specified, previously installed package from your computer. You can uninstall immediately after installation or at any time in the future. (Technical note: `ssc uninstall` is a synonym for `ado uninstall`, so it can uninstall any installed package, not just packages obtained from the SSC.)

```
. ssc uninstall bidensity
package bidensity from http://fmwww.bc.edu/repec/bocode/b
      'BIDENSITY': module to produce and graph bivariate density estimates
(package uninstalled)
```

`ssc type` *filename* types a specific file stored at the SSC. Although not shown in the syntax diagram, `ssc cat` is a synonym for `ssc type`, which may appeal to those familiar with Unix. To view only the `bidensity` help file for the `bidensity` package, you would type

```
. ssc type bidensity.sthlp
-------------------------------------------------------------------------------
help for bidensity
-------------------------------------------------------------------------------

Bivariate kernel density estimation

        bidensity varnameY varnameX [if exp] [in range] [, n(#)
                  kernel(kernelname) xwidth(#) ywidth(#) saving( name) replace
                  nograph scatter[(scatter_options)] contourline_options
                  mname(name)
  (output omitted)
```

`ssc copy` *filename* copies a specific file stored at the SSC to your computer. By default, the file is copied to the current directory, but you can use options to change this. `ssc copy` is a rarely used alternative to `ssc install ..., all`. `ssc cp` is a synonym for `ssc copy`.

```
. ssc copy bidensity.ado
(file bidensity.ado copied to current directory)
```

◁

For more details on the SSC archive and for information on how to submit your own programs to the SSC, see http://repec.org/bocode/s/sscsubmit.html.

Acknowledgments

ssc is based on archutil by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* and Christopher F. Baum of the Department of Economics at Boston College and author of the Stata Press books *An Introduction to Modern Econometrics Using Stata* and *An Introduction to Stata Programming*. The reworking of the original was done with their blessing and their participation.

Christopher Baum maintains the Stata-related files stored at the SSC archive. We thank him for this contribution to the Stata community.

Title

stem — Stem-and-leaf displays

Syntax | Menu | Description | Options
Remarks and examples | Stored results | References | Also see

Syntax

`stem` *varname* [*if*] [*in*] [, *options*]

options	Description
Main	
`prune`	do not print stems that have no leaves
`round(#)`	round data to this value; default is `round(1)`
`truncate(#)`	truncate data to this value
`digits(#)`	digits per leaf; default is `digits(1)`
`lines(#)`	number of stems per interval of $10^{\texttt{digits}}$
`width(#)`	stem width; equal to $10^{\texttt{digits}}/\texttt{width}$

`by` is allowed; see [D] **by**.

Menu

Statistics > Summaries, tables, and tests > Distributional plots and tests > Stem-and-leaf display

Description

`stem` displays stem-and-leaf plots.

Options

Main

`prune` prevents printing any stems that have no leaves.

`round(#)` rounds the data to this value and displays the plot in these units. If `round()` is not specified, noninteger data will be rounded automatically.

`truncate(#)` truncates the data to this value and displays the plot in these units.

`digits(#)` sets the number of digits per leaf. The default is 1.

`lines(#)` sets the number of stems per every data interval of $10^{\texttt{digits}}$. The value of `lines()` must divide $10^{\texttt{digits}}$; that is, if `digits(1)` is specified, then `lines()` must divide 10. If `digits(2)` is specified, then `lines()` must divide 100, etc. Only one of `lines()` or `width()` may be specified. If neither is specified, an appropriate value will be set automatically.

`width(#)` sets the width of a stem. `lines()` is equal to $10^{\texttt{digits}}/\texttt{width}$, and this option is merely an alternative way of setting `lines()`. The value of `width()` must divide $10^{\texttt{digits}}$. Only one of `width()` or `lines()` may be specified. If neither is specified, an appropriate value will be set automatically.

Note: If `lines()` or `width()` is not specified, `digits()` may be decreased in some circumstances to make a better-looking plot. If `lines()` or `width()` is set, the user-specified value of `digits()` will not be altered.

Remarks and examples

▷ Example 1

Stem-and-leaf displays are a compact way to present considerable information about a batch of data. For instance, using our automobile data (described in [U] **1.2.2 Example datasets**):

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. stem mpg
Stem-and-leaf plot for mpg (Mileage (mpg))
  1t | 22
  1f | 44444455
  1s | 66667777
  1. | 88888888899999999
  2* | 00011111
  2t | 22222333
  2f | 444455555
  2s | 666
  2. | 8889
  3* | 001
  3t |
  3f | 455
  3s |
  3. |
  4* | 1
```

The stem-and-leaf display provides a way to list our data. The expression to the left of the vertical bar is called the stem; the digits to the right are called the leaves. All the stems that begin with the same digit and the corresponding leaves, written beside each other, reconstruct an observation of the data. Thus, if we look at the four stems that begin with the digit 1 and their corresponding leaves, we see that we have two cars rated at 12 mpg, 6 cars at 14, 2 at 15, and so on. The car with the highest mileage rating in our data is rated at 41 mpg.

The above plot is a five-line plot with `lines()` equal to 5 (five lines per interval of 10) and `width()` equal to 2 (two leaves per stem).

Instead, we could specify `lines(2)`:

```
. stem mpg, lines(2)
Stem-and-leaf plot for mpg (Mileage (mpg))
  1* | 22444444
  1. | 556666777788888888899999999
  2* | 00011111222223334444
  2. | 555556668889
  3* | 0014
  3. | 55
  4* | 1
```

`stem mpg, width(5)` would produce the same plot as above.

The stem-and-leaf display provides a crude histogram of our data, one not so pretty as that produced by `histogram` (see [R] **histogram**), but one that is nonetheless informative.

◁

▷ Example 2

The miles per gallon rating fits easily into a stem-and-leaf display because, in our data, it has two digits. However, `stem` does not require two digits.

```
. stem price, lines(1) digits(3)
Stem-and-leaf plot for price (Price)
   3*** | 291,299,667,748,798,799,829,895,955,984,995
   4*** | 010,060,082,099,172,181,187,195,296,389,424,425,453,482,499, ... (26)
   5*** | 079,104,172,189,222,379,397,705,719,788,798,799,886,899
   6*** | 165,229,295,303,342,486,850
   7*** | 140,827
   8*** | 129,814
   9*** | 690,735
  10*** | 371,372
  11*** | 385,497,995
  12*** | 990
  13*** | 466,594
  14*** | 500
  15*** | 906
```

The `(26)` at the right of the second stem shows that there were 26 leaves on this stem—too many to display on one line.

We can make a more compact stem-and-leaf plot by rounding. To display `stem` in units of 100, we could type

```
. stem price, round(100)
Stem-and-leaf plot for price (Price)
price rounded to nearest multiple of 100
plot in units of 100
   3* | 33778889
   4* | 000011122223444555556677778 99

```

`price`, in our data, has four or five digits. `stem` presented the display in terms of units of 100, so a car that cost $3,291 was treated for display purposes as $3,300.

◁

❑ Technical note

Stem-and-leaf diagrams have been used in Japanese railway timetables, as shown in Tufte (1990, 46–47).

❑

Stored results

`stem` stores the following in `r()`:

Scalars
- `r(width)` width of a stem
- `r(digits)` number of digits per leaf; default is 1

Macros
- `r(round)` number specified in `round()`
- `r(truncate)` number specified in `truncate()`

Syntax

```
stepwise [ , options ] : command
```

options	Description
Model	
*pr(#)	significance level for removal from the model
*pe(#)	significance level for addition to the model
Model2	
forward	perform forward-stepwise selection
hierarchical	perform hierarchical selection
lockterm1	keep the first term
lr	perform likelihood-ratio test instead of Wald test
Reporting	
display_options	control column formats and line width

* At least one of `pr(#)` or `pe(#)` must be specified.

`by` and `xi` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are allowed if *command* allows them; see **[U] 11.1.6 weight**.

All postestimation commands behave as they would after *command* without the `stepwise` prefix; see the postestimation manual entry for *command*.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Other > Stepwise estimation

Description

`stepwise` performs stepwise estimation. Typing

```
. stepwise, pr(#): command
```

performs backward-selection estimation for *command*. The stepwise selection method is determined by the following option combinations:

options	Description
`pr(#)`	backward selection
`pr(#) hierarchical`	backward hierarchical selection
`pr(#) pe(#)`	backward stepwise
`pe(#)`	forward selection
`pe(#) hierarchical`	forward hierarchical selection
`pr(#) pe(#) forward`	forward stepwise

command defines the estimation command to be executed. The following Stata commands are supported by `stepwise`:

`clogit`	`nbreg`	`regress`
`cloglog`	`ologit`	`scobit`
`glm`	`oprobit`	`stcox`
`intreg`	`poisson`	`stcrreg`
`logistic`	`probit`	`streg`
`logit`	`qreg`	`tobit`

`stepwise` expects *command* to have the following form:

command_name [*depvar*] *term* [*term* ...] [*if*] [*in*] [*weight*] [, *command_options*]

where *term* is either *varname* or (*varlist*) (a *varlist* in parentheses indicates that this group of variables is to be included or excluded together). *depvar* is not present when *command_name* is `stcox`, `stcrreg`, or `streg`; otherwise, *depvar* is assumed to be present. For `intreg`, *depvar* is actually two dependent variable names ($depvar_1$ and $depvar_2$).

`sw` is a synonym for `stepwise`.

Options

Model

`pr(#)` specifies the significance level for removal from the model; terms with $p \geq$ `pr()` are eligible for removal.

`pe(#)` specifies the significance level for addition to the model; terms with $p <$ `pe()` are eligible for addition.

Model 2

`forward` specifies the forward-stepwise method and may be specified only when both `pr()` and `pe()` are also specified. Specifying both `pr()` and `pe()` without `forward` results in backward-stepwise selection. Specifying only `pr()` results in backward selection, and specifying only `pe()` results in forward selection.

`hierarchical` specifies hierarchical selection.

`lockterm1` specifies that the first term be included in the model and not be subjected to the selection criteria.

`lr` specifies that the test of term significance be the likelihood-ratio test. The default is the less computationally expensive Wald test; that is, the test is based on the estimated variance–covariance matrix of the estimators.

Reporting

display_options: `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Search logic for a step
Full search logic
Examples
Estimation sample considerations
Messages
Programming for stepwise

Introduction

Typing

```
. stepwise, pr(.10): regress y1 x1 x2 d1 d2 d3 x4 x5
```

performs a backward-selection search for the regression model `y1` on `x1`, `x2`, `d1`, `d2`, `d3`, `x4`, and `x5`. In this search, each explanatory variable is said to be a term. Typing

```
. stepwise, pr(.10): regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

performs a similar backward-selection search, but the variables `d1`, `d2`, and `d3` are treated as one term, as are `x4` and `x5`. That is, `d1`, `d2`, and `d3` may or may not appear in the final model, but they appear or do not appear together.

▷ Example 1

Using the automobile dataset, we fit a backward-selection model of `mpg`:

```
. use http://www.stata-press.com/data/r13/auto
. generate weight2 = weight*weight
. stepwise, pr(.2): regress mpg weight weight2 displ gear turn headroom foreign
> price
                     begin with full model
p = 0.7116 >= 0.2000  removing headroom
p = 0.6138 >= 0.2000  removing displacement
p = 0.3278 >= 0.2000  removing price
```

Source	SS	df	MS		
Model	1736.31455	5	347.262911	Number of obs	= 74
Residual	707.144906	68	10.3991898	F(5, 68)	= 33.39
				Prob > F	= 0.0000
Total	2443.45946	73	33.4720474	R-squared	= 0.7106
				Adj R-squared	= 0.6893
				Root MSE	= 3.2248

mpg	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
weight	-.0158002	.0039169	-4.03	0.000	-.0236162	-.0079842
weight2	1.77e-06	6.20e-07	2.86	0.006	5.37e-07	3.01e-06
foreign	-3.615107	1.260844	-2.87	0.006	-6.131082	-1.099131
gear_ratio	2.011674	1.468831	1.37	0.175	-.9193321	4.94268
turn	-.3087038	.1763099	-1.75	0.084	-.6605248	.0431172
_cons	59.02133	9.3903	6.29	0.000	40.28327	77.75938

This estimation treated each variable as its own term and thus considered each one separately. The engine displacement and gear ratio should really be considered together:

```
. stepwise, pr(.2): regress mpg weight weight2 (displ gear) turn headroom
> foreign price
                    begin with full model
p = 0.7116 >= 0.2000  removing headroom
p = 0.3944 >= 0.2000  removing displacement gear_ratio
p = 0.2798 >= 0.2000  removing price
```

Search logic for a step

Before discussing the complete search logic, consider the logic for a step—the first step—in detail. The other steps follow the same logic. If you type

```
. stepwise, pr(.20): regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

the logic is

1. Fit the model `y` on `x1 x2 d1 d2 d3 x4 x5`.
2. Consider dropping `x1`.
3. Consider dropping `x2`.
4. Consider dropping `d1 d2 d3`.
5. Consider dropping `x4 x5`.
6. Find the term above that is least significant. If its significance level is ≥ 0.20, remove that term.

If you type

```
. stepwise, pr(.20) hierarchical: regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

the logic would be different because the `hierarchical` option states that the terms are ordered. The initial logic would become

1. Fit the model `y` on `x1 x2 d1 d2 d3 x4 x5`.
2. Consider dropping `x4 x5`—the last term.
3. If the significance of this last term is ≥ 0.20, remove the term.

The process would then stop or continue. It would stop if `x4 x5` were not dropped, and otherwise, `stepwise` would continue to consider the significance of the next-to-last term, `d1 d2 d3`.

Specifying `pe()` rather than `pr()` switches to forward estimation. If you type

```
. stepwise, pe(.20): regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

stepwise performs forward-selection search. The logic for the first step is

1. Fit a model of y on nothing (meaning a constant).
2. Consider adding x1.
3. Consider adding x2.
4. Consider adding d1 d2 d3.
5. Consider adding x4 x5.
6. Find the term above that is most significant. If its significance level is < 0.20, add that term.

As with backward estimation, if you specify hierarchical,

```
. stepwise, pe(.20) hierarchical: regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

the search for the most significant term is restricted to the next term:

1. Fit a model of y on nothing (meaning a constant).
2. Consider adding x1—the first term.
3. If the significance is < 0.20, add the term.

If x1 were added, stepwise would next consider x2; otherwise, the search process would stop.

stepwise can also use a stepwise selection logic that alternates between adding and removing terms. The full logic for all the possibilities is given below.

Full search logic

Option	Logic
`pr()` (backward selection)	Fit the full model on all explanatory variables. While the least-significant term is "insignificant", remove it and reestimate.
`pr() hierarchical` (backward hierarchical selection)	Fit full model on all explanatory variables. While the last term is "insignificant", remove it and reestimate.
`pr() pe()` (backward stepwise)	Fit full model on all explanatory variables. If the least-significant term is "insignificant", remove it and reestimate; otherwise, stop. Do that again: if the least-significant term is "insignificant", remove it and reestimate; otherwise, stop. Repeatedly, if the most-significant excluded term is "significant", add it and reestimate; if the least-significant included term is "insignificant", remove it and reestimate; until neither is possible.
`pe()` (forward selection)	Fit "empty" model. While the most-significant excluded term is "significant", add it and reestimate.
`pe() hierarchical` (forward hierarchical selection)	Fit "empty" model. While the next term is "significant", add it and reestimate.
`pr() pe() forward` (forward stepwise)	Fit "empty" model. If the most-significant excluded term is "significant", add it and reestimate; otherwise, stop. Do that again: if the most-significant excluded term is "significant", add it and reestimate; otherwise, stop. Repeatedly, if the least-significant included term is "insignificant", remove it and reestimate; if the most-significant excluded term is "significant", add it and reestimate; until neither is possible.

Examples

The following two statements are equivalent; both include solely single-variable terms:

```
. stepwise, pr(.2): regress price mpg weight displ
. stepwise, pr(.2): regress price (mpg) (weight) (displ)
```

The following two statements are equivalent; the last term in each is `r1`, ..., `r4`:

```
. stepwise, pr(.2) hierarchical: regress price mpg weight displ (r1-r4)
. stepwise, pr(.2) hierarchical: regress price (mpg) (weight) (displ) (r1-r4)
```

To group variables `weight` and `displ` into one term, type

```
. stepwise, pr(.2) hierarchical: regress price mpg (weight displ) (r1-r4)
```

`stepwise` can be used with commands other than `regress`; for instance,

```
. stepwise, pr(.2): logit outcome (sex weight) treated1 treated2
. stepwise, pr(.2): logistic outcome (sex weight) treated1 treated2
```

Either statement would fit the same model because `logistic` and `logit` both perform logistic regression; they differ only in how they report results; see [R] **logit** and [R] **logistic**.

We use the `lockterm1` option to force the first term to be included in the model. To keep `treated1` and `treated2` in the model no matter what, we type

```
. stepwise, pr(.2) lockterm1: logistic outcome (treated1 treated2) ...
```

After `stepwise` estimation, we can type `stepwise` without arguments to redisplay results,

```
. stepwise
(output from logistic appears)
```

or type the underlying estimation command:

```
. logistic
(output from logistic appears)
```

At estimation time, we can specify options unique to the command being stepped:

```
. stepwise, pr(.2): logit outcome (sex weight) treated1 treated2, or
```

`or` is `logit`'s option to report odds ratios rather than coefficients; see [R] **logit**.

Estimation sample considerations

Whether you use backward or forward estimation, `stepwise` forms an estimation sample by taking observations with nonmissing values of all the variables specified (except for $depvar_1$ and $depvar_2$ for `intreg`). The estimation sample is held constant throughout the stepping. Thus if you type

```
. stepwise, pr(.2) hierarchical: regress amount sk edul sval
```

and variable `sval` is missing in half the data, that half of the data will not be used in the reported model, even if `sval` is not included in the final model.

The function `e(sample)` identifies the sample that was used. `e(sample)` contains 1 for observations used and 0 otherwise. For instance, if you type

```
. stepwise, pr(.2) pe(.10): logistic outcome x1 x2 (x3 x4) (x5 x6 x7)
```

and the final model is outcome on x1, x5, x6, and x7, you could re-create the final regression by typing

```
. logistic outcome x1 x5 x6 x7 if e(sample)
```

You could obtain summary statistics within the estimation sample of the independent variables by typing

```
. summarize x1 x5 x6 x7 if e(sample)
```

If you fit another model, e(sample) will automatically be redefined. Typing

```
. stepwise, lock pr(.2): logistic outcome (x1 x2) (x3 x4) (x5 x6 x7)
```

would automatically drop e(sample) and re-create it.

Messages

note: _____ dropped because of collinearity

Each term is checked for collinearity, and variables within the term are dropped if collinearity is found. For instance, say that you type

```
. stepwise, pr(.2): regress y x1 x2 (r1-r4) (x3 x4)
```

and assume that variables r1 through r4 are mutually exclusive and exhaustive dummy variables—perhaps r1, ..., r4 indicate in which of four regions the subject resides. One of the r1, ..., r4 variables will be automatically dropped to identify the model.

This message should cause you no concern.

Error message: between-term collinearity, variable _____

After removing any within-term collinearity, if stepwise still finds collinearity between terms, it refuses to continue. For instance, assume that you type

```
. stepwise, pr(.2): regress y1 x1 x2 (d1-d8) (r1-r4)
```

Assume that r1, ..., r4 identify in which of four regions the subject resides, and that d1, ..., d8 identify the same sort of information, but more finely. r1, say, amounts to d1 and d2; r2 to d3, d4, and d5; r3 to d6 and d7; and r4 to d8. You can estimate the d* variables or the r* variables, but not both.

It is your responsibility to specify noncollinear terms.

note: _____ dropped because of estimability
note: _____ obs. dropped because of estimability

You probably received this message in fitting a logistic or probit model. Regardless of estimation strategy, stepwise checks that the full model can be fit. The indicated variable had a 0 or infinite standard error.

For logistic, logit, and probit, this message is typically caused by one-way causation. Assume that you type

```
. stepwise, pr(.2): logistic outcome (x1 x2 x3) d1
```

and assume that variable d1 is an indicator (dummy) variable. Further assume that whenever d1 = 1, outcome = 1 in the data. Then the coefficient on d1 is infinite. One (conservative) solution to this problem is to drop the d1 variable and the d1==1 observations. The underlying estimation commands probit, logit, and logistic report the details of the difficulty and solution; stepwise simply accumulates such problems and reports the above summary messages. Thus if you see this message, you could type

```
. logistic outcome x1 x2 x3 d1
```

to see the details. Although you should think carefully about such situations, Stata's solution of dropping the offending variables and observations is, in general, appropriate.

Programming for stepwise

stepwise requires that *command_name* follow standard Stata syntax and allow the if qualifier; see [U] **11 Language syntax**. Furthermore, *command_name* must have sw or swml as a program property; see [P] **program properties**. If *command_name* has swml as a property, *command_name* must store the log-likelihood value in e(ll) and model degrees of freedom in e(df_m).

Stored results

stepwise stores whatever is stored by the underlying estimation command.

Also, stepwise stores stepwise in e(stepwise).

Methods and formulas

Some statisticians do not recommend stepwise procedures; see Sribney (1998) for a summary.

Syntax Description Option Remarks and examples References Also see

Syntax

List results from general commands, stored in r()

```
return list [, all]
```

List results from estimation commands, stored in e()

```
ereturn list [, all]
```

List results from parsing commands, stored in s()

```
sreturn list
```

Description

Results of calculations are stored by many Stata commands so that they can be easily accessed and substituted into later commands.

`return list` lists results stored in `r()`.

`ereturn list` lists results stored in `e()`.

`sreturn list` lists results stored in `s()`.

This entry discusses using stored results. Programmers wishing to store results should see [P] **return** and [P] **ereturn**.

Option

`all` is for use with `return list` and `ereturn list`. `all` specifies that hidden and historical stored results be listed along with the usual stored results. This option is seldom used. See *Using hidden and historical stored results* and *Programming hidden and historical stored results* under *Remarks and examples* of [P] **return** for more information. These sections are written in terms of `return list`, but everything said there applies equally to `ereturn list`.

`all` is not allowed with `sreturn list` because `s()` does not allow hidden or historical results.

Remarks and examples

Stata commands are classified as being

r-class	general commands that store results in `r()`
e-class	estimation commands that store results in `e()`
s-class	parsing commands that store results in `s()`
n-class	commands that do not store in `r()`, `e()`, or `s()`

There is also a c-class, `c()`, containing the values of system parameters and settings, along with certain constants, such as the value of pi; see [P] **creturn**. A program, however, cannot be c-class.

You can look at the *Stored results* section of the manual entry of a command to determine whether it is r-, e-, s-, or n-class, but it is easy enough to guess.

Commands producing statistical results are either r-class or e-class. They are e-class if they present estimation results and r-class otherwise. s-class is a class used by programmers and is primarily used in subprograms performing parsing. n-class commands explicitly state where the result is to go. For instance, `generate` and `replace` are n-class because their syntax is `generate` *varname* `=` ... and `replace` *varname* `=` ....

After executing a command, you can type `return list`, `ereturn list`, or `sreturn list` to see what has been stored.

▷ Example 1

```
. use http://www.stata-press.com/data/r13/auto4
(1978 Automobile Data)
. describe

              r(width) =  28
                  r(k) =  6
                  r(N) =  74
Historical; used before Stata 12, may exist only under version control
scalars:
           r(widthmax) =  1048576
              r(k_max) =  2048
              r(N_max) =  2147483646
```

`r(widthmax)`, `r(k_max)`, and `r(N_max)` are historical stored results. They are no longer relevant because Stata dynamically adjusts memory beginning with Stata 12.

◁

❑ Technical note

In the above example, we stated that `r(widthmax)` and `r(N_max)` are no longer relevant. In fact, they are not useful. Stata no longer has a fixed memory size, so the methods used to calculate `r(widthmax)` and `r(N_max)` are no longer appropriate.

❑

▷ Example 2

You can use stored results in expressions.

```
. summarize mpg
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
         mpg |         74     21.2973    5.785503        12         41

. return list
scalars:
                  r(N) =  74
              r(sum_w) =  74
               r(mean) =  21.2972972972973
                r(Var) =  33.47204738985561
                 r(sd) =  5.785503209735141
               r(min) =  12
               r(max) =  41
               r(sum) =  1576

. generate double mpgstd = (mpg-r(mean))/r(sd)
. summarize mpgstd
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
      mpgstd |         74   -1.64e-16           1  -1.606999    3.40553
```

Be careful to use results stored in `r()` soon because they will be replaced the next time you execute another r-class command. For instance, although `r(mean)` was 21.3 (approximately) after `summarize mpg`, it is −1.64e–16 now because you just ran `summarize` with `mpgstd`.

◁

▷ Example 3

e-class is really no different from r-class, except for where results are stored and that, when an estimation command stores results, it tends to store a lot of them:

```
. regress mpg weight length
  (output omitted)
. ereturn list
scalars:
                  e(N) =  74
               e(df_m) =  2
               e(df_r) =  71
                  e(F) =  69.34050004300228
                e(r2) =  .6613903979336324
              e(rmse) =  3.413681741382589
               e(mss) =  1616.08062422659
               e(rss) =  827.3788352328694
              e(r2_a) =  .6518520992838756
                e(ll) =  -194.3267619410807
              e(ll_0) =  -234.3943376482347
              e(rank) =  3
```

```
macros:
            e(cmdline) : "regress mpg weight length"
              e(title) : "Linear regression"
          e(marginsok) : "XB default"
                e(vce) : "ols"
            e(depvar) : "mpg"
                e(cmd) : "regress"
         e(properties) : "b V"
            e(predict) : "regres_p"
              e(model) : "ols"
          e(estat_cmd) : "regress_estat"
matrices:
                  e(b) :  1 x 3
                  e(V) :  3 x 3
functions:
             e(sample)
```

These e-class results will stick around until you run another estimation command. Typing `return list` and `ereturn list` is the easy way to find out what a command stores.

◁

Both r- and e-class results come in four flavors: scalars, macros, matrices, and functions. (s-class results come in only one flavor—macros—and as earlier noted, s-class is used solely by programmers, so ignore it.)

Scalars are just that—numbers by any other name. You can subsequently refer to `r(mean)` or `e(rmse)` in numeric expressions and obtain the result to full precision.

Macros are strings. For instance, `e(depvar)` contains "`mpg`". You can refer to it, too, in subsequent expressions, but really that would be of most use to programmers, who will refer to it using constructs like `"‘e(depvar)’"`. In any case, macros are macros, and you obtain their contents just as you would a local macro, by enclosing their name in single quotes. The name here is the full name, so `‘e(depvar)’` is `mpg`.

Matrices are matrices, and all estimation commands store `e(b)` and `e(V)` containing the coefficient vector and variance–covariance matrix of the estimates (VCE).

Functions are stored by e-class commands only, and the only function existing is `e(sample)`. `e(sample)` evaluates to 1 (meaning true) if the observation was used in the previous estimation and to 0 (meaning false) otherwise.

❑ Technical note

Say that some command set `r(scalar)` and `r(macro)`, the first being stored as a scalar and the second as a macro. In theory, in subsequent use you are supposed to refer to `r(scalar)` and `‘r(macro)’`. In fact, however, you can refer to either one with or without quotes, so you could refer to `‘r(scalar)’` and `r(macro)`. Programmers sometimes do this.

When you refer to `r(scalar)`, you are referring to the full double-precision stored result. Think of `r(scalar)` without quotes as a function returning the value of the stored result `scalar`. When you refer to `r(scalar)` in quotes, Stata understands `‘r(scalar)’` to mean "substitute the printed result of evaluating `r(scalar)`". Pretend that `r(scalar)` equals the number 23. Then `‘r(scalar)’` is `23`, the character `2` followed by `3`.

Referring to `r(scalar)` in quotes is sometimes useful. Say that you want to use the immediate command `ci` with `r(scalar)`. The immediate command `ci` requires its arguments to be numbers—numeric literals in programmer's jargon—and it will not take an expression. Thus you could not type

‘ci r(scalar) ...’. You could, however, type ‘ci ‘r(scalar)’ ...’ because ‘r(scalar)’ is just a numeric literal.

For r(macro), you are supposed to refer to it in quotes: ‘r(macro)’. If, however, you omit the quotes in an expression context, Stata evaluates the macro and then pretends that it is the result of function-returning-string. There are side effects of this, the most important being that the result is trimmed to 80 characters.

Referring to r(macro) without quotes is never a good idea; the feature was included merely for completeness.

You can even refer to r(matrix) in quotes (assume that r(matrix) is a matrix). ‘r(matrix)’ does not result in the matrix being substituted; it returns the word matrix. Programmers sometimes find that useful.

Title

suest — Seemingly unrelated estimation

Syntax | Menu | Description | Options
Remarks and examples | Stored results | Methods and formulas | Acknowledgment
References | Also see

Syntax

`suest` *namelist* [`,` *options*]

where *namelist* is a list of one or more names under which estimation results were stored via `estimates store`; see [R] **estimates store**. Wildcards may be used. `*` and `_all` refer to all stored results. A period (`.`) may be used to refer to the last estimation results, even if they have not (yet) been stored.

options	Description
SE/Robust	
`svy`	survey data estimation
`vce(`*vcetype*`)`	*vcetype* may be `robust` or `cluster` *clustvar*
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`dir`	display a table describing the models
`eform(`*string*`)`	report exponentiated coefficients and label as *string*
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
`coeflegend`	display legend instead of statistics

`coeflegend` does not appear in the dialog box.

Menu

Statistics > Postestimation > Tests > Seemingly unrelated estimation

Description

`suest` is a postestimation command; see **[U] 20 Estimation and postestimation commands**.

`suest` combines the estimation results—parameter estimates and associated (co)variance matrices—stored under *namelist* into one parameter vector and *simultaneous* (co)variance matrix of the sandwich/robust type. This (co)variance matrix is appropriate even if the estimates were obtained on the same or on overlapping data.

Typical applications of `suest` are tests for intramodel and cross-model hypotheses using `test` or `testnl`, for example, a generalized Hausman specification test. `lincom` and `nlcom` may be used after `suest` to estimate linear combinations and nonlinear functions of coefficients. `suest` may also be used to adjust a standard VCE for clustering or survey design effects.

Different estimators are allowed, for example, a `regress` model and a `probit` model; the only requirement is that `predict` produce equation-level scores with the `score` option after an estimation command. The models may be estimated on different samples, due either to explicit `if` or `in` selection or to missing values. If weights are applied, the same weights (type and values) should be applied to all models in *namelist*. The estimators should be estimated without `vce(robust)` or `vce(cluster` *clustvar*`)` options. `suest` returns the robust VCE, allows the `vce(cluster` *clustvar*`)` option, and automatically works with results from the `svy` prefix command (only for `vce(linearized)`). See example 7 in [SVY] **svy postestimation** for an example using `suest` with `svy: ologit`.

Because `suest` posts its results like a proper estimation command, its results can be stored via `estimates store`. Moreover, like other estimation commands, `suest` typed without arguments replays the results.

Options

SE/Robust

`svy` specifies that estimation results should be modified to reflect the survey design effects according to the `svyset` specifications, see [SVY] **svyset**.

The `svy` option is implied when `suest` encounters survey estimation results from the `svy` prefix; see [SVY] **svy**. Poststratification is allowed only with survey estimation results from the `svy` prefix.

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`) and that allow for intragroup correlation (`cluster` *clustvar*; see [R] ***vce_option***.

The `vce()` option may not be combined with the `svy` option or estimation results from the `svy` prefix.

Reporting

`level(#)` specifies the confidence level, as a percentage, for confidence intervals of the coefficients; see [R] **level**.

`dir` displays a table describing the models in *namelist* just like `estimates dir` *namelist*.

`eform(`*string*`)` displays the coefficient table in exponentiated form: for each coefficient, $\exp(b)$ rather than b is displayed, and standard errors and confidence intervals are transformed. *string* is the table header that will be displayed above the transformed coefficients and must be 11 characters or fewer, for example, `eform("Odds ratio")`.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

The following option is available with `suest` but is not shown in the dialog box:

`coeflegend`; see [R] **estimation options**.

Remarks and examples

Remarks are presented under the following headings:

Using suest
Remarks on regress
Testing the assumption of the independence of irrelevant alternatives
Testing proportionality
Testing cross-model hypotheses

Using suest

If you plan to use suest, you must take precautions when fitting the original models. These restrictions are relaxed when using svy commands; see [SVY] **svy postestimation**.

1. suest works with estimation commands that allow predict to generate equation-level score variables when supplied with the score (or scores) option. For example, equation-level score variables are generated after running mlogit by typing

```
. predict sc*, scores
```

2. Estimation should take place *without* the vce(robust) or vce(cluster *clustvar*) option. suest always computes the robust estimator of the (co)variance, and suest has a vce(cluster *clustvar*) option.

   The within-model covariance matrices computed by suest are identical to those obtained by specifying a vce(robust) or vce(cluster *clustvar*) option during estimation. suest, however, also estimates the between-model covariances of parameter estimates.

3. Finally, the estimation results to be combined should be stored by estimates store; see [R] **estimates store**.

After estimating and storing a series of estimation results, you are ready to combine the estimation results with suest,

. suest *name1* [*name2* ...] [, vce(cluster *clustvar*)]

and you can subsequently use postestimation commands, such as test, to test hypotheses. Here an important issue is how suest assigns names to the equations. If you specify one model *name*, the original equation names are left unchanged; otherwise, suest constructs new equation names. The coefficients of a single-equation model (such as logit and poisson) that was estimate stored under name *X* are collected under equation *X*. With a multiequation model stored under name *X*, suest prefixes *X*_ to an original equation name *eq*, forming equation name, *X*_*eq*.

❑ Technical note

Earlier we said that standard errors from suest are identical to those obtained by specifying the vce(robust) option with each command individually. Thus if you fit a logistic model using logit with the vce(robust) option, you will get the same standard errors when you type

```
. suest .
```

directly after logit using the same data without the vce(robust) option.

This is not true for multiple estimation results when the estimation samples are not all the same. The standard errors from suest will be slightly smaller than those from individual model fits using the vce(robust) option because suest uses a larger number of observations to estimate the simultaneous (co)variance matrix.

❑

❑ Technical note

In rare circumstances, suest may have to truncate equation names to 32 characters. When equation names are not unique because of truncation, suest numbers the equations within models, using equations named *X*_#.

❑

Remarks on regress

`regress` (see [R] **regress**) does not include its ancillary parameter, the residual variance, in its coefficient vector and (co)variance matrix. Moreover, while the `score` option is allowed with `predict` after `regress`, a score variable is generated for the mean but not for the variance parameter. `suest` contains special code that assigns the equation name `mean` to the coefficients for the mean, adds the equation `lnvar` for the log variance, and computes the appropriate two score variables itself.

Testing the assumption of the independence of irrelevant alternatives

The multinomial logit model and the closely related conditional logit model satisfy a probabilistic version of the assumption of the independence of irrelevant alternatives (IIA), implying that the ratio of the probabilities for two alternatives does not depend on what other alternatives are available. Hausman and McFadden (1984) proposed a test for this assumption that is implemented in the `hausman` command. The standard Hausman test has several limitations. First, the test statistic may be undefined because the estimated VCE does not satisfy the required asymptotic properties of the test. Second, the classic Hausman test applies only to the test of the equality of two estimators. Third, the test requires access to a fully efficient estimator; such an estimator may not be available, for example, if you are analyzing complex survey data. Using `suest` can overcome these three limitations.

▷ Example 1

In our first example, we follow the analysis of the type of health insurance reported in [R] **mlogit** and demonstrate the `hausman` command with the `suest`/`test` combination. We fit the full multinomial logit model for all three alternatives and two restricted multinomial models in which one alternative is excluded. After fitting each of these models, we store the results by using the `store` subcommand of `estimates`. `title()` simply documents the models.

Comparing the coefficients between models does not suggest substantial differences. We can formally test that coefficients are the same for the full model `m1` and the restricted models `m2` and `m3` by using the `hausman` command. `hausman` expects the models to be specified in the order "always consistent" first and "efficient under H_0" second.

```
. hausman m2 m1, alleqs constant
```

                                 see suest for a generalized test
```

According to the test of `m1` against `m2`, we cannot reject the hypothesis that the coefficients of `m1` and `m2` are the same. The second Hausman test is not well defined—something that happens fairly often. The problem is due to the estimator of the variance `V(b-B)` as `V(b)-V(B)`, which is a feasible estimator only asymptotically. Here it simply is not a proper variance matrix, and the Hausman test becomes undefined.

`suest m1 m2` estimates the simultaneous (co)variance of the coefficients of models `m1` and `m2`. Although `suest` is technically a postestimation command, it acts like an estimation command in that it stores the simultaneous coefficients in `e(b)` and the full (co)variance matrix in `e(V)`. We could have used the `estat vce` command to display the full (co)variance matrix to show that the cross-model covariances were indeed estimated. Typically, we would not have a direct interest in `e(V)`.

```
. suest m1 m2, noomitted
Simultaneous results for m1, m2
                                                  Number of obs   =        615

suest created equation names by combining the name under which we stored the results using estimates store with the original equation names. Thus, in the simultaneous estimation result, equation Prepaid originating in model m1 is named m1_Prepaid. According to the McFadden–Hausman specification of a test for IIA, the coefficients of the equations m1_PrePaid and m2_PrePaid should be equal. This equality can be tested easily with the test command. The cons option specifies that the intercept _cons be included in the test.

```
. test [m1_Prepaid = m2_Prepaid], cons
 ( 1)  [m1_Prepaid]age - [m2_Prepaid]age = 0
 ( 2)  [m1_Prepaid]male - [m2_Prepaid]male = 0
 ( 3)  [m1_Prepaid]_cons - [m2_Prepaid]_cons = 0
           chi2(  3) =    0.89
         Prob > chi2 =    0.8266
```

The Hausman test via suest is comparable to that computed by hausman, but they use different estimators of the variance of the difference of the estimates. The hausman command estimates $V(b-B)$ by $V(b)-V(B)$, whereas suest estimates $V(b-B)$ by $V(b)-\mathrm{cov}(b,B)-\mathrm{cov}(B,b)+V(B)$. One advantage of the second estimator is that it is always admissible, so the resulting test is always well defined. This quality is illustrated in the Hausman-type test of IIA comparing models m1 and m3.

```

Although the classic Hausman test computed by hausman is not defined here, the suest-based test is just fine. We cannot reject the equality of the common coefficients across m1 and m3.

A second advantage of the suest approach is that we can estimate the (co)variance matrix of the multivariate normal distribution of the estimators of the three models m1, m2, and m3 and test that the common coefficients are equal.

Again we do not find evidence against the correct specification of the multinomial logit for type of insurance. The classic Hausman test assumes that one of the estimators (named `B` in `hausman`) is efficient, that is, it has minimal (asymptotic) variance. This assumption ensures that $V(b) - V(B)$ is an admissible, viable estimator for $V(b - B)$. The assumption that we have an efficient estimator is a restrictive one. It is violated, for instance, if our data are clustered. We want to adjust for clustering via a `vce(cluster` *clustvar*`)` option by requesting the cluster-adjusted sandwich estimator of variance. Consequently, in such a case, `hausman` cannot be used. This problem does not exist with the `suest` version of the Hausman test. To illustrate this feature, we suppose that the data are clustered by city—we constructed an imaginary variable `cityid` for this illustration. If we plan to apply `suest`, we would not specify the `vce(cluster` *clustvar*`)` option at the time of estimation.

suest has a vce(cluster *clustvar*) option. Thus we do not need to refit the models; we can call suest and test right away.

suest provides some descriptive information about the clustering on cityid. Like any other estimation command, suest informs us that the standard errors are adjusted for clustering. The Hausman-type test obtained from the test command uses a simultaneous (co)variance of m1 and m2 appropriately adjusted for clustering. In this example, we still do not have reason to conclude that the multinomial logit model in this application is misspecified, that is, that IIA is violated.

◁

The multinomial logistic regression model is a special case of the conditional logistic regression model; see [R] **clogit**. Like the multinomial logistic regression model, the conditional logistic regression model also makes the IIA assumption. Consider an example, introduced in [R] **asclogit**, in which the demand for American, Japanese, and European cars is modeled in terms of the number of local dealers of the respective brands and of some individual attributes incorporated in interaction with the nationality of cars. We want to perform a Hausman-type test for IIA comparing the decision between all nationalities with the decision between non-American cars. The following code fragment demonstrates how to conduct a Hausman test for IIA via suest in this case.

```
. clogit choice japan europe maleJap maleEur incJap incEur dealer, group(id)
. estimates store allcars
. clogit choice japan maleJap incJap dealer if car!=1 , group(id)
. estimates store foreign
```

```
. suest allcars foreign
. test [allcars_choice=foreign_choice], common
```

Testing proportionality

The applications of suest that we have discussed so far concern Hausman-type tests for misspecification. To test such a hypothesis, we compared two estimators that have the same probability limit if the hypothesis holds true, but otherwise have different limits. We may also want to compare the coefficients of models (estimators) for other substantive reasons. Although we most often want to test whether coefficients differ between models or estimators, we may occasionally want to test other constraints (see Hausman and Ruud [1987]).

▷ Example 2

In this example, using simulated labor market data for siblings, we consider two dependent variables, income (inc) and whether a person was promoted in the last year (promo). We apply familiar economic arguments regarding human capital, according to which employees have a higher income and a higher probability of being promoted, by having more human capital. Human capital is acquired through formal education (edu) and on-the-job training experience (exp). We study whether income and promotion are "two sides of the same coin", that is, whether they reflect a common latent variable, "human capital". Accordingly, we want to compare the effects of different aspects of human capital on different outcome variables.

We estimate fairly simple labor market equations. The income model is estimated with regress, and the estimation results are stored under the name Inc.

```
. use http://www.stata-press.com/data/r13/income
. regress inc edu exp male
```

Source	SS	df	MS	Number of obs =	277

. est store Inc
```

Being sibling data, the observations are clustered on family of origin, famid. In the estimation of the regression parameters, we did not specify a vce(cluster famid) option to adjust standard errors for clustering on family (famid). Thus the standard errors reported by regress are potentially flawed. This problem will, however, be corrected by specifying a vce(cluster *clustvar*) option with suest.

Next we estimate the promotion equation with probit and again store the results under an appropriate name.

```
. probit promo edu exp male, nolog
Probit regression                                 Number of obs   =        277

```
. est store Promo
```

The coefficients in the income and promotion equations definitely seem to be different. However, because the scales of the two variables are different, we would not expect the coefficients to be equal. The correct hypothesis here is that the proportionality of the coefficients of the two models, apart from the constant, are equal. This formulation would still reflect that the relative effects of the different aspects of human capital do not differ between the dependent variables. We can obtain a nonlinear Wald test for the hypothesis of proportionality by using the `testnl` command on the combined estimation results of the two estimators. Thus we first have to form the combined estimation results. At this point, we specify the `vce(cluster famid)` option to adjust for the clustering of observations on `famid`.

```
. suest Inc Promo, vce(cluster famid)
Simultaneous results for Inc, Promo
                                                  Number of obs   =        277
                                  (Std. Err. adjusted for 135 clusters in famid)
```

	Coef.	Robust Std. Err.	z	P>|z|	[95% Conf.	Interval]

The standard errors reported by `suest` are identical to those reported by the respective estimation commands when invoked with the `vce(cluster famid)` option. We are now ready to test for proportionality:

$$H_0 : \frac{\beta_{\text{edu}}^{\text{Income}}}{\beta_{\text{edu}}^{\text{Promotion}}} = \frac{\beta_{\text{exp}}^{\text{Income}}}{\beta_{\text{exp}}^{\text{Promotion}}} = \frac{\beta_{\text{male}}^{\text{Income}}}{\beta_{\text{male}}^{\text{Promotion}}}$$

It is straightforward to translate this into syntax suitable for `testnl`, recalling that the coefficient of variable v in equation eq is denoted by `[`eq`]`v.

```
. testnl [Inc_mean]edu/[Promo_promo]edu =
>        [Inc_mean]exp/[Promo_promo]exp =
>        [Inc_mean]male/[Promo_promo]male

  (1)  [Inc_mean]edu/[Promo_promo]edu = [Inc_mean]exp/[Promo_promo]exp
  (2)  [Inc_mean]edu/[Promo_promo]edu = [Inc_mean]male/[Promo_promo]male

           chi2(2) =        0.61
         Prob > chi2 =        0.7385
```

From the evidence, we fail to reject the hypotheses that the coefficients of the income and promotion equations are proportional. Thus it is not unreasonable to assume that income and promotion can be explained by the same latent variable, "labor market success".

A disadvantage of the nonlinear Wald test is that it is not invariant with respect to representation: a Wald test for a mathematically equivalent formulation of the nonlinear constraint usually leads to a different test result. An equivalent formulation of the proportionality hypothesis is

$$H_0\colon \quad \beta_{\text{edu}}^{\text{Income}}\beta_{\text{exp}}^{\text{Promotion}} = \beta_{\text{edu}}^{\text{Promotion}}\beta_{\text{exp}}^{\text{Income}} \quad \text{and}$$
$$\beta_{\text{edu}}^{\text{Income}}\beta_{\text{male}}^{\text{Promotion}} = \beta_{\text{edu}}^{\text{Promotion}}\beta_{\text{male}}^{\text{Income}}$$

This formulation is "more linear" in the coefficients. The asymptotic χ^2 distribution of the nonlinear Wald statistic can be expected to be more accurate for this representation.

```
. testnl ([Inc_mean]edu*[Promo_promo]exp = [Inc_mean]exp*[Promo_promo]edu)
>        ([Inc_mean]edu*[Promo_promo]male = [Inc_mean]male*[Promo_promo]edu)

  (1)  [Inc_mean]edu*[Promo_promo]exp = [Inc_mean]exp*[Promo_promo]edu
  (2)  [Inc_mean]edu*[Promo_promo]male = [Inc_mean]male*[Promo_promo]edu

           chi2(2) =        0.46
         Prob > chi2 =        0.7936
```

Here the two representations lead to similar test statistics and p-values. As before, we fail to reject the hypothesis of proportionality of the coefficients of the two models.

◁

Testing cross-model hypotheses

▷ Example 3

In this example, we demonstrate how some cross-model hypotheses can be tested using the facilities already available in most estimation commands. This demonstration will explain the intricate relationship between the cluster adjustment of the robust estimator of variance and the `suest` command. It will also be made clear that a new facility is required to perform more general cross-model testing.

We want to test whether the effect of x_1 on the binary variable y_1 is the same as the effect of x_2 on the binary y_2; see Clogg, Petkova, and Haritou (1995). In this setting, x_1 may equal x_2, and y_1 may equal y_2. We assume that logistic regression models can be used to model the responses, and for simplicity, we ignore further predictor variables in these models. If the two logit models are fit on independent samples so that the estimators are (stochastically) independent, a Wald test for `_b[x1] = _b[x2]` rejects the null hypothesis if

$$\frac{\widehat{b}(x_1) - \widehat{b}(x_2)}{\left[\widehat{\sigma}^2\left\{\widehat{b}(x_1)\right\} + \widehat{\sigma}^2\left\{\widehat{b}(x_2)\right\}\right]^{1/2}}$$

is larger than the appropriate χ^2_1 threshold. If the models are fit on the *same* sample (or on dependent samples), so that the estimators are stochastically dependent, the above test that ignores the covariance between the estimators is not appropriate.

It is instructive to see how this problem can be tackled by "stacking" data. In the stacked format, we doubled the number of observations. The dependent variable is y_1 in the first half of the data and is y_2 in the second half of the data. The predictor variable z_1 is set to x_1 in the first half of the expanded data and to 0 in the rest. Similarly, z_2 is 0 in the first half and x_2 in the second half. The following diagram illustrates the transformation, in the terminology of the `reshape` command, from wide to long format.

$$\left(\begin{array}{ccccc} \texttt{id} & y_1 & y_2 & x_1 & x_2 \\ \hline 1 & y_{11} & y_{21} & x_{11} & x_{21} \\ 2 & y_{12} & y_{22} & x_{12} & x_{22} \\ 3 & y_{13} & y_{23} & x_{13} & x_{23} \end{array}\right) \Longrightarrow \left(\begin{array}{ccccc} \texttt{id} & y & z_1 & z_2 & \texttt{model} \\ \hline 1 & y_{11} & x_{11} & 0 & 1 \\ 2 & y_{12} & x_{12} & 0 & 1 \\ 3 & y_{13} & x_{13} & 0 & 1 \\ 1 & y_{21} & 0 & x_{21} & 2 \\ 2 & y_{22} & 0 & x_{22} & 2 \\ 3 & y_{23} & 0 & x_{23} & 2 \end{array}\right)$$

The observations in the long format data organization are *clustered* on the original subjects and are identified with the identifier `id`. The clustering on `id` has to be accounted for when fitting a simultaneous model. The simplest way to deal with clustering is to use the cluster adjustment of the robust or sandwich estimator; see [P] **_robust**. The data manipulation can be accomplished easily with the `stack` command; see [D] **stack**. Subsequently, we fit a simultaneous logit model and perform a Wald test for the hypothesis that the coefficients of `z1` and `z2` are the same. A full setup to obtain the cross-model Wald test could then be as follows:

```
. generate zero = 0          // a variable that is always 0
. generate one  = 1          // a variable that is always 1
. generate two  = 2          // a variable that is always 2
. stack  id y1 x1 zero one   id y2 zero x2 two, into(id y z1 z2 model)
. generate model2 = (model==2)
. logit y model2 z1 z2, vce(cluster id)
. test _b[z1] = _b[z2]
```

The coefficient of `z1` represents the effect of `x1` on `y1`, and similarly, `z2` for the effect of `x2` on `y2`. The variable `model2` is a dummy for the "second model", which is included to allow the intercept in the second model to differ from that in the first model. The estimates of the coefficient of `z1` and its standard error in the combined model are the same as the estimates of the coefficient of `z1` and its standard error if we fit the model on the unstacked data.

```
. logit y1 x1, vce(robust)
```

The vce(cluster *clustvar*) option specified with the logit command for the stacked data ensures that the covariances of _b[z1] and _b[z2] are indeed estimated. This estimation ensures that the Wald test for the equality of the coefficients is correct. If we had not specified the vce(cluster *clustvar*) option, the (co)variance matrix of the coefficients would have been block-diagonal; that is, the covariances of _b[z1] and _b[z2] would have been 0. Then test would have effectively used the invalid formula for the Wald test for two independent samples.

In this example, the two logit models were fit on the same data. The same setup would apply, without modification, when the two logit models were fit on overlapping data that resulted, for instance, if the y or x variables were missing in some observations.

The suest command allows us to obtain the above Wald test more efficiently by avoiding the data manipulation, obviating the need to fit a model with twice the number of coefficients. The test statistic produced by the above code fragment is *identical* to that obtained via suest on the original (unstacked) data:

```
. logit y1 x1
. estimates store M1
. logit y2 x2
. estimates store M2
. suest M1 M2
. test [M1]x1=[M2]x2
```

The stacking method can be applied not only to the testing of cross-model hypotheses for logit models but also to any estimation command that supports the vce(cluster *clustvar*) option. The stacking approach clearly generalizes to stacking more than two logit or other models, testing more general linear hypotheses, and testing nonlinear cross-model hypotheses (see [R] **testnl**). In all of these cases, suest would yield identical statistical results but at smaller costs in terms of data management, computer storage, and computer time.

Is suest nothing but a convenience command? No, there are two disadvantages to the stacking method, both of which are resolved via suest. First, if the models include ancillary parameters (in a regression model, the residual variance; in an ordinal response model, the cutpoints; and in lognormal survival-time regression, the time scale parameter), these parameters are constrained to be equal between the stacked models. In suest, this constraint is relaxed. Second, the stacking method does not generalize to compare different statistical models, such as a probit model and a regression model. As demonstrated in the previous section, suest can deal with this situation.

◁

Stored results

suest stores the following in e():

Scalars

e(N)	number of observations
e(N_clust)	number of clusters
e(rank)	rank of e(V)

Macros

e(cmd)	suest
e(eqnames#)	original names of equations of model #
e(names)	list of model names
e(wtype)	weight type
e(wexp)	weight expression
e(clustvar)	name of cluster variable
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(properties)	b V

Matrices

e(b)	stacked coefficient vector of the models
e(V)	variance–covariance matrix of the estimators

Functions

e(sample)	marks estimation sample

Methods and formulas

The estimation of the simultaneous (co)variance of a series of k estimators is a nonstandard application of the sandwich estimator, as implemented by the command [P] **_robust**. You may want to read this manual entry before reading further.

The starting point is that we have fit k different models on the *same* data—partially overlapping or nonoverlapping data are special cases. We want to derive the *simultaneous* distribution of these k estimators, for instance, to test a cross-estimator hypothesis H_0. As in the framework of Hausman testing, H_0 will often be of the form that different estimators have the same probability limit under some hypothesis, while the estimators have different limits if the hypothesis is violated.

We consider (vector) estimators $\widehat{\boldsymbol{\beta}}_i$ to be defined as "the" solution of the estimation equations $\mathbf{G}_i$,

$$\mathbf{G}_i(\mathbf{b}_i) = \sum_j w_{ij}\mathbf{u}_{ij}(\mathbf{b}_i) = \mathbf{0}, \qquad i = 1, \ldots, k$$

We refer to the $\mathbf{u}_{ij}$ as the "scores". Specifying some weights $w_{ij} = 0$ trivially accommodates for partially overlapping or even disjointed data. Under "suitable regularity conditions" (see White [1982; 1996] for details), the $\widehat{\boldsymbol{\beta}}_i$ are asymptotically normally distributed, with the variance estimated consistently by the sandwich estimator

$$V_i = \mathrm{Var}(\widehat{\boldsymbol{\beta}}_i) = \mathbf{D}_i^{-1} \sum_j w_{ij}\mathbf{u}_{ij}\mathbf{u}_{ij}' \mathbf{D}_i^{-1}$$

where $\mathbf{D}_i$ is the Jacobian of $\mathbf{G}_i$ evaluated at $\widehat{\boldsymbol{\beta}}_i$. In the context of maximum likelihood estimation, $\mathbf{D}_i$ can be estimated consistently by (minus) the Hessian of the log likelihood or by the Fisher information matrix. If the model is also well specified, the sandwiched term $(\sum_j w_{ij}\mathbf{u}_{ij}\mathbf{u}_{ij}')$ converges in probability to $\mathbf{D}_i$, so V_i may be consistently estimated by $\mathbf{D}_i^{-1}$.

To derive the simultaneous distribution of the estimators, we consider the "stacked" estimation equation,

$$\mathbf{G}(\widehat{\boldsymbol{\beta}}) = \left\{ \mathbf{G}_1(\widehat{\boldsymbol{\beta}}_1)' \quad \mathbf{G}_1(\widehat{\boldsymbol{\beta}}_2)' \quad \dots \quad \mathbf{G}_k(\widehat{\boldsymbol{\beta}}_k)' \right\}' = \mathbf{0}$$

Under "suitable regularity conditions" (see White [1996] for details), $\widehat{\boldsymbol{\beta}}$ is asymptotically *jointly* normally distributed. The Jacobian and scores of the simultaneous equation are easily expressed in the Jacobian and scores of the separate equations. The Jacobian of $\mathbf{G}$,

$$\mathbf{D}(\widehat{\boldsymbol{\beta}}) = \left. \frac{d\mathbf{G}(\boldsymbol{\beta})}{d\boldsymbol{\beta}} \right|_{\boldsymbol{\beta}=\widehat{\boldsymbol{\beta}}}$$

is block diagonal with blocks $\mathbf{D}_1, \dots, \mathbf{D}_k$. The inverse of $\mathbf{D}(\widehat{\boldsymbol{\beta}})$ is again block diagonal, with the inverses of $\mathbf{D}_i$ on the diagonal. The scores $\mathbf{u}$ of $\mathbf{G}$ are simply obtained as the *concatenated* scores of the separate equations:

$$\mathbf{u}_j = (\mathbf{u}_{1j}' \quad \mathbf{u}_{2j}' \quad \dots \quad \mathbf{u}_{kj}')'$$

Out-of-sample (that is, where $w_{ij} = 0$) values of the score variables are defined as 0 (thus we drop the i subscript from the common weight variable). The sandwich estimator for the asymptotic variance of $\widehat{\boldsymbol{\beta}}$ reads

$$V = \mathrm{Var}(\widehat{\boldsymbol{\beta}}) = \mathbf{D}(\widehat{\boldsymbol{\beta}})^{-1} \left(\sum_j w_j \mathbf{u}_j \mathbf{u}_j' \right) \mathbf{D}(\widehat{\boldsymbol{\beta}})^{-1}$$

Taking a "partitioned" look at this expression, we see that $V(\widehat{\boldsymbol{\beta}}_i)$ is estimated by

$$\mathbf{D}_i^{-1} \left(\sum_j w_j \mathbf{u}_{ij} \mathbf{u}_{ij}' \right) \mathbf{D}_i^{-1}$$

which is, yet again, the familiar sandwich estimator for $\widehat{\boldsymbol{\beta}}_i$ based on the separate estimation equation $\mathbf{G}_i$. Thus considering several estimators simultaneously in this way does not affect the estimators of the asymptotic variances of these estimators. However, as a bonus of stacking, we obtained a sandwich-type estimate of the *covariance* V_{ih} of estimators $\widehat{\boldsymbol{\beta}}_i$ and $\widehat{\boldsymbol{\beta}}_h$,

$$V_{ih} = \mathrm{Cov}(\widehat{\boldsymbol{\beta}}_i, \widehat{\boldsymbol{\beta}}_h) = \mathbf{D}_i^{-1} \left(\sum_j w_j \mathbf{u}_{ij} \mathbf{u}_{ih}' \right) \mathbf{D}_h^{-1}$$

which is also obtained by White (1982).

This estimator for the covariance of estimators is an application of the cluster modification of the sandwich estimator proposed by Rogers (1993). Consider the stacked data format as discussed in the logit example, and assume that Stata would be able to estimate a "stacked model" in which different models apply to different observations, for example, a probit model for the first half, a regression model for the second half, and a one-to-one cluster relation between the first and second half. If there are no common parameters to both models, the score statistics of parameters for the stacked models are zero in the half of the data in which they do not occur. In Rogers' method, we have to sum the score statistics over the observations within a cluster. This step boils down to concatenating the score statistics at the level of the cluster.

We compare the sandwich estimator of the (co)variance V_{12} of two estimators with the estimator of variance $\widetilde{V}_{12}$ applied in the classic Hausman test. Hausman (1978) showed that if $\widehat{\boldsymbol{\beta}}_1$ is consistent under H_0 and $\widehat{\boldsymbol{\beta}}_2$ is efficient under H_0, then asymptotically

$$\mathrm{Cov}(\widehat{\boldsymbol{\beta}}_1, \widehat{\boldsymbol{\beta}}_2) = \mathrm{Var}(\widehat{\boldsymbol{\beta}}_2)$$

and so $\mathrm{var}(\widehat{\boldsymbol{\beta}}_1 - \widehat{\boldsymbol{\beta}}_2)$ is consistently estimated by $V_1 - V_2$.

Acknowledgment

`suest` was written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands. This research is supported by grant PGS 50-370 by The Netherlands Organization for Scientific Research.

An earlier version of `suest` was published in the *Stata Technical Bulletin* (1999). The current version of `suest` is not backward compatible with the STB version because of the introduction of new ways to manage estimation results via the `estimates` command.

Syntax

```
summarize [varlist] [if] [in] [weight] [, options]
```

options	Description
Main	
`detail`	display additional statistics
`meanonly`	suppress the display; calculate only the mean; programmer's option
`format`	use variable's display format
`separator(#)`	draw separator line after every # variables; default is `separator(5)`
display_options	control spacing, line width, and base and empty cells

varlist may contain factor variables; see [U] **11.4.3 Factor variables**.

varlist may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

`by`, `rolling`, and `statsby` are allowed; see [U] **11.1.10 Prefix commands**.

`aweights`, `fweights`, and `iweights` are allowed. However, `iweights` may not be used with the `detail` option; see [U] **11.1.6 weight**.

Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Summary statistics

Description

`summarize` calculates and displays a variety of univariate summary statistics. If no *varlist* is specified, summary statistics are calculated for all the variables in the dataset.

Also see [R] **ci** for calculating the standard error and confidence intervals of the mean.

Options

Main

`detail` produces additional statistics, including skewness, kurtosis, the four smallest and largest values, and various percentiles.

`meanonly`, which is allowed only when `detail` is not specified, suppresses the display of results and calculation of the variance. Ado-file writers will find this useful for fast calls.

format requests that the summary statistics be displayed using the display formats associated with the variables rather than the default g display format; see [U] 12.5 Formats: Controlling how data are displayed.

separator(#) specifies how often to insert separation lines into the output. The default is separator(5), meaning that a line is drawn after every five variables. separator(10) would draw a line after every 10 variables. separator(0) suppresses the separation line.

display_options: vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), and fvwrapon(*style*); see [R] estimation options.

Remarks and examples

summarize can produce two different sets of summary statistics. Without the detail option, the number of nonmissing observations, the mean and standard deviation, and the minimum and maximum values are presented. With detail, the same information is presented along with the variance, skewness, and kurtosis; the four smallest and four largest values; and the 1st, 5th, 10th, 25th, 50th (median), 75th, 90th, 95th, and 99th percentiles.

▷ Example 1: summarize with the separator() option

We have data containing information on various automobiles, among which is the variable mpg, the mileage rating. We can obtain a quick summary of the mpg variable by typing

```
. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
. summarize mpg
```

Variable	Obs	Mean	Std. Dev.	Min	Max
mpg	74	21.2973	5.785503	12	41

We see that we have 74 observations. The mean of mpg is 21.3 miles per gallon, and the standard deviation is 5.79. The minimum is 12, and the maximum is 41.

If we had not specified the variable (or variables) we wanted to summarize, we would have obtained summary statistics on all the variables in the dataset:

```
. summarize, separator(4)
```

Variable	Obs	Mean	Std. Dev.	Min	Max
make	0				
price	74	6165.257	2949.496	3291	15906
mpg	74	21.2973	5.785503	12	41
rep78	69	3.405797	.9899323	1	5
headroom	74	2.993243	.8459948	1.5	5
trunk	74	13.75676	4.277404	5	23
weight	74	3019.459	777.1936	1760	4840
length	74	187.9324	22.26634	142	233
turn	74	39.64865	4.399354	31	51
displacement	74	197.2973	91.83722	79	425
gear_ratio	74	3.014865	.4562871	2.19	3.89
foreign	74	.2972973	.4601885	0	1

There are only 69 observations on rep78, so some of the observations are missing. There are no observations on make because it is a string variable.

◁

The idea of the mean is quite old (Plackett 1958), but its extension to a scheme of moment-based measures was not done until the end of the 19th century. Between 1893 and 1905, Pearson discussed and named the standard deviation, skewness, and kurtosis, but he was not the first to use any of these. Thiele (1889), in contrast, had earlier firmly grasped the notion that the m_r provide a systematic basis for discussing distributions. However, even earlier anticipations can also be found. For example, Euler in 1778 used m_2 and m_3 in passing in a treatment of estimation (Hald 1998, 87), but seemingly did not build on that.

Similarly, the idea of the median is quite old. The history of the interquartile range is tangled up with that of the probable error, a long-popular measure. Extending this in various ways to a more general approach based on quantiles (to use a later term) occurred to several people in the nineteenth century. Galton (1875) is a nice example, particularly because he seems so close to the key idea of the quantiles as a function, which took another century to reemerge strongly.

Thorvald Nicolai Thiele (1838–1910) was a Danish scientist who worked in astronomy, mathematics, actuarial science, and statistics. He made many pioneering contributions to statistics, several of which were overlooked until recently. Thiele advocated graphical analysis of residuals checking for trends, symmetry of distributions, and changes of sign, and he even warned against overinterpreting such graphs.

▷ Example 2: summarize with the detail option

The `detail` option provides all the information of a normal `summarize` and more. The format of the output also differs, as shown here:

```
. summarize mpg, detail
                        Mileage (mpg)
-------------------------------------------------------------
      Percentiles      Smallest
 1%           12             12
 5%           14             12
10%           14             14       Obs                  74
25%           18             14       Sum of Wgt.          74
50%           20                      Mean            21.2973
                        Largest       Std. Dev.       5.785503
75%           25             34
90%           29             35       Variance        33.47205
95%           34             35       Skewness        .9487176
99%           41             41       Kurtosis        3.975005
```

As in the previous example, we see that the mean of `mpg` is 21.3 miles per gallon and that the standard deviation is 5.79. We also see the various percentiles. The median of `mpg` (the 50th percentile) is 20 miles per gallon. The 25th percentile is 18, and the 75th percentile is 25.

When we performed `summarize`, we learned that the minimum and maximum were 12 and 41, respectively. We now see that the four smallest values in our dataset are 12, 12, 14, and 14. The four largest values are 34, 35, 35, and 41. The skewness of the distribution is 0.95, and the kurtosis is 3.98. (A normal distribution would have a skewness of 0 and a kurtosis of 3.)

Skewness is a measure of the lack of symmetry of a distribution. If the distribution is symmetric, the coefficient of skewness is 0. If the coefficient is negative, the median is usually greater than the mean and the distribution is said to be skewed left. If the coefficient is positive, the median is usually less than the mean and the distribution is said to be skewed right. *Kurtosis* (from the Greek *kyrtosis*, meaning curvature) is a measure of peakedness of a distribution. The smaller the coefficient of kurtosis, the flatter the distribution. The normal distribution has a coefficient of kurtosis of 3 and provides a convenient benchmark. ◁

❑ Technical note

The convention of calculating the median of an even number of values by averaging the central two order statistics is of long standing. (That is, given 8 values, average the 4th and 5th smallest values, or given 42, average the 21st and 22nd smallest.) Stigler (1977) filled a much-needed gap in the literature by naming such paired central order statistics as "comedians", although it remains unclear how far he was joking.

❑

▷ Example 3: summarize with the by prefix

`summarize` can usefully be combined with the by *varlist*: prefix. In our dataset, we have a variable, `foreign`, that distinguishes foreign and domestic cars. We can obtain summaries of `mpg` and `weight` within each subgroup by typing

```
. by foreign: summarize mpg weight
```

```
-> foreign = Domestic
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
         mpg |         52    19.82692    4.743297        12         34
      weight |         52    3317.115    695.3637      1800       4840

-> foreign = Foreign
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
         mpg |         22    24.77273    6.611187        14         41
      weight |         22    2315.909    433.0035      1760       3420
```

Domestic cars in our dataset average 19.8 miles per gallon, whereas foreign cars average 24.8.

Because by *varlist*: can be combined with `summarize`, it can also be combined with `summarize, detail`:

```
. by foreign: summarize mpg, detail
```

```
-> foreign = Domestic
                          Mileage (mpg)
-------------------------------------------------------------
      Percentiles      Smallest
 1%           12             12
 5%           14             12
10%           14             14       Obs                  52
25%         16.5             14       Sum of Wgt.          52

50%           19                      Mean           19.82692
                        Largest       Std. Dev.      4.743297
75%           22             28
90%           26             29       Variance       22.49887
95%           29             30       Skewness       .7712432
99%           34             34       Kurtosis       3.441459
```

```
-> foreign = Foreign
                          Mileage (mpg)
-------------------------------------------------------------
      Percentiles      Smallest
 1%           14             14
 5%           17             17
10%           17             17       Obs                  22
25%           21             18       Sum of Wgt.          22

50%         24.5                      Mean           24.77273
                        Largest       Std. Dev.      6.611187
75%           28             31
90%           35             35       Variance       43.70779
95%           35             35       Skewness        .657329
99%           41             41       Kurtosis        3.10734
```

◁

❑ Technical note

`summarize` respects display formats if we specify the `format` option. When we type `summarize price weight`, we obtain

```
. summarize price weight
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
       price |         74    6165.257    2949.496       3291      15906
      weight |         74    3019.459    777.1936       1760       4840
```

The display is accurate but is not as aesthetically pleasing as we may wish, particularly if we plan to use the output directly in published work. By placing formats on the variables, we can control how the table appears:

```
. format price weight %9.2fc
. summarize price weight, format
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
       price |         74    6,165.26    2,949.50    3,291.00  15,906.00
      weight |         74    3,019.46      777.19    1,760.00   4,840.00
```

❑

If you specify a weight (see [U] 11.1.6 weight), each observation is multiplied by the value of the weighting expression before the summary statistics are calculated so that the weighting expression is interpreted as the discrete density of each observation.

Example 4: summarize with factor variables

You can also use `summarize` to obtain summary statistics for factor variables. For example, if you type

```
. summarize i.rep78
```

Variable	Obs	Mean	Std. Dev.	Min	Max
rep78					
Fair	69	.115942	.3225009	0	1
Average	69	.4347826	.4993602	0	1
Good	69	.2608696	.4423259	0	1
Excellent	69	.1594203	.3687494	0	1

you obtain the sample proportions for four of the five levels of the `rep78` variable. For example, 11.6% of the 69 cars with nonmissing values of `rep78` have a fair repair record. When you use factor-variable notation, the base category is suppressed by default. If you type

```
. summarize bn.rep78
```

Variable	Obs	Mean	Std. Dev.	Min	Max
rep78					
Poor	69	.0289855	.1689948	0	1
Fair	69	.115942	.3225009	0	1
Average	69	.4347826	.4993602	0	1
Good	69	.2608696	.4423259	0	1
Excellent	69	.1594203	.3687494	0	1

the notation `bn.rep78` indicates that Stata should not suppress the base category so that we see the proportions for all five levels.

We could have used `tabulate oneway rep78` to obtain the sample proportions along with the cumulative proportions. Alternatively, we could have used `proportions rep78` to obtain the sample proportions along with the standard errors of the proportions instead of the standard deviations of the proportions.

◁

Example 5: summarize with weights

We have 1980 census data on each of the 50 states. Included in our variables is `medage`, the median age of the population of each state. If we type `summarize medage`, we obtain unweighted statistics:

```
. use http://www.stata-press.com/data/r13/census
(1980 Census data by state)
. summarize medage
```

Variable	Obs	Mean	Std. Dev.	Min	Max
medage	50	29.54	1.693445	24.2	34.7

Also among our variables is `pop`, the population in each state. Typing `summarize medage [w=pop]` produces population-weighted statistics:

```
. summarize medage [w=pop]
(analytic weights assumed)
    Variable |       Obs      Weight        Mean   Std. Dev.       Min        Max
-------------+--------------------------------------------------------------------
      medage |        50   225907472    30.11047    1.66933        24.2       34.7
```

The number listed under `Weight` is the sum of the weighting variable, `pop`, indicating that there are roughly 226 million people in the United States. The `pop`-weighted mean of `medage` is 30.11 (compared with 29.54 for the unweighted statistic), and the weighted standard deviation is 1.67 (compared with 1.69).

◁

▷ Example 6: summarize with weights and the detail option

We can obtain detailed summaries of weighted data as well. When we do this, *all* the statistics are weighted, including the percentiles.

```
. summarize medage [w=pop], detail
(analytic weights assumed)
                          Median age
-------------------------------------------------------------
      Percentiles      Smallest
 1%         27.1           24.2
 5%         27.7           26.1
10%         28.2           27.1       Obs                  50
25%         29.2           27.4       Sum of Wgt.   225907472
50%         29.9                      Mean           30.11047
                        Largest       Std. Dev.      1.66933
75%         30.9             32
90%         32.1           32.1       Variance       2.786661
95%         32.2           32.2       Skewness       .5281972
99%         34.7           34.7       Kurtosis       4.494223
```

◁

❑ Technical note

If you are writing a program and need to access the mean of a variable, the `meanonly` option provides for fast calls. For example, suppose that your program reads as follows:

```
program mean
        summarize ‘1’, meanonly
        display "  mean = " r(mean)
end
```

The result of executing this is

```
. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
. mean price
  mean = 6165.2568
```

❑

Video example

Descriptive statistics in Stata

Stored results

`summarize` stores the following in `r()`:

Scalars

`r(N)`	number of observations	`r(p50)`	50th percentile (`detail` only)
`r(mean)`	mean	`r(p75)`	75th percentile (`detail` only)
`r(skewness)`	skewness (`detail` only)	`r(p90)`	90th percentile (`detail` only)
`r(min)`	minimum	`r(p95)`	95th percentile (`detail` only)
`r(max)`	maximum	`r(p99)`	99th percentile (`detail` only)
`r(sum_w)`	sum of the weights	`r(Var)`	variance
`r(p1)`	1st percentile (`detail` only)	`r(kurtosis)`	kurtosis (`detail` only)
`r(p5)`	5th percentile (`detail` only)	`r(sum)`	sum of variable
`r(p10)`	10th percentile (`detail` only)	`r(sd)`	standard deviation
`r(p25)`	25th percentile (`detail` only)		

Methods and formulas

Let x denote the variable on which we want to calculate summary statistics, and let x_i, $i = 1, \ldots, n$, denote an individual observation on x. Let v_i be the weight, and if no weight is specified, define $v_i = 1$ for all i.

Define V as the *sum of the weight*:

$$V = \sum_{i=1}^{n} v_i$$

Define w_i to be v_i normalized to sum to n, $w_i = v_i(n/V)$.

The *mean*, $\overline{x}$, is defined as

$$\overline{x} = \frac{1}{n}\sum_{i=1}^{n} w_i x_i$$

The *variance*, s^2, is defined as

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n} w_i(x_i - \overline{x})^2$$

The *standard deviation*, s, is defined as $\sqrt{s^2}$.

Define m_r as the rth moment about the mean $\overline{x}$:

$$m_r = \frac{1}{n}\sum_{i=1}^{n} w_i(x_i - \overline{x})^r$$

The *coefficient of skewness* is then defined as $m_3 m_2^{-3/2}$. The *coefficient of kurtosis* is defined as $m_4 m_2^{-2}$.

Let $x_{(i)}$ refer to the x in ascending order, and let $w_{(i)}$ refer to the corresponding weights of $x_{(i)}$. The four smallest values are $x_{(1)}$, $x_{(2)}$, $x_{(3)}$, and $x_{(4)}$. The four largest values are $x_{(n)}$, $x_{(n-1)}$, $x_{(n-2)}$, and $x_{(n-3)}$.

To obtain the pth *percentile*, which we will denote as $x_{[p]}$, let $P = np/100$. Let

$$W_{(i)} = \sum_{j=1}^{i} w_{(j)}$$

Find the first index i such that $W_{(i)} > P$. The pth percentile is then

$$x_{[p]} = \begin{cases} \dfrac{x_{(i-1)} + x_{(i)}}{2} & \text{if } W_{(i-1)} = P \\ x_{(i)} & \text{otherwise} \end{cases}$$

fweights are allowed; see [U] **11.1.6 weight**.

Menu

Graphics > Smoothing and densities > Density-distribution sunflower plot

Description

sunflower draws density-distribution sunflower plots (Plummer and Dupont 2003). These plots are useful for displaying bivariate data whose density is too great for conventional scatterplots to be effective.

A sunflower is several line segments of equal length, called petals, that radiate from a central point. There are two varieties of sunflowers: light and dark. Each petal of a light sunflower represents 1 observation. Each petal of a dark sunflower represents several observations. Dark and light sunflowers represent high- and medium-density regions of the data, and marker symbols represent individual observations in low-density regions.

The plane defined by the variables *yvar* and *xvar* is divided into contiguous hexagonal bins. The number of observations contained within a bin determines how the bin will be represented.

- When there are fewer than light(#) observations in a bin, each point is plotted using the usual marker symbols in a scatterplot.
- Bins with at least light(#) but fewer than dark(#) observations are represented by a light sunflower.
- Bins with at least dark(#) observations are represented by a dark sunflower.

Options

Main

nograph prevents the graph from being generated.

`notable` prevents the summary table from being displayed. This option is implied when the `by()` option is specified.

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] ***marker_options***.

Bins/Petals

`binwidth(#)` specifies the horizontal width of the hexagonal bins in the same units as *xvar*. By default,

$$binwidth = \texttt{max(}\text{rbw, nbw}\texttt{)}$$

where

$$\text{rbw} = \text{range of } xvar/40$$

$$\text{nbw} = \text{range of } xvar/\texttt{max(1,}\text{nb}\texttt{)}$$

and

$$\text{nb} = \texttt{int(min(sqrt(}n\texttt{),10 * log10(}n\texttt{)))}$$

where

$$n = \text{the number of observations in the dataset}$$

`binar(#)` specifies the aspect ratio for the hexagonal bins. The height of the bins is given by

$$binheight = binwidth \times \# \times 2/\sqrt{3}$$

where *binheight* and *binwidth* are specified in the units of *yvar* and *xvar*, respectively. The default is `binar(`*r*`)`, where *r* results in the rendering of regular hexagons.

bin_options affect how the hexagonal bins are rendered.

`lbstyle(`*areastyle*`)` and `dbstyle(`*areastyle*`)` specify the look of the light and dark hexagonal bins, respectively. The options listed below allow you to change each attribute, but `lbstyle()` and `dbstyle()` provide the starting points. See [G-4] ***areastyle*** for a list of available area styles.

`lbcolor(`*colorstyle*`)` and `dbcolor(`*colorstyle*`)` specify one color to be used both to outline the shape and to fill the interior of the light and dark hexagonal bins, respectively. See [G-4] ***colorstyle*** for a list of color choices.

`lbfcolor(`*colorstyle*`)` and `dbfcolor(`*colorstyle*`)` specify the color to be used to fill the interior of the light and dark hexagonal bins, respectively. See [G-4] ***colorstyle*** for a list of color choices.

`lblstyle(`*linestyle*`)` and `dblstyle(`*linestyle*`)` specify the overall style of the line used to outline the area, which includes its pattern (solid, dashed, etc.), thickness, and color. The other options listed below allow you to change the line's attributes, but `lblstyle()` and `dblstyle()` are the starting points. See [G-4] ***linestyle*** for a list of choices.

`lblcolor(`*colorstyle*`)` and `dblcolor(`*colorstyle*`)` specify the color to be used to outline the light and dark hexagonal bins, respectively. See [G-4] ***colorstyle*** for a list of color choices.

`lblwidth(`*linewidthstyle*`)` and `dblwidth(`*linewidthstyle*`)` specify the thickness of the line to be used to outline the light and dark hexagonal bins, respectively. See [G-4] ***linewidthstyle*** for a list of choices.

`light(#)` specifies the minimum number of observations needed for a bin to be represented by a light sunflower. The default is `light(3)`.

`dark(#)` specifies the minimum number of observations needed for a bin to be represented by a dark sunflower. The default is `dark(13)`.

`xcenter(#)` and `ycenter(#)` specify the center of the reference bin. The default values are the median values of *xvar* and *yvar*, respectively. The centers of the other bins are implicitly defined by the location of the reference bin together with the common bin width and height.

`petalweight(#)` specifies the number of observations represented by each petal of a dark sunflower. The default value is chosen so that the maximum number of petals on a dark sunflower is 14.

`petallength(#)` specifies the length of petals in the sunflowers. The value specified is interpreted as a percentage of half the bin width. The default is 100%.

petal_options affect how the sunflower petals are rendered.

`lflstyle(`*linestyle*`)` and `dflstyle(`*linestyle*`)` specify the overall style of the light and dark sunflower petals, respectively.

`lflcolor(`*colorstyle*`)` and `dflcolor(`*colorstyle*`)` specify the color of the light and dark sunflower petals, respectively.

`lflwidth(`*linewidthstyle*`)` and `dflwidth(`*linewidthstyle*`)` specify the width of the light and dark sunflower petals, respectively.

`flowersonly` suppresses rendering of the bins. This option is equivalent to specifying `lbcolor(none)` and `dbcolor(none)`.

`nosinglepetal` suppresses flowers from being drawn in light bins that contain only 1 observation and dark bins that contain as many observations as the petal weight (see the `petalweight()` option).

Add plots

`addplot(`*plot*`)` provides a way to add other plots to the generated graph; see [G-3] ***addplot_option***.

Y axis, X axis, Titles, Legend, Overall, By

twoway_options are any of the options documented in [G-3] ***twoway_options***. These include options for titling the graph (see [G-3] ***title_options***), options for saving the graph to disk (see [G-3] ***saving_option***), and the `by()` option (see [G-3] ***by_option***).

Remarks and examples

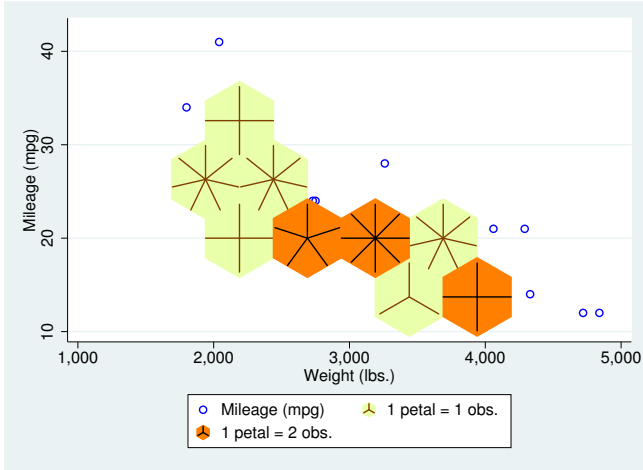
See Dupont (2009, 87–92) for a discussion of sunflower plots and how to create them using Stata.

▷ Example 1

Using the auto dataset, we want to examine the relationship between `weight` and `mpg`. To do that, we type

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. sunflower mpg weight, binwid(500) petalw(2) dark(8) scheme(s2color)
Bin width          =       500
Bin height         =   8.38703
Bin aspect ratio   =  .0145268
Max obs in a bin   =        15
Light              =         3
Dark               =         8
X-center           =      3190
Y-center           =        20
Petal weight       =         2
```

flower type	petal weight	No. of petals	No. of flowers	estimated obs.	actual obs.
none				10	10
light	1	3	1	3	3
light	1	4	2	8	8
light	1	7	3	21	21
dark	2	4	1	8	8
dark	2	5	1	10	9
dark	2	8	1	16	15
				76	74



The three darkly shaded sunflowers immediately catch our eyes, indicating a group of eight cars that are heavy (nearly 4,000 pounds) and fuel inefficient and two groups of cars that get about 20 miles per gallon and weight in the neighborhood of 3,000 pounds, one with 10 cars and one with 8 cars. The lighter sunflowers with seven petals each indicate groups of seven cars that share similar weight and fuel economy characteristics. To obtain the number of cars in each group, we counted the number of petals in each flower and consulted the graph legend to see how many observations each petal represents.

◁

Acknowledgments

We thank William D. Dupont and W. Dale Plummer Jr., both of the Department of Biostatistics at Vanderbilt University, who are the authors of the original `sunflower` command, for their assistance in producing this version.

`small`	report small-sample statistics
`dfk`	use small-sample adjustment
`dfk2`	use alternate adjustment
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`corr`	perform Breusch–Pagan test
`nocnsreport`	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Optimization	
optimization_options	control the optimization process; seldom used
`noheader`	suppress header table from above coefficient table
`notable`	suppress coefficient table
`coeflegend`	display legend instead of statistics

varlist$_1$, ..., *varlist*$_N$ may contain factor variables; see **[U] 11.4.3 Factor variables**. You must have the same levels of factor variables in all equations that have factor variables.

*depvar*s and the *varlist*s may contain time-series operators; see **[U] 11.4.4 Time-series varlists**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, and `statsby` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`aweight`s are not allowed with the `jackknife` prefix; see [R] **jackknife**.

`aweight`s and `fweight`s are allowed; see **[U] 11.1.6 weight**.

`noheader`, `notable`, and `coeflegend` do not appear in the dialog box.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Statistics > Linear models and related > Multiple-equation models > Seemingly unrelated regression

Description

`sureg` fits seemingly unrelated regression models (Zellner 1962; Zellner and Huang 1962; Zellner 1963). The acronyms SURE and SUR are often used for the estimator.

Options

Model

`isure` specifies that `sureg` iterate over the estimated disturbance covariance matrix and parameter estimates until the parameter estimates converge. Under seemingly unrelated regression, this iteration converges to the maximum likelihood results. If this option is not specified, `sureg` produces two-step estimates.

`constraints(`*constraints*`)`; see [R] **estimation options**.

df adj.

`small` specifies that small-sample statistics be computed. It shifts the test statistics from chi-squared and z statistics to F statistics and t statistics. Although the standard errors from each equation are computed using the degrees of freedom for the equation, the degrees of freedom for the t statistics are all taken to be those for the first equation.

`dfk` specifies the use of an alternate divisor in computing the covariance matrix for the equation residuals. As an asymptotically justified estimator, `sureg` by default uses the number of sample observations (n) as a divisor. When the `dfk` option is set, a small-sample adjustment is made and the divisor is taken to be $\sqrt{(n-k_i)(n-k_j)}$, where k_i and k_j are the numbers of parameters in equations i and j, respectively.

`dfk2` specifies the use of an alternate divisor in computing the covariance matrix for the equation residuals. When the `dfk2` option is set, the divisor is taken to be the mean of the residual degrees of freedom from the individual equations.

Reporting

`level(#)`; see [R] **estimation options**.

`corr` displays the correlation matrix of the residuals between equations and performs a Breusch–Pagan test for independent equations; that is, the disturbance covariance matrix is diagonal.

`nocnsreport`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Optimization

optimization_options control the iterative process that minimizes the sum of squared errors when `isure` is specified. These options are seldom used.

`iterate(#)` specifies the maximum number of iterations. When the number of iterations equals #, the optimizer stops and presents the current results, even if the convergence tolerance has not been reached. The default value of `iterate()` is the current value of `set maxiter` (see [R] **maximize**), which is `iterate(16000)` if `maxiter` has not been changed.

`trace` adds to the iteration log a display of the current parameter vector

`nolog` suppresses the display of the iteration log.

`tolerance(#)` specifies the tolerance for the coefficient vector. When the relative change in the coefficient vector from one iteration to the next is less than or equal to #, the optimization process is stopped. `tolerance(1e-6)` is the default.

The following options are available with sureg but are not shown in the dialog box:

noheader suppresses display of the table reporting F statistics, R-squared, and root mean squared error above the coefficient table.

notable suppresses display of the coefficient table.

coeflegend; see [R] **estimation options**.

Remarks and examples

Seemingly unrelated regression models are so called because they appear to be joint estimates from several regression models, each with its own error term. The regressions are related because the (contemporaneous) errors associated with the dependent variables may be correlated. Chapter 5 of Cameron and Trivedi (2010) contains a discussion of the seemingly unrelated regression model and the feasible generalized least-squares estimator underlying it.

▷ Example 1

When we fit models with the same set of right-hand-side variables, the seemingly unrelated regression results (in terms of coefficients and standard errors) are the same as fitting the models separately (using, say, regress). The same is true when the models are nested. Even in such cases, sureg is useful when we want to perform joint tests. For instance, let us assume that we think

$$\texttt{price} = \beta_0 + \beta_1\texttt{foreign} + \beta_2\texttt{length} + u_1$$
$$\texttt{weight} = \gamma_0 + \gamma_1\texttt{foreign} + \gamma_2\texttt{length} + u_2$$

Because the models have the same set of explanatory variables, we could estimate the two equations separately. Yet, we might still choose to estimate them with sureg because we want to perform the joint test $\beta_1 = \gamma_1 = 0$.

We use the small and dfk options to obtain small-sample statistics comparable with regress or mvreg.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. sureg (price foreign length) (weight foreign length), small dfk
Seemingly unrelated regression
```

Equation	Obs	Parms	RMSE	"R-sq"	F-Stat	P
price	74	2	2474.593	0.3154	16.35	0.0000
weight	74	2	250.2515	0.8992	316.54	0.0000

	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
price						
foreign	2801.143	766.117	3.66	0.000	1286.674	4315.611
length	90.21239	15.83368	5.70	0.000	58.91219	121.5126
_cons	-11621.35	3124.436	-3.72	0.000	-17797.77	-5444.93
weight						
foreign	-133.6775	77.47615	-1.73	0.087	-286.8332	19.4782
length	31.44455	1.601234	19.64	0.000	28.27921	34.60989
_cons	-2850.25	315.9691	-9.02	0.000	-3474.861	-2225.639

These two equations have a common set of regressors, and we could have used a shorthand syntax to specify the equations:

```
. sureg (price weight = foreign length), small dfk
```

Here the results presented by `sureg` are the same as if we had estimated the equations separately:

```
. regress price foreign length
  (output omitted)
. regress weight foreign length
  (output omitted)
```

There is, however, a difference. We have allowed u_1 and u_2 to be correlated and have estimated the full variance–covariance matrix of the coefficients. `sureg` has estimated the correlations, but it does not report them unless we specify the `corr` option. We did not remember to specify `corr` when we fit the model, but we can redisplay the results:

```
. sureg, notable noheader corr

Correlation matrix of residuals:

         price  weight
 price  1.0000
weight  0.5840  1.0000

Breusch-Pagan test of independence: chi2(1) =    25.237, Pr = 0.0000
```

The `notable` and `noheader` options prevented `sureg` from redisplaying the header and coefficient tables. We find that, for the same cars, the correlation of the residuals in the `price` and `weight` equations is 0.5840 and that we can reject the hypothesis that this correlation is zero.

We can test that the coefficients on `foreign` are jointly zero in both equations—as we set out to do—by typing `test foreign`; see [R] **test**. When we type a variable without specifying the equation, that variable is tested for zero in all equations in which it appears:

```
. test foreign
 ( 1)  [price]foreign = 0
 ( 2)  [weight]foreign = 0
       F(  2,   142) =   17.99
            Prob > F =    0.0000
```

◁

▷ Example 2

When the models do not have the same set of explanatory variables and are not nested, `sureg` may lead to more efficient estimates than running the models separately as well as allowing joint tests. This time, let us assume that we believe

$$\texttt{price} = \beta_0 + \beta_1\texttt{foreign} + \beta_2\texttt{mpg} + \beta_3\texttt{displ} + u_1$$
$$\texttt{weight} = \gamma_0 + \gamma_1\texttt{foreign} + \gamma_2\texttt{length} + u_2$$

To fit this model, we type

```
. sureg (price foreign mpg displ) (weight foreign length), corr
Seemingly unrelated regression
```

Equation	Obs	Parms	RMSE	"R-sq"	chi2	P
price	74	3	2165.321	0.4537	49.64	0.0000
weight	74	2	245.2916	0.8990	661.84	0.0000

	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
price						
foreign	3058.25	685.7357	4.46	0.000	1714.233	4402.267
mpg	-104.9591	58.47209	-1.80	0.073	-219.5623	9.644042
displacement	18.18098	4.286372	4.24	0.000	9.779842	26.58211
_cons	3904.336	1966.521	1.99	0.047	50.0263	7758.645
weight						
foreign	-147.3481	75.44314	-1.95	0.051	-295.2139	.517755
length	30.94905	1.539895	20.10	0.000	27.93091	33.96718
_cons	-2753.064	303.9336	-9.06	0.000	-3348.763	-2157.365

```
Correlation matrix of residuals:

         price  weight
 price  1.0000
weight  0.3285  1.0000

Breusch-Pagan test of independence: chi2(1) =     7.984, Pr = 0.0047
```

In comparison, if we had fit the `price` model separately,

```
. regress price foreign mpg displ
```

Source	SS	df	MS		
Model	294104790	3	98034929.9	Number of obs	= 74
Residual	340960606	70	4870865.81	F(3, 70)	= 20.13
				Prob > F	= 0.0000
				R-squared	= 0.4631
				Adj R-squared	= 0.4401
Total	635065396	73	8699525.97	Root MSE	= 2207

price	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
foreign	3545.484	712.7763	4.97	0.000	2123.897	4967.072
mpg	-98.88559	63.17063	-1.57	0.122	-224.8754	27.10426
displacement	22.40416	4.634239	4.83	0.000	13.16146	31.64686
_cons	2796.91	2137.873	1.31	0.195	-1466.943	7060.763

The coefficients are slightly different, but the standard errors are uniformly larger. This would still be true if we specified the `dfk` option to make a small-sample adjustment to the estimated covariance of the disturbances.

◁

❑ Technical note

Constraints can be applied to SURE models using Stata's standard syntax for constraints. For a general discussion of constraints, see [R] **constraint**; for examples similar to seemingly unrelated regression models, see [R] **reg3**.

❑

Stored results

sureg stores the following in e():

Scalars

e(N)	number of observations
e(k)	number of parameters
e(k_eq)	number of equations in e(b)
e(mss_#)	model sum of squares for equation #
e(df_m#)	model degrees of freedom for equation #
e(rss_#)	residual sum of squares for equation #
e(df_r)	residual degrees of freedom
e(r2_#)	R-squared for equation #
e(F_#)	F statistic for equation # (small only)
e(rmse_#)	root mean squared error for equation #
e(dfk2_adj)	divisor used with VCE when dfk2 specified
e(ll)	log likelihood
e(chi2_#)	χ^2 for equation #
e(p_#)	significance for equation #
e(cons_#)	1 if equation # has a constant, 0 otherwise
e(chi2_bp)	Breusch–Pagan χ^2
e(df_bp)	degrees of freedom for Breusch–Pagan χ^2 test
e(cons_#)	1 when equation # has a constant; 0, otherwise
e(rank)	rank of e(V)
e(ic)	number of iterations

Macros

e(cmd)	sureg
e(cmdline)	command as typed
e(method)	sure or isure
e(depvar)	names of dependent variables
e(exog)	names of exogenous variables
e(eqnames)	names of equations
e(wtype)	weight type
e(wexp)	weight expression
e(corr)	correlation structure
e(small)	small
e(dfk)	alternate divisor (dfk or dfk2 only)
e(properties)	b V
e(predict)	program used to implement predict
e(marginsok)	predictions allowed by margins
e(marginsnotok)	predictions disallowed by margins
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(Cns)	constraints matrix
e(Sigma)	$\widehat{\Sigma}$ matrix
e(V)	variance–covariance matrix of the estimators

Functions

e(sample)	marks estimation sample

Methods and formulas

sureg uses the asymptotically efficient, feasible, generalized least-squares algorithm described in Greene (2012, 292–304). The computing formulas are given on page 293–294.

The R-squared reported is the percent of variance explained by the predictors. It may be used for descriptive purposes, but R-squared is not a well-defined concept when GLS is used.

sureg will refuse to compute the estimators if the same equation is named more than once or the covariance matrix of the residuals is singular.

The Breusch and Pagan (1980) χ^2 statistic—a Lagrange multiplier statistic—is given by

$$\lambda = T \sum_{m=1}^{M} \sum_{n=1}^{m-1} r_{mn}^2$$

where r_{mn} is the estimated correlation between the residuals of the M equations and T is the number of observations. It is distributed as χ^2 with $M(M-1)/2$ degrees of freedom.

Arnold Zellner (1927–2010) was born in New York. He studied physics at Harvard and economics at Berkeley, and then he taught economics at the Universities of Washington and Wisconsin before settling in Chicago in 1966. Among his many major contributions to econometrics and statistics are his work on seemingly unrelated regression, three-stage least squares, and Bayesian econometrics.

Title

sureg postestimation — Postestimation tools for sureg

Description Syntax for predict Menu for predict Options for predict
Remarks and examples Also see

Description

The following postestimation commands are available after `sureg`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estimates`	cataloging estimation results
`forecast`	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

Syntax for predict

`predict` [*type*] *newvar* [*if*] [*in*] [`,` `equation(`*eqno*[`,`*eqno*]`)` *statistic*]

statistic	Description
Main	
`xb`	linear prediction; the default
`stdp`	standard error of the linear prediction
`residuals`	residuals
`difference`	difference between the linear predictions of two equations
`stddp`	standard error of the difference in linear predictions

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`equation(`*eqno*`[ ,`*eqno*`])` specifies to which equation(s) you are referring.

`equation()` is filled in with one *eqno* for the `xb`, `stdp`, and `residuals` options. `equation(#1)` would mean that the calculation is to be made for the first equation, `equation(#2)` would mean the second, and so on. You could also refer to the equations by their names. `equation(income)` would refer to the equation named income and `equation(hours)` to the equation named hours.

If you do not specify `equation()`, the results are the same as if you specified `equation(#1)`.

`difference` and `stddp` refer to between-equation concepts. To use these options, you must specify two equations, for example, `equation(#1,#2)` or `equation(income,hours)`. When two equations must be specified, `equation()` is required.

`xb`, the default, calculates the linear prediction (fitted values)—the prediction of $\mathbf{x}_j\mathbf{b}$ for the specified equation.

`stdp` calculates the standard error of the prediction for the specified equation. It can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`residuals` calculates the residuals.

`difference` calculates the difference between the linear predictions of two equations in the system. With `equation(#1,#2)`, `difference` computes the prediction of `equation(#1)` minus the prediction of `equation(#2)`.

`stddp` is allowed only after you have previously fit a multiple-equation model. The standard error of the difference in linear predictions $(\mathbf{x}_{1j}\mathbf{b} - \mathbf{x}_{2j}\mathbf{b})$ between equations 1 and 2 is calculated.

For more information on using `predict` after multiple-equation estimation commands, see [R] **predict**.

Remarks and examples

For an example of cross-equation testing of parameters using the `test` command, see example 1 in [R] **sureg**.

▷ Example 1

In example 1 of [R] **sureg**, we fit a seemingly unrelated regressions model of `price` and `weight`. Here we obtain the fitted values.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. sureg (price foreign length) (weight foreign length), small dfk
  (output omitted)
. predict phat, equation(price)
(option xb assumed; fitted values)
. predict what, equation(weight)
(option xb assumed; fitted values)
```

```
. summarize price phat weight what
```

Variable	Obs	Mean	Std. Dev.	Min	Max
price	74	6165.257	2949.496	3291	15906
phat	74	6165.257	1656.407	1639.872	9398.138
weight	74	3019.459	777.1936	1760	4840
what	74	3019.459	736.9666	1481.199	4476.331

Just as in single-equation OLS regression, in a SURE model the sample mean of the fitted values for an equation equals the sample mean of the dependent variable.

◁

▷ Example 2

Suppose that for whatever reason we were interested in the difference between the predicted values of `price` and `weight`. `predict` has an option to compute this difference in one step:

```
. predict diff, equation(price, weight) difference
```

`diff` is the same as `phat - what`:

```
. generate mydiff = phat - what
. summarize diff mydiff
```

Variable	Obs	Mean	Std. Dev.	Min	Max
diff	74	3145.797	1233.26	-132.2275	5505.914
mydiff	74	3145.797	1233.26	-132.2275	5505.914

Title

swilk — Shapiro–Wilk and Shapiro–Francia tests for normality

Syntax | Menu | Description | Options for swilk
Options for sfrancia | Remarks and examples | Stored results | Methods and formulas
Acknowledgment | References | Also see

Syntax

Shapiro–Wilk normality test

`swilk` *varlist* [*if*] [*in*] [, *swilk_options*]

Shapiro–Francia normality test

`sfrancia` *varlist* [*if*] [*in*] [, *sfrancia_options*]

swilk_options	Description
Main	
`generate(`*newvar*`)`	create *newvar* containing W test coefficients
`lnnormal`	test for three-parameter lognormality
`noties`	do not use average ranks for tied values

sfrancia_options	Description
Main	
`boxcox`	use the Box–Cox transformation for W'; the default is to use the log transformation
`noties`	do not use average ranks for tied values

`by` is allowed with `swilk` and `sfrancia`; see [D] **by**.

Menu

swilk

Statistics > Summaries, tables, and tests > Distributional plots and tests > Shapiro-Wilk normality test

sfrancia

Statistics > Summaries, tables, and tests > Distributional plots and tests > Shapiro-Francia normality test

Description

`swilk` performs the Shapiro–Wilk W test for normality, and `sfrancia` performs the Shapiro–Francia W' test for normality. `swilk` can be used with $4 \leq n \leq 2000$ observations, and `sfrancia` can be used with $5 \leq n \leq 5000$ observations; see [R] **sktest** for a test allowing more observations. See [MV] **mvtest normality** for multivariate tests of normality.

Options for swilk

Main

`generate(`*newvar*`)` creates new variable *newvar* containing the W test coefficients.

`lnnormal` specifies that the test be for three-parameter lognormality, meaning that $\ln(X-k)$ is tested for normality, where k is calculated from the data as the value that makes the skewness coefficient zero. When simply testing $\ln(X)$ for normality, do not specify this option. See [R] **lnskew0** for estimation of k.

`noties` suppresses use of averaged ranks for tied values when calculating the W test coefficients.

Options for sfrancia

Main

`boxcox` specifies that the Box–Cox transformation of Royston (1983) for calculating W' test coefficients be used instead of the default log transformation (Royston 1993a). Under the Box–Cox transformation, the normal approximation to the sampling distribution of W', used by `sfrancia`, is valid for $5 \leq n \leq 1000$. Under the log transformation, it is valid for $10 \leq n \leq 5000$.

`noties` suppresses use of averaged ranks for tied values when calculating the W' test coefficients.

Remarks and examples

▷ Example 1

Using our automobile dataset, we will test whether the variables `mpg` and `trunk` are normally distributed:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. swilk mpg trunk
                    Shapiro-Wilk W test for normal data
    Variable |   Obs       W           V         z       Prob>z
-------------+--------------------------------------------------
         mpg |    74    0.94821      3.335     2.627    0.00430
       trunk |    74    0.97921      1.339     0.637    0.26215
. sfrancia mpg trunk
                   Shapiro-Francia W' test for normal data
    Variable |   Obs       W'          V'        z       Prob>z
-------------+--------------------------------------------------
         mpg |    74    0.94872      3.650     2.510    0.00604
       trunk |    74    0.98446      1.106     0.195    0.42271
```

We can reject the hypothesis that `mpg` is normally distributed, but we cannot reject that `trunk` is normally distributed.

The values reported under W and W' are the Shapiro–Wilk and Shapiro–Francia test statistics. The tests also report V and V', which are more appealing indexes for departure from normality. The median values of V and V' are 1 for samples from normal populations. Large values indicate nonnormality. The 95% critical values of V (V'), which depend on the sample size, are between 1.2 and 2.4 (2.0 and 2.8); see Royston (1991b). There is no more information in V (V') than in W (W')—one is just the transform of the other.

◁

▷ Example 2

We have data on a variable called `studytime`, which we suspect is distributed lognormally:

```
. use http://www.stata-press.com/data/r13/cancer
(Patient Survival in Drug Trial)
. generate lnstudytime = ln(studytime)
. swilk lnstudytime
                    Shapiro-Wilk W test for normal data
    Variable |   Obs        W           V         z       Prob>z
-------------+--------------------------------------------------
 lnstudytime |    48    0.92731       3.311     2.547     0.00543
```

We can reject the lognormal assumption. We do *not* specify the `lnnormal` option when testing for lognormality. The `lnnormal` option is for three-parameter lognormality.

◁

▷ Example 3

Having discovered that ln(`studytime`) is not distributed normally, we now test that ln(`studytime` $- k$) is normally distributed, where k is chosen so that the resulting skewness is zero. We obtain the estimate for k from `lnskew0`; see [R] **lnskew0**:

```
. lnskew0 lnstudytimek = studytime, level(95)
       Transform |          k     [95% Conf. Interval]        Skewness
-----------------+-----------------------------------------------------
  ln(studytim-k) |  -11.01181    -infinity  -.9477328       -.0000173
. swilk lnstudytimek, lnnormal
        Shapiro-Wilk W test for 3-parameter lognormal data
    Variable |   Obs        W           V         z       Prob>z
-------------+--------------------------------------------------
lnstudytimek |    48    0.97064       1.337     1.261     0.10363
```

We cannot reject the hypothesis that ln(`studytime` $+ 11.01181$) is distributed normally. We do specify the `lnnormal` option when using an estimated value of k.

◁

Stored results

`swilk` and `sfrancia` store the following in `r()`:

Scalars

`r(N)`	number of observations	`r(W)`	W or W'
`r(p)`	significance	`r(V)`	V or V'
`r(z)`	z statistic		

Methods and formulas

The Shapiro–Wilk test is based on Shapiro and Wilk (1965) with a new approximation accurate for $4 \leq n \leq 2000$ (Royston 1992). The calculations made by `swilk` are based on Royston (1982, 1992, 1993b).

The Shapiro–Francia test (Shapiro and Francia 1972; Royston 1983; Royston 1993a) is an approximate test that is similar to the Shapiro–Wilk test for very large samples.

Samuel Sanford Shapiro (1930–) earned degrees in statistics and engineering from City College of New York, Columbia, and Rutgers. After employment in the U.S. Army and industry, he joined the faculty at Florida International University in 1972. Shapiro has coauthored various texts in statistics and published several papers on distributional testing and other statistical topics.

Acknowledgment

`swilk` and `sfrancia` were written by Patrick Royston of the MRC Clinical Trials Unit, London and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

symmi

Statistics > Epidemiology and related > Other > Symmetry and marginal homogeneity test calculator

Description

`symmetry` performs asymptotic symmetry and marginal homogeneity tests, as well as an exact symmetry test on $K \times K$ tables where there is a 1-to-1 matching of cases and controls (nonindependence). This testing is used to analyze matched-pair case–control data with multiple discrete levels of the exposure (outcome) variable. In genetics, the test is known as the transmission/disequilibrium test (TDT) and is used to test the association between transmitted and nontransmitted parental marker alleles to an affected child (Spieldman, McGinnis, and Ewens 1993). For 2×2 tables, the asymptotic test statistics reduce to the McNemar test statistic, and the exact symmetry test produces an exact McNemar test; see [ST] **epitab**. For many exposure variables, `symmetry` can optionally perform a test for linear trend in the log relative risk.

symmetry expects the data to be in the wide format; that is, each observation contains the matched case and control values in variables *casevar* and *controlvar*. Variables can be numeric or string.

symmi is the immediate form of symmetry. The symmi command uses the values specified on the command line; rows are separated by '\', and options are the same as for symmetry. See [U] 19 Immediate commands for a general introduction to immediate commands.

Options

Main

notable suppresses the output of the contingency table. By default, symmetry displays the $n \times n$ contingency table at the top of the output.

contrib reports the contribution of each off-diagonal cell pair to the overall symmetry χ^2.

exact performs an exact test of table symmetry. This option is recommended for sparse tables. CAUTION: The exact test requires substantial amounts of time and memory for large tables.

mh performs two marginal homogeneity tests that do not require the inversion of the variance–covariance matrix.

By default, symmetry produces the Stuart–Maxwell test statistic, which requires the inversion of the nondiagonal variance–covariance matrix, $\mathbf{V}$. When the table is sparse, the matrix may not be of full rank, and then the command substitutes a generalized inverse $\mathbf{V}^*$ for $\mathbf{V}^{-1}$. mh calculates optional marginal homogeneity statistics that do not require the inversion of the variance–covariance matrix. These tests may be preferred in certain situations. See *Methods and formulas* and Bickeböller and Clerget-Darpoux (1995) for details on these test statistics.

trend performs a test for linear trend in the (log) relative risk (RR). This option is allowed only for numeric exposure (outcome) variables, and its use should be restricted to measurements on the ordinal or the interval scales.

cc specifies that the continuity correction be used when calculating the test for linear trend. This correction should be specified only when the levels of the exposure variable are equally spaced.

Remarks and examples

symmetry and symmi may be used to analyze 1-to-1 matched case–control data with multiple discrete levels of the exposure (outcome) variable.

▷ Example 1

Consider a survey of 344 individuals (BMDP 1990, 267–270) who were asked in October 1986 whether they agreed with President Reagan's handling of foreign affairs. In January 1987, after the Iran-Contra affair became public, these same individuals were surveyed again and asked the same question. We would like to know if public opinion changed over this period.

We first describe the dataset and list a few observations.

```
. use http://www.stata-press.com/data/r13/iran
. describe
Contains data from http://www.stata-press.com/data/r13/iran.dta

Sorted by:
. list in 1/5

     +-------------------------+
     |   before       after    |
     |-------------------------|
  1. |    agree       agree    |
  2. |    agree    disagree    |
  3. |    agree      unsure    |
  4. | disagree       agree    |
  5. | disagree    disagree    |
     +-------------------------+
```

Each observation corresponds to one of the 344 individuals. The data are in wide form so that each observation has a before and an after measurement. We now perform the test without options.

```
. symmetry before after
```

Public Opinion before IC	Public Opinion after IC: agree	disagree	unsure	Total
agree	47	56	38	141
disagree	28	61	31	120
unsure	26	47	10	83
Total	101	164	79	344

	chi2	df	Prob>chi2
Symmetry (asymptotic)	14.87	3	0.0019
Marginal homogeneity (Stuart-Maxwell)	14.78	2	0.0006

The test first tabulates the data in a $K \times K$ table and then performs Bowker's (1948) test for table symmetry and the Stuart–Maxwell (Stuart 1955; Maxwell 1970) test for marginal homogeneity.

Both the symmetry test and the marginal homogeneity test are highly significant, thus indicating a shift in public opinion.

An exact test of symmetry is provided for use on sparse tables. This test is computationally intensive, so it should not be used on large tables. Because we are working on a fast computer, we will run the symmetry test again and this time include the `exact` option. We will suppress the output of the contingency table by specifying `notable` and include the `contrib` option so that we may further examine the cells responsible for the significant result.

```
. symmetry before after, contrib exact mh notable
```

Cells	Contribution to symmetry chi-squared
n1_2 & n2_1	9.3333
n1_3 & n3_1	2.2500
n2_3 & n3_2	3.2821

	chi2	df	Prob>chi2
Symmetry (asymptotic)	14.87	3	0.0019
Marginal homogeneity (Stuart-Maxwell)	14.78	2	0.0006
Marginal homogeneity (Bickenboller)	13.53	2	0.0012
Marginal homogeneity (no diagonals)	15.25	2	0.0005
Symmetry (exact significance probability)			0.0018

The largest contribution to the symmetry χ^2 is due to cells n_{12} and n_{21}. These correspond to changes between the agree and disagree categories. Of the 344 individuals, 56 (16.3%) changed from the agree to the disagree response, whereas only 28 (8.1%) changed in the opposite direction.

For these data, the results from the exact test are similar to those from the asymptotic test.

◁

▷ Example 2

Breslow and Day (1980, 163) reprinted data from Mack et al. (1976) from a case–control study of the effect of exogenous estrogen on the risk of endometrial cancer. The data consist of 59 elderly women diagnosed with endometrial cancer and 59 disease-free control subjects living in the same community as the cases. Cases and controls were matched on age, marital status, and time living in the community. The data collected included information on the daily dose of conjugated estrogen therapy. Breslow and Day analyzed these data by creating four levels of the dose variable. Here are the data as entered into a Stata dataset:

```
. use http://www.stata-press.com/data/r13/bd163
. list, noobs divider
```

case	control	count
0	0	6
0	0.1-0.299	2
0	0.3-0.625	3
0	0.626+	1
0.1-0.299	0	9
0.1-0.299	0.1-0.299	4
0.1-0.299	0.3-0.625	2
0.1-0.299	0.626+	1
0.3-0.625	0	9
0.3-0.625	0.1-0.299	2
0.3-0.625	0.3-0.625	3
0.3-0.625	0.626+	1
0.626+	0	12
0.626+	0.1-0.299	1
0.626+	0.3-0.625	2
0.626+	0.626+	1

This dataset is in a different format from that of the previous example. Instead of each observation representing one matched pair, each observation represents possibly multiple pairs indicated by the `count` variable. For instance, the first observation corresponds to six matched pairs where neither the case nor the control was on estrogen, the second observation corresponds to two matched pairs where the case was not on estrogen and the control was on 0.1 to 0.299 mg/day, etc.

To use `symmetry` to analyze this dataset, we must specify `fweight` to indicate that in our data there are observations corresponding to more than one matched pair.

```
. symmetry case control [fweight=count]
```

	control				
case	0	0.1-0.299	0.3-0.625	0.626+	Total
0	6	2	3	1	12
0.1-0.299	9	4	2	1	16
0.3-0.625	9	2	3	1	15
0.626+	12	1	2	1	16
Total	36	9	10	4	59

	chi2	df	Prob>chi2
Symmetry (asymptotic)	17.10	6	0.0089
Marginal homogeneity (Stuart-Maxwell)	16.96	3	0.0007

Both the test of symmetry and the test of marginal homogeneity are highly significant, thus leading us to reject the null hypothesis that there is no effect of exposure to estrogen on the risk of endometrial cancer.

Breslow and Day perform a test for trend assuming that the estrogen exposure levels were equally spaced by recoding the exposure levels as 1, 2, 3, and 4.

We can easily reproduce their results by recoding our data in this way and by specifying the `trend` option. Two new numeric variables were created, `ca` and `co`, corresponding to the variables `case` and `control`, respectively. Below we list some of the data and our results from `symmetry`:

```
. encode case, gen(ca)
. encode control, gen(co)
. label values ca
. label values co
. list in 1/4
```

	case	control	count	ca	co
1.	0	0	6	1	1
2.	0	0.1-0.299	2	1	2
3.	0	0.3-0.625	3	1	3
4.	0	0.626+	1	1	4

```
. symmetry ca co [fw=count], notable trend cc
```

	chi2	df	Prob>chi2
Symmetry (asymptotic)	17.10	6	0.0089
Marginal homogeneity (Stuart-Maxwell)	16.96	3	0.0007
Linear trend in the (log) RR	14.43	1	0.0001

We requested the continuity correction by specifying `cc`. Doing so is appropriate because our coded exposure levels are equally spaced.

The test for trend was highly significant, indicating an increased risk of endometrial cancer with increased dosage of conjugated estrogen.

You must be cautious: the way in which you code the exposure variable affects the linear trend statistic. If instead of coding the levels as 1, 2, 3, and 4, we had instead used 0, 0.2, 0.46, and 0.7 (roughly the midpoint in the range of each level), we would have obtained a χ^2 statistic of 11.19 for these data.

◁

Stored results

`symmetry` stores the following in `r()`:

Scalars

`r(N_pair)`	number of matched pairs
`r(chi2)`	asymptotic symmetry χ^2
`r(df)`	asymptotic symmetry degrees of freedom
`r(p)`	asymptotic symmetry p-value
`r(chi2_sm)`	MH (Stuart–Maxwell) χ^2
`r(df_sm)`	MH (Stuart–Maxwell) degrees of freedom
`r(p_sm)`	MH (Stuart–Maxwell) p-value
`r(chi2_b)`	MH (Bickenböller) χ^2
`r(df_b)`	MH (Bickenböller) degrees of freedom
`r(p_b)`	MH (Bickenböller) p-value
`r(chi2_nd)`	MH (no diagonals) χ^2
`r(df_nd)`	MH (no diagonals) degrees of freedom
`r(p_nd)`	MH (no diagonals) p-value
`r(chi2_t)`	χ^2 for linear trend
`r(p_trend)`	p-value for linear trend
`r(p_exact)`	exact symmetry p-value

Methods and formulas

Methods and formulas are presented under the following headings:

Asymptotic tests
Exact symmetry test

Asymptotic tests

Consider a square table with K exposure categories, that is, K rows and K columns. Let n_{ij} be the count corresponding to row i and column j of the table, $N_{ij} = n_{ij} + n_{ji}$, for $i, j = 1, 2, \ldots, K$, and $n_{i.}$, and let $n_{.j}$ be the marginal totals for row i and column j, respectively. Asymptotic tests for symmetry and marginal homogeneity for this $K \times K$ table are calculated as follows:

The null hypothesis of complete symmetry $p_{ij} = p_{ji}$, $i \neq j$, is tested by calculating the test statistic (Bowker 1948)

$$T_{\text{cs}} = \sum_{i<j} \frac{(n_{ij} - n_{ji})^2}{n_{ij} + n_{ji}}$$

which is asymptotically distributed as χ^2 with $K(K-1)/2 - R$ degrees of freedom, where R is the number of off-diagonal cells with $N_{ij} = 0$.

The null hypothesis of marginal homogeneity, $p_{i.} = p_{.i}$, is tested by calculating the Stuart–Maxwell test statistic (Stuart 1955; Maxwell 1970),

$$T_{\text{sm}} = \mathbf{d}'\mathbf{V}^{-1}\mathbf{d}$$

where $\mathbf{d}$ is a column vector with elements equal to the differences $d_i = n_{i.} - n_{.i}$ for $i = 1, 2, \ldots, K$, and $\mathbf{V}$ is the variance–covariance matrix with elements

$$v_{ii} = n_{i.} + n_{.i} - 2n_{ii}$$
$$v_{ij} = -(n_{ij} + n_{ji}), \quad i \neq j$$

T_{sm} is asymptotically χ^2 with $K - 1$ degrees of freedom.

This test statistic properly accounts for the dependence between the table's rows and columns. When the matrix $\mathbf{V}$ is not of full rank, a generalized inverse $\mathbf{V}^*$ is substituted for $\mathbf{V}^{-1}$.

The Bickeböller and Clerget-Darpoux (1995) marginal homogeneity test statistic is calculated by

$$T_{\text{mh}} = \sum_i \frac{(n_{i.} - n_{.i})^2}{n_{i.} + n_{.i}}$$

This statistic is asymptotically distributed, under the assumption of marginal independence, as χ^2 with $K - 1$ degrees of freedom.

The marginal homogeneity (no diagonals) test statistic T^0_{mh} is calculated in the same way as T_{mh}, except that the diagonal elements do not enter into the calculation of the marginal totals. Unlike the previous test statistic, T^0_{mh} reduces to a McNemar test statistic for 2×2 tables. The test statistic $\{(K-1)/2\}T^0_{\text{mh}}$ is asymptotically distributed as χ^2 with $K - 1$ degrees of freedom (Cleves, Olson, and Jacobs 1997; Spieldman and Ewens 1996).

Breslow and Day's test statistic for linear trend in the (log) of RR is

$$\frac{\left\{\sum_{i<j}(n_{ij} - n_{ji})(X_j - X_i) - cc\right\}^2}{\sum_{i<j}(n_{ij} + n_{ji})(X_j - X_i)^2}$$

where the X_j are the doses associated with the various levels of exposure and cc is the continuity correction; it is asymptotically distributed as χ^2 with 1 degree of freedom.

The continuity correction option is applicable only when the levels of the exposure variable are equally spaced.

Exact symmetry test

The exact test is based on a permutation algorithm applied to the null distribution. The distribution of the off-diagonal elements n_{ij}, $i \neq j$, conditional on the sum of the complementary off-diagonal cells, $N_{ij} = n_{ij} + n_{ji}$, can be written as the product of $K(K-1)/2$ binomial random variables,

$$P(\mathbf{n}) = \prod_{i<j} \binom{N_{ij}}{n_{ij}} {\pi_{ij}}^{n_{ij}} (1 - \pi_{ij})^{n_{ij}}$$

where $\mathbf{n}$ is a vector with elements n_{ij} and $\pi_{ij} = E(n_{ij}/N_{ij}|N_{ij})$. Under the null hypothesis of complete symmetry, $\pi_{ij} = \pi_{ji} = 1/2$, and thus the permutation distribution is given by

$$P_0(\mathbf{n}) = \prod_{i<j} \binom{N_{ij}}{n_{ij}} \left(\frac{1}{2}\right)^{N_{ij}}$$

The exact significance test is performed by evaluating

$$P_{\text{cs}} = \sum_{n \in p} P_0(\mathbf{n})$$

where $p = \{n : P_0(\mathbf{n}) < P_0(\mathbf{n}^*)\}$ and $\mathbf{n}^*$ is the observed contingency table data vector. The algorithm evaluates p_{cs} exactly. For information about permutation tests, see Good (2005, 2006).

```
table rowvar [colvar [supercolvar]] [if] [in] [weight] [, options]
```

options	Description
Main	
`contents(`*clist*`)`	contents of table cells; select up to five statistics; default is `contents(freq)`
`by(`*superrowvarlist*`)`	superrow variables
Options	
`cellwidth(#)`	cell width
`csepwidth(#)`	column-separation width
`stubwidth(#)`	stub width
`scsepwidth(#)`	supercolumn-separation width
`center`	center-align table cells; default is right-align
`left`	left-align table cells; default is right-align
`cw`	perform casewise deletion
`row`	add row totals
`column`	add column totals
`scolumn`	add supercolumn totals
`concise`	suppress rows with all missing entries
`missing`	show missing statistics with period
`replace`	replace current data with table statistics
`name(`*string*`)`	name new variables with prefix *string*
`format(%`*fmt*`)`	display format for numbers in cells; default is `format(%9.0g)`

`by` is allowed; see [D] **by**.

`fweights`, `iweights`, and `pweights` are allowed; see [U] **11.1.6 weight**. `pweights` may not be used with `sd`, `semean`, `sebinomial`, or `sepoisson`. `iweights` may not be used with `semean`, `sebinomial`, or `sepoisson`.

where the elements of *clist* may be

`freq`	frequency	`n` *varname*	same as `count`
`mean` *varname*	mean of *varname*	`max` *varname*	maximum
`sd` *varname*	standard deviation	`min` *varname*	minimum
`semean` *varname*	standard error of the mean (`sd/sqrt(n)`)	`median` *varname*	median
		`p1` *varname*	1st percentile
`sebinomial` *varname*	standard error of the mean, binomial distribution (`sqrt(p(1-p)/n)`)	`p2` *varname*	2nd percentile
		`...`	3rd–49th percentiles
`sepoisson` *varname*	standard error of the mean, Poisson distribution (`sqrt(mean)`)	`p50` *varname*	50th percentile (`median`)
		`...`	51st–97th percentiles
`sum` *varname*	sum	`p98` *varname*	98th percentile
`rawsum` *varname*	sums ignoring optionally specified weight	`p99` *varname*	99th percentile
`count` *varname*	count of nonmissing observations	`iqr` *varname*	interquartile range

Rows, columns, supercolumns, and superrows are thus defined as

row 1	.
row 2	.

	supercol 1		supercol 2	
	col 1	col 2	col 1	col 2
row 1	.	.	.	.
row 2	.	.	.	.

	col 1	col 2
row 1	.	.
row 2	.	.

	supercol 1		supercol 2	
	col 1	col 2	col 1	col 2
superrow 1:				
row 1	.	.	.	.
row 2	.	.	.	.
superrow 2:				
row 1	.	.	.	.
row 2	.	.	.	.

Menu

Statistics > Summaries, tables, and tests > Other tables > Flexible table of summary statistics

Description

`table` calculates and displays tables of statistics.

Options

Main

`contents(`*clist*`)` specifies the contents of the table's cells; if not specified, `contents(freq)` is used by default. `contents(freq)` produces a table of frequencies. `contents(mean mpg)` produces a table of the means of variable `mpg`. `contents(freq mean mpg sd mpg)` produces a table of frequencies together with the mean and standard deviation of variable `mpg`. Up to five statistics may be specified.

`by(`*superrowvarlist*`)` specifies that numeric or string variables be treated as superrows. Up to four variables may be specified in *superrowvarlist*. The `by()` option may be specified with the `by` prefix.

Options

`cellwidth(#)` specifies the width of the cell in units of digit widths; 10 means the space occupied by 10 digits, which is `0123456789`. The default `cellwidth()` is not a fixed number, but a number chosen by `table` to spread the table out while presenting a reasonable number of columns across the page.

`csepwidth(#)` specifies the separation between columns in units of digit widths. The default is not a fixed number, but a number chosen by `table` according to what it thinks looks best.

`stubwidth(#)` specifies the width, in units of digit widths, to be allocated to the left stub of the table. The default is not a fixed number, but a number chosen by `table` according to what it thinks looks best.

`scsepwidth(#)` specifies the separation between supercolumns in units of digit widths. The default is not a fixed number, but a number chosen by `table` to present the results best.

`center` specifies that results be centered in the table's cells. The default is to right-align results. For centering to work well, you typically need to specify a display format as well. `center format(%9.2f)` is popular.

`left` specifies that column labels be left-aligned. The default is to right-align column labels to distinguish them from supercolumn labels, which are left-aligned.

`cw` specifies casewise deletion. If `cw` is not specified, all observations possible are used to calculate each of the specified statistics. `cw` is relevant only when you request a table containing statistics on multiple variables. For instance, `contents(mean mpg mean weight)` would produce a table reporting the means of variables `mpg` and `weight`. Consider an observation in which `mpg` is known but `weight` is missing. By default, that observation will be used in the calculation of the mean of `mpg`. If you specify `cw`, the observation will be excluded in the calculation of the means of both `mpg` and `weight`.

`row` specifies that a row be added to the table reflecting the total across the rows.

`column` specifies that a column be added to the table reflecting the total across columns.

`scolumn` specifies that a supercolumn be added to the table reflecting the total across supercolumns.

`concise` specifies that rows with all missing entries not be displayed.

`missing` specifies that missing statistics be shown in the table as periods (Stata's missing-value indicator). The default is that missing entries be left blank.

`replace` specifies that the data in memory be replaced with data containing 1 observation per cell (row, column, supercolumn, and superrow) and with variables containing the statistics designated in `contents()`.

This option is rarely specified. If you do not specify this option, the data in memory remain unchanged.

If you do specify this option, the first statistic will be named `table1`, the second `table2`, and so on. For instance, if `contents(mean mpg sd mpg)` was specified, the means of `mpg` would be in variable `table1` and the standard deviations in `table2`.

`name(`*string*`)` is relevant only if you specify `replace`. `name()` allows changing the default stub name that `replace` uses to name the new variables associated with the statistics. If you specify `name(stat)`, the first statistic will be placed in variable `stat1`, the second in `stat2`, and so on.

`format(%`*fmt*`)` specifies the display format for presenting numbers in the table's cells. `format(%9.0g)` is the default; `format(%9.2f)` and `format(%9.2fc)` are popular alternatives. The width of the format you specify does not matter, except that `%`*fmt* must be valid. The width of the cells is chosen by `table` to present the results best. The `cellwidth()` option allows you to override `table`'s choice.

Limits

Up to four variables may be specified in the by(), so with the three row, column, and supercolumn variables, seven-way tables may be displayed.

Up to five statistics may be displayed in each cell of the table.

The sum of the number of rows, columns, supercolumns, and superrows is called the number of margins. A table may contain up to 3,000 margins. Thus a one-way table may contain 3,000 rows. A two-way table could contain 2,998 rows and two columns, 2,997 rows and three columns, ..., 1,500 rows and 1,500 columns, ..., two rows and 2,998 columns. A three-way table is similarly limited by the sum of the number of rows, columns, and supercolumns. A $r \times c \times d$ table is feasible if $r + c + d \leq 3{,}000$. The limit is set in terms of the sum of the rows, columns, supercolumns, and superrows, and not, as you might expect, in terms of their product.

Remarks and examples

Remarks are presented under the following headings:

One-way tables
Two-way tables
Three-way tables
Four-way and higher-dimensional tables
Video example

One-way tables

▷ Example 1

From the automobile dataset, here is a simple one-way table:

```
. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
. table rep78, contents(mean mpg)
```

Repair Record 1978	mean(mpg)
Poor	21
Fair	19.125
Average	19.4333
Good	21.6667
Excellent	27.3636

We are not limited to including only one statistic:

```
. table rep78, c(n mpg  mean mpg  sd mpg  median mpg)
```

Repair Record 1978	N(mpg)	mean(mpg)	sd(mpg)	med(mpg)
Poor	2	21	4.24264	21
Fair	8	19.125	3.758324	18
Average	30	19.4333	4.141325	19
Good	18	21.6667	4.93487	22.5
Excellent	11	27.3636	8.732385	30

We abbreviated `contents()` as `c()`. The `format()` option will allow us to better format the numbers in the table:

```
. table rep78, c(n mpg  mean mpg  sd mpg  median mpg) format(%9.2f)
```

Repair Record 1978	N(mpg)	mean(mpg)	sd(mpg)	med(mpg)
Poor	2	21.00	4.24	21.00
Fair	8	19.12	3.76	18.00
Average	30	19.43	4.14	19.00
Good	18	21.67	4.93	22.50
Excellent	11	27.36	8.73	30.00

The `center` option will center the results under the headings:

```
. table rep78, c(n mpg  mean mpg  sd mpg  median mpg) format(%9.2f) center
```

Repair Record 1978	N(mpg)	mean(mpg)	sd(mpg)	med(mpg)
Poor	2	21.00	4.24	21.00
Fair	8	19.12	3.76	18.00
Average	30	19.43	4.14	19.00
Good	18	21.67	4.93	22.50
Excellent	11	27.36	8.73	30.00

◁

Two-way tables

▷ Example 2

In example 1, when we typed '`table rep78, ...`', we obtained a one-way table. If we were to type '`table rep78 foreign, ...`', we would obtain a two-way table:

```
. table rep78 foreign, c(mean mpg)
```

Repair Record 1978	Car type Domestic	Foreign
Poor	21	
Fair	19.125	
Average	19	23.3333
Good	18.4444	24.8889
Excellent	32	26.3333

Note the missing cells. Certain combinations of repair record and car type do not exist in our dataset.

As with one-way tables, we can specify a display format for the cells and center the numbers within the cells if we wish.

```
. table rep78 foreign, c(mean mpg) format(%9.2f) center
```

Repair Record 1978	Car type	
	Domestic	Foreign
Poor	21.00	
Fair	19.12	
Average	19.00	23.33
Good	18.44	24.89
Excellent	32.00	26.33

We can obtain row totals by specifying the `row` option and obtain column totals by specifying the `col` option. We specify both below:

```
. table rep78 foreign, c(mean mpg) format(%9.2f) center row col
```

Repair Record 1978	Car type		
	Domestic	Foreign	Total
Poor	21.00		21.00
Fair	19.12		19.12
Average	19.00	23.33	19.43
Good	18.44	24.89	21.67
Excellent	32.00	26.33	27.36
Total	19.54	25.29	21.29

`table` can display multiple statistics within cells, but once we move beyond one-way tables, the table becomes busy:

```
. table foreign rep78, c(mean mpg  n mpg) format(%9.2f) center
```

	Repair Record 1978				
Car type	Poor	Fair	Average	Good	Excellent
Domestic	21.00	19.12	19.00	18.44	32.00
	2	8	27	9	2
Foreign			23.33	24.89	26.33
			3	9	9

This two-way table with two statistics per cell works well here. That was, in part, helped along by our interchanging the rows and columns. We turned the table around by typing `table foreign rep78` rather than `table rep78 foreign`.

Another way to display two-way tables is to specify a row and superrow rather than a row and column. We do that below and display three statistics per cell:

```
. table foreign, by(rep78) c(mean mpg  sd mpg  n mpg) format(%9.2f) center
```

Repair Record 1978 and Car type	mean(mpg)	sd(mpg)	N(mpg)
Poor			
Domestic	21.00	4.24	2
Foreign			
Fair			
Domestic	19.12	3.76	8
Foreign			
Average			
Domestic	19.00	4.09	27
Foreign	23.33	2.52	3
Good			
Domestic	18.44	4.59	9
Foreign	24.89	2.71	9
Excellent			
Domestic	32.00	2.83	2
Foreign	26.33	9.37	9

Three-way tables

▷ Example 3

We have data on the prevalence of byssinosis, a form of pneumoconiosis to which workers exposed to cotton dust are susceptible. The dataset is on 5,419 workers in a large cotton mill. We know whether each worker smokes, his or her race, and the dustiness of the work area. The categorical variables are

smokes	Smoker or nonsmoker in the last five years.
race	White or other.
workplace	1 (most dusty), 2 (less dusty), 3 (least dusty).

Moreover, this dataset includes a frequency-weight variable pop. Here is a three-way table showing the fraction of workers with byssinosis:

```
. use http://www.stata-press.com/data/r13/byssin
(Byssinosis incidence)
. table workplace smokes race [fw=pop], c(mean prob)
```

Dustiness of workplace	Race and Smokes			
	other		white	
	no	yes	no	yes
least	.0107527	.0101523	.0081549	.0162774
less	.02	.0081633	.0136612	.0143149
most	.0820896	.1679105	.0833333	.2295082

This table would look better if we showed the fraction to four digits:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f)
```

Dustiness of workplace	Race and Smokes			
	other		white	
	no	yes	no	yes
least	0.0108	0.0102	0.0082	0.0163
less	0.0200	0.0082	0.0137	0.0143
most	0.0821	0.1679	0.0833	0.2295

In this table, the rows are the dustiness of the workplace, the columns are whether the worker smokes, and the supercolumns are the worker's race.

Now we request that the table include the supercolumn totals by specifying the `sctotal` option, which we can abbreviate as `sc`:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f) sc
```

Dustiness of workplace	Race and Smokes					
	other		white		Total	
	no	yes	no	yes	no	yes
least	0.0108	0.0102	0.0082	0.0163	0.0090	0.0145
less	0.0200	0.0082	0.0137	0.0143	0.0159	0.0123
most	0.0821	0.1679	0.0833	0.2295	0.0826	0.1929

The supercolumn total is the total over `race` and is divided into its columns based on `smokes`. Here is the table with the column rather than the supercolumn totals:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f) col
```

Dustiness of workplace	Race and Smokes					
	other			white		
	no	yes	Total	no	yes	Total
least	0.0108	0.0102	0.0104	0.0082	0.0163	0.0129
less	0.0200	0.0082	0.0135	0.0137	0.0143	0.0140
most	0.0821	0.1679	0.1393	0.0833	0.2295	0.1835

Here is the table with both column and supercolumn totals:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f) sc col
```

Dustiness of workplace	Race and Smokes								
	other			white			Total		
	no	yes	Total	no	yes	Total	no	yes	Total
least	0.0108	0.0102	0.0104	0.0082	0.0163	0.0129	0.0090	0.0145	0.0122
less	0.0200	0.0082	0.0135	0.0137	0.0143	0.0140	0.0159	0.0123	0.0138
most	0.0821	0.1679	0.1393	0.0833	0.2295	0.1835	0.0826	0.1929	0.1570

`table` is struggling to keep this table from becoming too wide—notice how it divided the words in the title in the top-left stub. Here, if the table had more columns, or, if we demanded more digits, `table` would be forced to segment the table and present it in pieces, which it would do:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.6f) sc col
```

Dustiness of workplace	Race and Smokes: other: no	other: yes	other: Total	white: no	white: yes	white: Total
least	0.010753	0.010152	0.010417	0.008155	0.016277	0.012949
less	0.020000	0.008163	0.013483	0.013661	0.014315	0.014035
most	0.082090	0.167910	0.139303	0.083333	0.229508	0.183521

Dustiness of workplace	Race and Smokes: Total: no	Total: yes	Total: Total
least	0.008990	0.014471	0.012174
less	0.015901	0.012262	0.013846
most	0.082569	0.192905	0.156951

Here three digits is probably enough, so here is the table including all the row, column, and supercolumn totals:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.3f) sc col row
```

Dustiness of workplace	Race and Smokes: other: no	other: yes	other: Total	white: no	white: yes	white: Total	Total: no	Total: yes	Total: Total
least	0.011	0.010	0.010	0.008	0.016	0.013	0.009	0.014	0.012
less	0.020	0.008	0.013	0.014	0.014	0.014	0.016	0.012	0.014
most	0.082	0.168	0.139	0.083	0.230	0.184	0.083	0.193	0.157
Total	0.025	0.048	0.038	0.014	0.035	0.026	0.018	0.039	0.030

We can show multiple statistics:

```
. table workplace smokes race [fw=pop], c(mean prob  n prob) format(%9.3f) sc
> col row
```

Dustiness of workplace	Race and Smokes: other: no	other: yes	other: Total	white: no	white: yes	white: Total	Total: no	Total: yes	Total: Total
least	0.011	0.010	0.010	0.008	0.016	0.013	0.009	0.014	0.012
	465	591	1,056	981	1,413	2,394	1,446	2,004	3,450
less	0.020	0.008	0.013	0.014	0.014	0.014	0.016	0.012	0.014
	200	245	445	366	489	855	566	734	1,300
most	0.082	0.168	0.139	0.083	0.230	0.184	0.083	0.193	0.157
	134	268	402	84	183	267	218	451	669
Total	0.025	0.048	0.038	0.014	0.035	0.026	0.018	0.039	0.030
	799	1,104	1,903	1,431	2,085	3,516	2,230	3,189	5,419

◁

Four-way and higher-dimensional tables

▷ Example 4

Let's pretend that our byssinosis dataset also recorded each worker's sex (it does not, and we have made up this extra information). We obtain a four-way table just as we would a three-way table, but we specify the fourth variable as a superrow by including it in the `by()` option:

```
. use http://www.stata-press.com/data/r13/byssin1
(Byssinosis incidence)
. table workplace smokes race [fw=pop], by(sex) c(mean prob)  format(%9.3f) sc
> col row
```

Sex and Dustiness of workplace	Race and Smokes: other — no	other — yes	other — Total	white — no	white — yes	white — Total	Total — no	Total — yes	Total — Total
Female									
least	0.006	0.009	0.008	0.009	0.021	0.016	0.009	0.018	0.014
less	0.020	0.008	0.010	0.015	0.015	0.015	0.016	0.012	0.014
most	0.057	0.154	0.141				0.057	0.154	0.141
Total	0.017	0.051	0.043	0.011	0.020	0.016	0.012	0.032	0.024
Male									
least	0.013	0.011	0.012	0.006	0.007	0.006	0.009	0.008	0.009
less	0.020	0.000	0.019	0.000	0.013	0.011	0.016	0.013	0.014
most	0.091	0.244	0.136	0.083	0.230	0.184	0.087	0.232	0.167
Total	0.029	0.041	0.033	0.020	0.056	0.043	0.025	0.052	0.039

If our dataset also included work group and we wanted a five-way table, we could include both the sex and work-group variables in the `by()` option. You may include up to four variables in `by()`, and so produce up to 7-way tables.

[D] **collapse** — Make dataset of summary statistics

[P] **tabdisp** — Display tables

Title

tabstat — Compact table of summary statistics

Syntax | Menu | Description | Options
Remarks and examples | Acknowledgments | Also see

Syntax

```
tabstat varlist [if] [in] [weight] [, options]
```

options	Description
Main	
`by(`*varname*`)`	group statistics by variable
`statistics(`*statname*`[...])`	report specified statistics
Options	
`labelwidth(#)`	width for `by()` variable labels; default is `labelwidth(16)`
`varwidth(#)`	variable width; default is `varwidth(12)`
`columns(variables)`	display variables in table columns; the default
`columns(statistics)`	display statistics in table columns
`format[(%`*fmt*`)]`	display format for statistics; default format is `%9.0g`
`casewise`	perform casewise deletion of observations
`nototal`	do not report overall statistics; use with `by()`
`missing`	report statistics for missing values of `by()` variable
`noseparator`	do not use separator line between `by()` categories
`longstub`	make left table stub wider
`save`	store summary statistics in `r()`

`by` is allowed; see [D] **by**.

`aweights` and `fweights` are allowed; see [U] **11.1.6 weight**.

Menu

Statistics > Summaries, tables, and tests > Other tables > Compact table of summary statistics

Description

`tabstat` displays summary statistics for a series of numeric variables in one table, possibly broken down on (conditioned by) another variable.

Without the `by()` option, `tabstat` is a useful alternative to `summarize` (see [R] **summarize**) because it allows you to specify the list of statistics to be displayed.

With the `by()` option, `tabstat` resembles `tabulate` used with its `summarize()` option in that both report statistics of *varlist* for the different values of *varname*. `tabstat` allows more flexibility in terms of the statistics presented and the format of the table.

`tabstat` is sensitive to the `linesize` (see `set linesize` in [R] **log**); it widens the table if possible and wraps if necessary.

Options

Main

`by(`*varname*`)` specifies that the statistics be displayed separately for each unique value of *varname*; *varname* may be numeric or string. For instance, `tabstat height` would present the overall mean of height. `tabstat height, by(sex)` would present the mean height of males, and of females, and the overall mean height. Do not confuse the `by()` option with the `by` prefix (see [D] **by**); both may be specified.

`statistics(`*statname* `[...])` specifies the statistics to be displayed; the default is equivalent to specifying `statistics(mean)`. (`stats()` is a synonym for `statistics()`.) Multiple statistics may be specified and are separated by white space, such as `statistics(mean sd)`. Available statistics are

statname	Definition	*statname*	Definition
`mean`	mean	`p1`	1st percentile
`count`	count of nonmissing observations	`p5`	5th percentile
`n`	same as `count`	`p10`	10th percentile
`sum`	sum	`p25`	25th percentile
`max`	maximum	`median`	median (same as `p50`)
`min`	minimum	`p50`	50th percentile (same as `median`)
`range`	range = `max` − `min`	`p75`	75th percentile
`sd`	standard deviation	`p90`	90th percentile
`variance`	variance	`p95`	95th percentile
`cv`	coefficient of variation (`sd/mean`)	`p99`	99th percentile
`semean`	standard error of mean ($\texttt{sd}/\sqrt{\texttt{n}}$)	`iqr`	interquartile range = `p75` − `p25`
`skewness`	skewness	`q`	equivalent to specifying `p25 p50 p75`
`kurtosis`	kurtosis		

Options

`labelwidth(#)` specifies the maximum width to be used within the stub to display the labels of the `by()` variable. The default is `labelwidth(16)`. $8 \leq \# \leq 32$.

`varwidth(#)` specifies the maximum width to be used within the stub to display the names of the variables. The default is `varwidth(12)`. `varwidth()` is effective only with `columns(statistics)`. Setting `varwidth()` implies `longstub`. $8 \leq \# \leq 16$.

`columns(variables | statistics)` specifies whether to display variables or statistics in the columns of the table. `columns(variables)` is the default when more than one variable is specified.

`format` and `format(%`*fmt*`)` specify how the statistics are to be formatted. The default is to use a `%9.0g` format.

`format` specifies that each variable's statistics be formatted with the variable's display format; see [D] **format**.

`format(%`*fmt*`)` specifies the format to be used for all statistics. The maximum width of the specified format should not exceed nine characters.

`casewise` specifies casewise deletion of observations. Statistics are to be computed for the sample that is not missing for any of the variables in *varlist*. The default is to use all the nonmissing values for each variable.

`nototal` is for use with `by()`; it specifies that the overall statistics not be reported.

missing specifies that missing values of the by() variable be treated just like any other value and that statistics should be displayed for them. The default is not to report the statistics for the by()== *missing* group. If the by() variable is a string variable, by()="" is considered to mean missing.

noseparator specifies that a separator line between the by() categories not be displayed.

longstub specifies that the left stub of the table be made wider so that it can include names of the statistics or variables in addition to the categories of by(*varname*). The default is to describe the statistics or variables in a header. longstub is ignored if by(*varname*) is not specified.

save specifies that the summary statistics be returned in r(). The overall (unconditional) statistics are returned in matrix r(StatTotal) (rows are statistics, columns are variables). The conditional statistics are returned in the matrices r(Stat1), r(Stat2), ..., and the names of the corresponding variables are returned in the macros r(name1), r(name2), ...

Remarks and examples

This command is probably most easily understood by going through a series of examples.

▷ Example 1

We have data on the price, weight, mileage rating, and repair record of 22 foreign and 52 domestic 1978 automobiles. We want to summarize these variables for the different origins of the automobiles.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. tabstat price weight mpg rep78, by(foreign)
Summary statistics: mean
  by categories of: foreign (Car type)
 foreign |     price    weight       mpg     rep78
---------+--------------------------------------------
Domestic |  6072.423  3317.115  19.82692  3.020833
 Foreign |  6384.682  2315.909  24.77273  4.285714
---------+--------------------------------------------
   Total |  6165.257  3019.459   21.2973  3.405797
------------------------------------------------------
```

More summary statistics can be requested via the statistics() option. The group totals can be suppressed with the nototal option.

```
. tabstat price weight mpg rep78, by(foreign) stat(mean sd min max) nototal
Summary statistics: mean, sd, min, max
  by categories of: foreign (Car type)
 foreign |     price    weight       mpg     rep78
---------+--------------------------------------------
Domestic |  6072.423  3317.115  19.82692  3.020833
         |  3097.104  695.3637  4.743297   .837666
         |      3291      1800        12         1
         |     15906      4840        34         5
---------+--------------------------------------------
 Foreign |  6384.682  2315.909  24.77273  4.285714
         |  2621.915  433.0035  6.611187  .7171372
         |      3748      1760        14         3
         |     12990      3420        41         5
------------------------------------------------------
```

Although the header of the table describes the statistics running vertically in the "cells", the table may become hard to read, especially with many variables or statistics. The longstub option specifies that a column be added describing the contents of the cells. The format option can be issued to

specify that tabstat display the statistics by using the display format of the variables rather than the overall default %9.0g.

```
. tabstat price weight mpg rep78, by(foreign) stat(mean sd min max) long format
```

foreign	stats	price	weight	mpg	rep78
Domestic	mean	6,072.4	3,317.1	19.8269	3.02083
	sd	3,097.1	695.364	4.7433	.837666
	min	3,291	1,800	12	1
	max	15,906	4,840	34	5
Foreign	mean	6,384.7	2,315.9	24.7727	4.28571
	sd	2,621.9	433.003	6.61119	.717137
	min	3,748	1,760	14	3
	max	12,990	3,420	41	5
Total	mean	6,165.3	3,019.5	21.2973	3.4058
	sd	2,949.5	777.194	5.7855	.989932
	min	3,291	1,760	12	1
	max	15,906	4,840	41	5

We can specify a layout of the table in which the statistics run horizontally and the variables run vertically by specifying the col(statistics) option.

```
. tabstat price weight mpg rep78, by(foreign) stat(min mean max) col(stat) long
```

foreign	variable	min	mean	max
Domestic	price	3291	6072.423	15906
	weight	1800	3317.115	4840
	mpg	12	19.82692	34
	rep78	1	3.020833	5
Foreign	price	3748	6384.682	12990
	weight	1760	2315.909	3420
	mpg	14	24.77273	41
	rep78	3	4.285714	5
Total	price	3291	6165.257	15906
	weight	1760	3019.459	4840
	mpg	12	21.2973	41
	rep78	1	3.405797	5

Finally, tabstat can also be used to enhance summarize so we can specify the statistics to be displayed. For instance, we can display the number of observations, the mean, the coefficient of variation, and the 25%, 50%, and 75% quantiles for a list of variables.

```
. tabstat price weight mpg rep78, stat(n mean cv q) col(stat)
```

variable	N	mean	cv	p25	p50	p75
price	74	6165.257	.478406	4195	5006.5	6342
weight	74	3019.459	.2573949	2240	3190	3600
mpg	74	21.2973	.2716543	18	20	25
rep78	69	3.405797	.290661	3	3	4

Because we did not specify the by() option, these statistics were not displayed for the subgroups of the data formed by the categories of the by() variable.

Title

tabulate oneway — One-way table of frequencies

Syntax | Menu | Description | Options
Remarks and examples | Stored results | References | Also see

Syntax

One-way table

`tabulate` *varname* [*if*] [*in*] [*weight*] [, *tabulate1_options*]

One-way table for each variable—a convenience tool

`tab1` *varlist* [*if*] [*in*] [*weight*] [, *tab1_options*]

tabulate1_options	Description
Main	
`subpop(`*varname*`)`	exclude observations for which *varname* = 0
`missing`	treat missing values like other values
`nofreq`	do not display frequencies
`nolabel`	display numeric codes rather than value labels
`plot`	produce a bar chart of the relative frequencies
`sort`	display the table in descending order of frequency
Advanced	
`generate(`*stubname*`)`	create indicator variables for *stubname*
`matcell(`*matname*`)`	save frequencies in *matname*; programmer's option
`matrow(`*matname*`)`	save unique values of *varname* in *matname*; programmer's option

tab1_options	Description
Main	
`subpop(`*varname*`)`	exclude observations for which *varname* = 0
`missing`	treat missing values like other values
`nofreq`	do not display frequencies
`nolabel`	display numeric codes rather than value labels
`plot`	produce a bar chart of the relative frequencies
`sort`	display the table in descending order of frequency

`by` is allowed with `tabulate` and `tab1`; see [D] **by**.

`fweights`, `aweights`, and `iweights` are allowed by `tabulate`. `fweights` are allowed by `tab1`. See [U] **11.1.6 weight**.

Menu

tabulate oneway

Statistics > Summaries, tables, and tests > Frequency tables > One-way table

tabulate ..., generate()

Data > Create or change data > Other variable-creation commands > Create indicator variables

tab1

Statistics > Summaries, tables, and tests > Frequency tables > Multiple one-way tables

Description

`tabulate` produces a one-way table of frequency counts.

For information about a two-way table of frequency counts along with various measures of association, including the common Pearson χ^2, the likelihood-ratio χ^2, Cramér's V, Fisher's exact test, Goodman and Kruskal's gamma, and Kendall's τ_b, see [R] **tabulate twoway**.

`tab1` produces a one-way tabulation for each variable specified in *varlist*.

Also see [R] **table** and [R] **tabstat** if you want one-, two-, or n-way table of frequencies and a wide variety of summary statistics. See [R] **tabulate, summarize()** for a description of `tabulate` with the `summarize()` option; it produces a table (breakdowns) of means and standard deviations. `table` is better than `tabulate, summarize()`, but `tabulate, summarize()` is faster. See [ST] **epitab** for a 2×2 table with statistics of interest to epidemiologists.

Options

Main

`subpop(`*varname*`)` excludes observations for which *varname* $= 0$ in tabulating frequencies. The mathematical results of `tabulate ..., subpop(myvar)` are the same as `tabulate ... if myvar !=0`, but the table may be presented differently. The identities of the rows and columns will be determined from all the data, including the `myvar` $= 0$ group, so there may be entries in the table with frequency 0.

Consider tabulating `answer`, a variable that takes on values 1, 2, and 3, but consider tabulating it just for the `male==1` subpopulation. Assume that `answer` is never 2 in this group. `tabulate answer if male==1` produces a table with two rows: one for answer 1 and one for answer 3. There will be no row for answer 2 because answer 2 was never observed. `tabulate answer, subpop(male)` produces a table with three rows. The row for answer 2 will be shown as having 0 frequency.

`missing` requests that missing values be treated like other values in calculations of counts, percentages, and other statistics.

`nofreq` suppresses the printing of the frequencies.

`nolabel` causes the numeric codes to be displayed rather than the value labels.

`plot` produces a bar chart of the relative frequencies in a one-way table. (Also see [R] **histogram**.)

`sort` puts the table in descending order of frequency (and ascending order of the variable within equal values of frequency).

Advanced

`generate(`*stubname*`)` creates a set of indicator variables (*stubname*`1`, *stubname*`2`, ...) reflecting the observed values of the tabulated variable. The `generate()` option may not be used with the `by` prefix.

`matcell(`*matname*`)` saves the reported frequencies in *matname*. This option is for use by programmers.

`matrow(`*matname*`)` saves the numeric values of the $r \times 1$ row stub in *matname*. This option is for use by programmers. `matrow()` may not be specified if the row variable is a string.

Limits

A one-way table may have a maximum of 12,000 rows (Stata/MP and Stata/SE), 3,000 rows (Stata/IC), or 500 rows (Small Stata).

Remarks and examples

Remarks are presented under the following headings:

tabulate
tab1
Video example

For each value of a specified variable, `tabulate` reports the number of observations with that value. The number of times a value occurs is called its *frequency*.

tabulate

▷ Example 1

We have data summarizing the speed limit and the accident rate per million vehicle miles along various Minnesota highways in 1973. The variable containing the speed limit is called `spdlimit`. If we `summarize` the variable, we obtain its mean and standard deviation:

```
. use http://www.stata-press.com/data/r13/hiway
(Minnesota Highway Data, 1973)
. summarize spdlimit
    Variable |        Obs        Mean    Std. Dev.       Min        Max
-------------+---------------------------------------------------------
    spdlimit |         39          55    5.848977        40         70
```

The average speed limit is 55 miles per hour. We can learn more about this variable by tabulating it:

```
. tabulate spdlimit
Speed Limit |      Freq.     Percent        Cum.
------------+-----------------------------------
         40 |          1        2.56        2.56
         45 |          3        7.69       10.26
         50 |          7       17.95       28.21
         55 |         15       38.46       66.67
         60 |         11       28.21       94.87
         65 |          1        2.56       97.44
         70 |          1        2.56      100.00
------------+-----------------------------------
      Total |         39      100.00
```

We see that one highway has a speed limit of 40 miles per hour, three have speed limits of 45, 7 of 50, and so on. The column labeled `Percent` shows the percentage of highways in the dataset that have the indicated speed limit. For instance, 38.46% of highways in our dataset have a speed limit of 55 miles per hour. The final column shows the cumulative percentage. We see that 66.67% of highways in our dataset have a speed limit of 55 miles per hour or less.

◁

▷ Example 2

The `plot` option places a sideways histogram alongside the table:

```
. tabulate spdlimit, plot
```

Speed Limit	Freq.	
40	1	*
45	3	***
50	7	*******
55	15	***************
60	11	**********
65	1	*
70	1	*
Total	39	

Of course, `graph` can produce better-looking histograms; see [R] **histogram**.

◁

▷ Example 3

`tabulate` labels tables using *variable* and *value labels* if they exist. To demonstrate how this works, let's add a new variable to our dataset that categorizes `spdlimit` into three categories. We will call this new variable `spdcat`:

```
. generate spdcat=recode(spdlimit,50,60,70)
```

The `recode()` function divides `spdlimit` into 50 miles per hour or below, 51–60, and above 60; see [D] **functions**. We specified the breakpoints in the arguments `(spdlimit,50,60,70)`. The first argument is the variable to be recoded. The second argument is the first breakpoint, the third argument is the second breakpoint, and so on. We can specify as many breakpoints as we wish.

`recode()` used our arguments not only as the breakpoints but also to label the results. If `spdlimit` is less than or equal to 50, `spdcat` is set to 50; if `spdlimit` is between 51 and 60, `spdcat` is 60; otherwise, `spdcat` is arbitrarily set to 70. (See [U] **25 Working with categorical data and factor variables**.)

Because we just created the variable `spdcat`, it is not yet labeled. When we make a table using this variable, `tabulate` uses the variable's name to label it:

```
. tabulate spdcat
```

spdcat	Freq.	Percent	Cum.
50	11	28.21	28.21
60	26	66.67	94.87
70	2	5.13	100.00
Total	39	100.00	

Even through the table is not well labeled, `recode()`'s coding scheme provides us with clues as to the table's meaning. The first line of the table corresponds to 50 miles per hour and below, the next to 51 through 60 miles per hour, and the last to above 60 miles per hour.

We can improve this table by labeling the values and variables:

```
. label define scat 50 "40 to 50" 60 "55 to 60" 70 "Above 60"
. label values spdcat scat
. label variable spdcat "Speed Limit Category"
```

We define a *value label* called `scat` that attaches labels to the numbers 50, 60, and 70 using the `label define` command; see **[U] 12.6.3 Value labels**. We label the value 50 as '`40 to 50`', because we looked back at our original tabulation in the first example and saw that the speed limit was never less than 40. Similarly, we could have labeled the last category '`65 to 70`' because the speed limit is never greater than 70 miles per hour.

Next we requested that Stata label the values of the new variable `spdcat` using the value label `scat`. Finally, we labeled our variable `Speed Limit Category`. We are now ready to `tabulate` the result:

```
. tabulate spdcat
Speed Limit
   Category |      Freq.     Percent        Cum.
------------+-----------------------------------
   40 to 50 |         11       28.21       28.21
   55 to 60 |         26       66.67       94.87
   Above 60 |          2        5.13      100.00
------------+-----------------------------------
      Total |         39      100.00
```

◁

▷ Example 4

If we have missing values in our dataset, `tabulate` ignores them unless we explicitly indicate otherwise. We have no missing data in our example, so let's add some:

```
. replace spdcat=. in 39
(1 real change made, 1 to missing)
```

We changed the first observation on `spdcat` to *missing*. Let's now `tabulate` the result:

```
. tabulate spdcat
Speed Limit
   Category |      Freq.     Percent        Cum.
------------+-----------------------------------
   40 to 50 |         11       28.95       28.95
   55 to 60 |         26       68.42       97.37
   Above 60 |          1        2.63      100.00
------------+-----------------------------------
      Total |         38      100.00
```

Comparing this output with that in the previous example, we see that the total frequency count is now one less than it was—38 rather than 39. Also, the '`Above 60`' category now has only one observation where it used to have two, so we evidently changed a road with a high speed limit.

We want `tabulate` to treat missing values just as it treats numbers, so we specify the `missing` option:

```
. tabulate spdcat, missing
```

Speed Limit Category	Freq.	Percent	Cum.
40 to 50	11	28.21	28.21
55 to 60	26	66.67	94.87
Above 60	1	2.56	97.44
.	1	2.56	100.00
Total	39	100.00	

We now see our missing value—the last category, labeled '.', shows a frequency count of 1. The table sum is once again 39.

Let's put our dataset back as it was originally:

```
. replace spdcat=70 in 39
(1 real change made)
```

◁

❑ Technical note

`tabulate` also can automatically create indicator variables from categorical variables. We will briefly review that capability here, but see **[U] 25 Working with categorical data and factor variables** for a complete description. Let's begin by describing our highway dataset:

```
. describe
Contains data from http://www.stata-press.com/data/r13/hiway.dta
  obs:            39                          Minnesota Highway Data, 1973
 vars:             3                          16 Nov 2012 12:39
 size:           351
```

variable name	storage type	display format	value label	variable label
spdlimit	byte	%8.0g		Speed Limit
rate	float	%9.0g	rcat	Accident rate per million vehicle miles
spdcat	float	%9.0g	scat	Speed Limit Category

```
Sorted by:
     Note:  dataset has changed since last saved
```

Our dataset contains three variables. We will type `tabulate spdcat, generate(spd)`, `describe` our data, and then explain what happened.

```
. tabulate spdcat, generate(spd)
```

Speed Limit Category	Freq.	Percent	Cum.
40 to 50	11	28.21	28.21
55 to 60	26	66.67	94.87
Above 60	2	5.13	100.00
Total	39	100.00	

```
. describe

```

When we typed `tabulate` with the `generate()` option, Stata responded by producing a one-way frequency table, so it appeared that the option did nothing. Yet when we `describe` our dataset, we find that we now have *six* variables instead of the original three. The new variables are named `spd1`, `spd2`, and `spd3`.

When we specify the `generate()` option, we are telling Stata to not only produce the table but also create a set of indicator variables that correspond to that table. Stata adds a numeric suffix to the name we specify in the parentheses. `spd1` refers to the first line of the table, `spd2` to the second line, and so on. Also Stata labels the variables so that we know what they mean. `spd1` is an indicator variable that is *true* (takes on the value 1) when `spdcat` is between 40 and 50; otherwise, it is zero. (There is an exception: if `spdcat` is missing, so are the `spd1`, `spd2`, and `spd3` variables. This did not happen in our dataset.)

We want to prove our claim. Because we have not yet introduced two-way tabulations, we will use the `summarize` statement:

```
. summarize spdlimit if spd1==1
    Variable |       Obs        Mean    Std. Dev.       Min        Max
-------------+--------------------------------------------------------
    spdlimit |        11    47.72727    3.437758        40         50

. summarize spdlimit if spd2==1
    Variable |       Obs        Mean    Std. Dev.       Min        Max
-------------+--------------------------------------------------------
    spdlimit |        26    57.11538    2.519157        55         60

. summarize spdlimit if spd3==1
    Variable |       Obs        Mean    Std. Dev.       Min        Max
-------------+--------------------------------------------------------
    spdlimit |         2        67.5    3.535534        65         70
```

Notice the indicated minimum and maximum in each of the tables above. When we restrict the sample to `spd1`, `spdlimit` is between 40 and 50; when we restrict the sample to `spd2`, `spdlimit` is between 55 and 60; when we restrict the sample to `spd3`, `spdlimit` is between 65 and 70.

Thus `tabulate` provides an easy way to create indicator (sometimes called dummy) variables. For an overview of indicator and categorical variables, see **[U] 25 Working with categorical data and factor variables**.

❑

tab1

tab1 is a convenience tool. Typing

```
. tab1 myvar thisvar thatvar, plot
```

is equivalent to typing

```
. tabulate myvar, plot
. tabulate thisvar, plot
. tabulate thatvar, plot
```

Video example

Tables and cross-tabulations in Stata

Stored results

tabulate and tab1 store the following in r():

Scalars

r(N)	number of observations	r(r)	number of rows

Syntax

Two-way table

`tabulate` *varname*$_1$ *varname*$_2$ [*if*] [*in*] [*weight*] [, *options*]

Two-way table for all possible combinations—a convenience tool

`tab2` *varlist* [*if*] [*in*] [*weight*] [, *options*]

Immediate form of two-way tabulations

`tabi` #$_{11}$ #$_{12}$ [...] \ #$_{21}$ #$_{22}$ [...] [\ ...] [, *options*]

options	Description
Main	
`chi2`	report Pearson's χ^2
`exact`[`(#)`]	report Fisher's exact test
`gamma`	report Goodman and Kruskal's gamma
`lrchi2`	report likelihood-ratio χ^2
`taub`	report Kendall's τ_b
`V`	report Cramér's V
`cchi2`	report Pearson's χ^2 in each cell
`column`	report relative frequency within its column of each cell
`row`	report relative frequency within its row of each cell
`clrchi2`	report likelihood-ratio χ^2 in each cell
`cell`	report the relative frequency of each cell
`expected`	report expected frequency in each cell
`nofreq`	do not display frequencies
`missing`	treat missing values like other values
`wrap`	do not wrap wide tables
[`no`]`key`	report/suppress cell contents key
`nolabel`	display numeric codes rather than value labels
`nolog`	do not display enumeration log for Fisher's exact test
* `firstonly`	show only tables that include the first variable in *varlist*

Advanced

`matcell(`*matname*`)`	save frequencies in *matname*; programmer's option
`matrow(`*matname*`)`	save unique values of $varname_1$ in *matname*; programmer's option
`matcol(`*matname*`)`	save unique values of $varname_2$ in *matname*; programmer's option
‡`replace`	replace current data with given cell frequencies
`all`	equivalent to specifying `chi2 lrchi2 V gamma taub`

*`firstonly` is available only for `tab2`.

‡`replace` is available only for `tabi`.

`by` is allowed with `tabulate` and `tab2`; see [D] **by**.

`fweights`, `aweights`, and `iweights` are allowed by `tabulate`. `fweights` are allowed by `tab2`. See [U] **11.1.6 weight**.

`all` does not appear in the dialog box.

Menu

tabulate

Statistics > Summaries, tables, and tests > Frequency tables > Two-way table with measures of association

tab2

Statistics > Summaries, tables, and tests > Frequency tables > All possible two-way tables

tabi

Statistics > Summaries, tables, and tests > Frequency tables > Table calculator

Description

`tabulate` produces a two-way table of frequency counts, along with various measures of association, including the common Pearson's χ^2, the likelihood-ratio χ^2, Cramér's V, Fisher's exact test, Goodman and Kruskal's gamma, and Kendall's τ_b.

Line size is respected. That is, if you resize the Results window before running `tabulate`, the resulting two-way tabulation will take advantage of the available horizontal space. Stata for Unix(console) users can instead use the `set linesize` command to take advantage of this feature.

`tab2` produces all possible two-way tabulations of the variables specified in *varlist*.

`tabi` displays the $r \times c$ table, using the values specified; rows are separated by '\'. If no options are specified, it is as if `exact` were specified for a 2×2 table and `chi2` were specified otherwise. See [U] **19 Immediate commands** for a general description of immediate commands. See *Tables with immediate data* below for examples using `tabi`.

See [R] **tabulate oneway** if you want a one-way table of frequencies. See [R] **table** and [R] **tabstat** if you want one-, two-, or n-way table of frequencies and a wide variety of summary statistics. See [R] **tabulate, summarize()** for a description of `tabulate` with the `summarize()` option; it produces a table (breakdowns) of means and standard deviations. `table` is better than `tabulate, summarize()`, but `tabulate, summarize()` is faster. See [ST] **epitab** for a 2×2 table with statistics of interest to epidemiologists.

Options

Main

chi2 calculates and displays Pearson's χ^2 for the hypothesis that the rows and columns in a two-way table are independent. chi2 may not be specified if aweights or iweights are specified.

exact[(#)] displays the significance calculated by Fisher's exact test and may be applied to $r \times c$ as well as to 2×2 tables. For 2×2 tables, both one- and two-sided probabilities are displayed. For $r \times c$ tables, one-sided probabilities are displayed. The optional positive integer # is a multiplier on the amount of memory that the command is permitted to consume. The default is 1. This option should not be necessary for reasonable $r \times c$ tables. If the command terminates with error 910, try exact(2). The maximum row or column dimension allowed when computing Fisher's exact test is the maximum row or column dimension for tabulate (see [R] **limits**).

gamma displays Goodman and Kruskal's gamma along with its asymptotic standard error. gamma is appropriate only when both variables are ordinal. gamma may not be specified if aweights or iweights are specified.

lrchi2 displays the likelihood-ratio χ^2 statistic. lrchi2 may not be specified if aweights or iweights are specified.

taub displays Kendall's τ_b along with its asymptotic standard error. taub is appropriate only when both variables are ordinal. taub may not be specified if aweights or iweights are specified.

V (note capitalization) displays Cramér's V. V may not be specified if aweights or iweights are specified.

cchi2 displays each cell's contribution to Pearson's chi-squared in a two-way table.

column displays the relative frequency of each cell within its column in a two-way table.

row displays the relative frequency of each cell within its row in a two-way table.

clrchi2 displays each cell's contribution to the likelihood-ratio chi-squared in a two-way table.

cell displays the relative frequency of each cell in a two-way table.

expected displays the expected frequency of each cell in a two-way table.

nofreq suppresses the printing of the frequencies.

missing requests that missing values be treated like other values in calculations of counts, percentages, and other statistics.

wrap requests that Stata take no action on wide, two-way tables to make them readable. Unless wrap is specified, wide tables are broken into pieces to enhance readability.

[no]key suppresses or forces the display of a key above two-way tables. The default is to display the key if more than one cell statistic is requested, and otherwise to omit it. key forces the display of the key. nokey suppresses its display.

nolabel causes the numeric codes to be displayed rather than the value labels.

nolog suppresses the display of the log for Fisher's exact test. Using Fisher's exact test requires counting all tables that have a probability exceeding that of the observed table given the observed row and column totals. The log counts down each stage of the network computations, starting from the number of columns and counting down to 1, displaying the number of nodes in the network at each stage. A log is not displayed for 2×2 tables.

firstonly, available only with tab2, restricts the output to only those tables that include the first variable in *varlist*. Use this option to interact one variable with a set of others.

Advanced

`matcell(`*matname*`)` saves the reported frequencies in *matname*. This option is for use by programmers.

`matrow(`*matname*`)` saves the numeric values of the $r \times 1$ row stub in *matname*. This option is for use by programmers. `matrow()` may not be specified if the row variable is a string.

`matcol(`*matname*`)` saves the numeric values of the $1 \times c$ column stub in *matname*. This option is for use by programmers. `matcol()` may not be specified if the column variable is a string.

`replace` indicates that the immediate data specified as arguments to the `tabi` command be left as the current data in place of whatever data were there.

The following option is available with `tabulate` but is not shown in the dialog box:

`all` is equivalent to specifying `chi2 lrchi2 V gamma taub`. Note the omission of `exact`. When `all` is specified, `no` may be placed in front of the other options. `all noV` requests all association measures except Cramér's V (and Fisher's exact). `all exact` requests all association measures, including Fisher's exact test. `all` may not be specified if `aweights` or `iweights` are specified.

Limits

Two-way tables may have a maximum of 1,200 rows and 80 columns (Stata/MP and Stata/SE), 300 rows and 20 columns (Stata/IC), or 160 rows and 20 columns (Small Stata). If larger tables are needed, see [R] **table**.

Remarks and examples

Remarks are presented under the following headings:

tabulate
Measures of association
N-way tables
Weighted data
Tables with immediate data
tab2
Video examples

For each value of a specified variable (or a set of values for a pair of variables), `tabulate` reports the number of observations with that value. The number of times a value occurs is called its *frequency*.

tabulate

▷ Example 1

`tabulate` will make two-way tables if we specify two variables following the word `tabulate`. In our highway dataset, we have a variable called `rate` that divides the accident rate into three categories: below 4, 4–7, and above 7 per million vehicle miles. Let's make a table of the speed limit category and the accident-rate category:

```
. use http://www.stata-press.com/data/r13/hiway2
(Minnesota Highway Data, 1973)
. tabulate spdcat rate
```

Speed Limit Category	Accident rate per million vehicle miles: Below 4	4-7	Above 7	Total
40 to 50	3	5	3	11
55 to 50	19	6	1	26
Above 60	2	0	0	2
Total	24	11	4	39

The table indicates that three stretches of highway have an accident rate below 4 and a speed limit of 40 to 50 miles per hour. The table also shows the row and column sums (called the *marginals*). The number of highways with a speed limit of 40 to 50 miles per hour is 11, which is the same result we obtained in our previous one-way tabulations.

Stata can present this basic table in several ways—16, to be precise—and we will show just a few below. It might be easier to read the table if we included the row percentages. For instance, of 11 highways in the lowest speed limit category, three are also in the lowest accident-rate category. Three-elevenths amounts to some 27.3%. We can ask Stata to fill in this information for us by using the `row` option:

```
. tabulate spdcat rate, row
```

Key
frequency *row percentage*

Speed Limit Category	Accident rate per million vehicle miles: Below 4	4-7	Above 7	Total
40 to 50	3	5	3	11
	27.27	45.45	27.27	100.00
55 to 50	19	6	1	26
	73.08	23.08	3.85	100.00
Above 60	2	0	0	2
	100.00	0.00	0.00	100.00
Total	24	11	4	39
	61.54	28.21	10.26	100.00

The number listed below each frequency is the percentage of cases that each cell represents out of its row. That is easy to remember because we see 100% listed in the "`Total`" column. The bottom row is also informative. We see that 61.54% of all the highways in our dataset fall into the lowest accident-rate category, that 28.21% are in the middle category, and that 10.26% are in the highest.

`tabulate` can calculate column percentages and cell percentages, as well. It does so when we specify the `column` or `cell` options, respectively. We can even specify them together. Below is a table that includes everything:

```
. tabulate spdcat rate, row column cell
```

Key
frequency *row percentage* *column percentage* *cell percentage*

Speed Limit Category	Accident rate per million vehicle miles: Below 4	4-7	Above 7	Total
40 to 50	3	5	3	11
	27.27	45.45	27.27	100.00
	12.50	45.45	75.00	28.21
	7.69	12.82	7.69	28.21
55 to 50	19	6	1	26
	73.08	23.08	3.85	100.00
	79.17	54.55	25.00	66.67
	48.72	15.38	2.56	66.67
Above 60	2	0	0	2
	100.00	0.00	0.00	100.00
	8.33	0.00	0.00	5.13
	5.13	0.00	0.00	5.13
Total	24	11	4	39
	61.54	28.21	10.26	100.00
	100.00	100.00	100.00	100.00
	61.54	28.21	10.26	100.00

The number at the top of each cell is the frequency count. The second number is the row percentage—they sum to 100% going across the table. The third number is the column percentage—they sum to 100% going down the table. The bottom number is the cell percentage—they sum to 100% going down all the columns and across all the rows. For instance, highways with a speed limit above 60 miles per hour and in the lowest accident rate category account for 100% of highways with a speed limit above 60 miles per hour; 8.33% of highways in the lowest accident-rate category; and 5.13% of all our data.

A fourth option, `nofreq`, tells Stata not to print the frequency counts. To construct a table consisting of only row percentages, we type

```
. tabulate spdcat rate, row nofreq
```

Speed Limit Category	Accident rate per million vehicle miles: Below 4	4-7	Above 7	Total
40 to 50	27.27	45.45	27.27	100.00
55 to 50	73.08	23.08	3.85	100.00
Above 60	100.00	0.00	0.00	100.00
Total	61.54	28.21	10.26	100.00

◁

Measures of association

▷ Example 2

`tabulate` will calculate the Pearson χ^2 test for the independence of the rows and columns if we specify the `chi2` option. Suppose that we have 1980 census data on 956 cities in the United States and wish to compare the age distribution across regions of the country. Assume that `agecat` is the median age in each city and that `region` denotes the region of the country in which the city is located.

```
. use http://www.stata-press.com/data/r13/citytemp2
(City Temperature Data)
. tabulate region agecat, chi2
```

Census Region	agecat 19-29	30-34	35+	Total
NE	46	83	37	166
N Cntrl	162	92	30	284
South	139	68	43	250
West	160	73	23	256
Total	507	316	133	956

Pearson chi2(6) = 61.2877 Pr = 0.000

We obtain the standard two-way table and, at the bottom, a summary of the χ^2 test. Stata informs us that the χ^2 associated with this table has 6 degrees of freedom and is 61.29. The observed differences are significant.

The table is, perhaps, easier to understand if we suppress the frequencies and print just the row percentages:

```
. tabulate region agecat, row nofreq chi2
```

Census Region	agecat 19-29	30-34	35+	Total
NE	27.71	50.00	22.29	100.00
N Cntrl	57.04	32.39	10.56	100.00
South	55.60	27.20	17.20	100.00
West	62.50	28.52	8.98	100.00
Total	53.03	33.05	13.91	100.00

Pearson chi2(6) = 61.2877 Pr = 0.000

◁

▷ Example 3

We have data on dose level and outcome for a set of patients and wish to evaluate the association between the two variables. We can obtain all the association measures by specifying the `all` and `exact` options:

```
. use http://www.stata-press.com/data/r13/dose
. tabulate dose function, all exact
Enumerating sample-space combinations:
stage 3:  enumerations = 1
stage 2:  enumerations = 9
stage 1:  enumerations = 0
```

Dosage	Function < 1 hr	1 to 4	4+	Total
1/day	20	10	2	32
2/day	16	12	4	32
3/day	10	16	6	32
Total	46	38	12	96

```
          Pearson chi2(4) =   6.7780   Pr = 0.148
 likelihood-ratio chi2(4) =   6.9844   Pr = 0.137
               Cramr's V =   0.1879
                   gamma =   0.3689  ASE = 0.129
         Kendall's tau-b =   0.2378  ASE = 0.086
          Fisher's exact =                 0.145
```

We find evidence of association but not enough to be truly convincing.

If we had not also specified the `exact` option, we would not have obtained Fisher's exact test. Stata can calculate this statistic both for 2×2 tables and for $r \times c$. For 2×2 tables, the calculation is almost instant. On more general tables, however, the calculation can take longer.

We carefully constructed our example so that `all` would be meaningful. Kendall's τ_b and Goodman and Kruskal's gamma are relevant only when both dimensions of the table can be ordered, say, from low to high or from worst to best. The other statistics, however, are always applicable.

◁

❑ Technical note

Be careful when attempting to compute the p-value for Fisher's exact test because the number of tables that contribute to the p-value can be extremely large and a solution may not be feasible. The errors that are indicative of this situation are errors 910, exceeded memory limitations, and 1401, integer overflow due to large row-margin frequencies. If execution terminates because of memory limitations, use `exact(2)` to permit the algorithm to consume twice the memory, `exact(3)` for three times the memory, etc. The default memory usage should be sufficient for reasonable tables.

❑

N-way tables

If you need more than two-way tables, your best alternative to is use `table`, not `tabulate`; see [R] **table**.

The technical note below shows you how to use `tabulate` to create a sequence of two-way tables that together form, in effect, a three-way table, but using `table` is easy and produces prettier results:

```
. use http://www.stata-press.com/data/r13/birthcat
(City data)
. table birthcat region agecat, c(freq)
```

birthcat	agecat and Census Region							
	19-29				30-34			
	NE	N Cntrl	South	West	NE	N Cntrl	South	West
29-136	11	23	11	11	34	27	10	8
137-195	31	97	65	46	48	58	45	42
196-529	4	38	59	91	1	3	12	21

birthcat	agecat and Census Region			
	35+			
	NE	N Cntrl	South	West
29-136	34	26	27	18
137-195	3	4	7	4
196-529			4	

❑ Technical note

We can make n-way tables by combining the by *varlist*: prefix with `tabulate`. Continuing with the dataset of 956 cities, say that we want to make a table of age category by birth-rate category by region of the country. The birth-rate category variable is named `birthcat` in our dataset. To make separate tables for each age category, we would type

```
. by agecat, sort: tabulate birthcat region
```

```
-> agecat = 19-29
```

birthcat	Census Region				
	NE	N Cntrl	South	West	Total
29-136	11	23	11	11	56
137-195	31	97	65	46	239
196-529	4	38	59	91	192
Total	46	158	135	148	487

```
-> agecat = 30-34
```

birthcat	Census Region				
	NE	N Cntrl	South	West	Total
29-136	34	27	10	8	79
137-195	48	58	45	42	193
196-529	1	3	12	21	37
Total	83	88	67	71	309

```
-> agecat = 35+
```

birthcat	Census Region NE	N Cntrl	South	West	Total
29-136	34	26	27	18	105
137-195	3	4	7	4	18
196-529	0	0	4	0	4
Total	37	30	38	22	127

❑

Weighted data

▷ Example 4

`tabulate` can process weighted as well as unweighted data. As with all Stata commands, we indicate the weight by specifying the [*weight*] modifier; see [U] **11.1.6 weight**.

Continuing with our dataset of 956 cities, we also have a variable called `pop`, the population of each city. We can make a table of region by age category, weighted by population, by typing

```
. tabulate region agecat [freq=pop]
```

Census Region	agecat 19-29	30-34	35+	Total
NE	4,721,387	10,421,387	5,323,610	20,466,384
N Cntrl	16,901,550	8,964,756	4,015,593	29,881,899
South	13,894,254	7,686,531	4,141,863	25,722,648
West	16,698,276	7,755,255	2,375,118	26,828,649
Total	52,215,467	34,827,929	15,856,184	102899580

If we specify the `cell`, `column`, or `row` options, they will also be appropriately weighted. Below we repeat the table, suppressing the counts and substituting row percentages:

```
. tabulate region agecat [freq=pop], nofreq row
```

Census Region	agecat 19-29	30-34	35+	Total
NE	23.07	50.92	26.01	100.00
N Cntrl	56.56	30.00	13.44	100.00
South	54.02	29.88	16.10	100.00
West	62.24	28.91	8.85	100.00
Total	50.74	33.85	15.41	100.00

◁

Tables with immediate data

▷ Example 5

`tabi` ignores the dataset in memory and uses as the table the values that we specify on the command line:

```
. tabi 30 18 \ 38 14
```

row	col 1	2	Total
1	30	18	48
2	38	14	52
Total	68	32	100

```
          Fisher's exact =                 0.289
  1-sided Fisher's exact =                 0.179
```

We may specify any of the options of `tabulate` and are not limited to 2×2 tables:

```
. tabi 30 18 38 \ 13 7 22, chi2 exact
Enumerating sample-space combinations:
stage 3:  enumerations = 1
stage 2:  enumerations = 3
stage 1:  enumerations = 0
```

row	col 1	2	3	Total
1	30	18	38	86
2	13	7	22	42
Total	43	25	60	128

```
       Pearson chi2(2) =   0.7967   Pr = 0.671
        Fisher's exact =                 0.707
. tabi 30 13 \ 18 7 \ 38 22, all exact col
```

Key
frequency *column percentage*

```
Enumerating sample-space combinations:
stage 3:  enumerations = 1
stage 2:  enumerations = 3
stage 1:  enumerations = 0
```

row	col 1	2	Total
1	30	13	43
	34.88	30.95	33.59
2	18	7	25
	20.93	16.67	19.53
3	38	22	60
	44.19	52.38	46.88
Total	86	42	128
	100.00	100.00	100.00

```
          Pearson chi2(2) =   0.7967   Pr = 0.671
 likelihood-ratio chi2(2) =   0.7985   Pr = 0.671
               Cramr's V =   0.0789
                    gamma =   0.1204   ASE = 0.160
          Kendall's tau-b =   0.0630   ASE = 0.084
           Fisher's exact =                 0.707
```

For 2×2 tables, both one- and two-sided Fisher's exact probabilities are displayed; this is true of both `tabulate` and `tabi`. See *Cumulative incidence data* and *Case–control data* in [ST] **epitab** for more discussion on the relationship between one- and two-sided probabilities.

◁

❑ Technical note

`tabi`, as with all immediate commands, leaves any data in memory undisturbed. With the `replace` option, however, the data in memory are replaced by the data from the table:

```
. tabi 30 18 \ 38 14, replace
```

row	col 1	2	Total
1	30	18	48
2	38	14	52
Total	68	32	100

```
          Fisher's exact =                 0.289
  1-sided Fisher's exact =                 0.179
. list
```

	row	col	pop
1.	1	1	30
2.	1	2	18
3.	2	1	38
4.	2	2	14

With this dataset, you could re-create the above table by typing

```
. tabulate row col [freq=pop], exact
```

row	col 1	2	Total
1	30	18	48
2	38	14	52
Total	68	32	100

```
          Fisher's exact =                 0.289
  1-sided Fisher's exact =                 0.179
```

❑

tab2

tab2 is a convenience tool. Typing

```
. tab2 myvar thisvar thatvar, chi2
```

is equivalent to typing

```
. tabulate myvar thisvar, chi2
. tabulate myvar thatvar, chi2
. tabulate thisvar thatvar, chi2
```

Tables and cross-tabulations in Stata

Immediate commands in Stata: Cross-tabulations and chi-squared tests from summary data

Stored results

tabulate, tab2, and tabi store the following in r():

Scalars

r(N)	number of observations	r(p_exact)	Fisher's exact p
r(r)	number of rows	r(chi2_lr)	likelihood-ratio χ^2
r(c)	number of columns	r(p_lr)	significance of likelihood-ratio χ^2
r(chi2)	Pearson's χ^2	r(CramersV)	Cramér's V
r(p)	significance of Pearson's χ^2	r(ase_gam)	ASE of gamma
r(gamma)	gamma	r(ase_taub)	ASE of τ_b
r(p1_exact)	one-sided Fisher's exact p	r(taub)	τ_b

r(p1_exact) is defined only for 2×2 tables. Also, the matrow(), matcol(), and matcell() options allow you to obtain the row values, column values, and frequencies, respectively.

Methods and formulas

Let n_{ij}, $i = 1, \ldots, I$ and $j = 1, \ldots, J$, be the number of observations in the ith row and jth column. If the data are not weighted, n_{ij} is just a count. If the data are weighted, n_{ij} is the sum of the weights of all data corresponding to the (i, j) cell.

Define the row and column marginals as

$$n_{i\cdot} = \sum_{j=1}^{J} n_{ij} \qquad\qquad n_{\cdot j} = \sum_{i=1}^{I} n_{ij}$$

and let $n = \sum_i \sum_j n_{ij}$ be the overall sum. Also, define the concordance and discordance as

$$A_{ij} = \sum_{k>i}\sum_{l>j} n_{kl} + \sum_{k<i}\sum_{l<j} n_{kl} \qquad\qquad D_{ij} = \sum_{k>i}\sum_{l<j} n_{kl} + \sum_{k<i}\sum_{l>j} n_{kl}$$

along with twice the number of concordances $P = \sum_i \sum_j n_{ij} A_{ij}$ and twice the number of discordances $Q = \sum_i \sum_j n_{ij} D_{ij}$.

The Pearson χ^2 statistic with $(I-1)(J-1)$ degrees of freedom (so called because it is based on Pearson (1900); see Conover [1999, 240] and Fienberg [1980, 9]) is defined as

$$X^2 = \sum_i \sum_j \frac{(n_{ij} - m_{ij})^2}{m_{ij}}$$

where $m_{ij} = n_{i\cdot}n_{\cdot j}/n$.

The likelihood-ratio χ^2 statistic with $(I-1)(J-1)$ degrees of freedom (Fienberg 1980, 40) is defined as

$$G^2 = 2\sum_i \sum_j n_{ij} \ln(n_{ij}/m_{ij})$$

Cramér's V (Cramér 1946) is a measure of association designed so that the attainable upper bound is 1. For 2×2 tables, $-1 \leq V \leq 1$, and otherwise, $0 \leq V \leq 1$.

$$V = \begin{cases} (n_{11}n_{22} - n_{12}n_{21})/(n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2})^{1/2} & \text{for } 2 \times 2 \\ \left\{(X^2/n)/\min(I-1, J-1)\right\}^{1/2} & \text{otherwise} \end{cases}$$

Gamma (Goodman and Kruskal 1954, 1959, 1963, 1972; also see Agresti [2010,186–188]) ignores tied pairs and is based only on the number of concordant and discordant pairs of observations, $-1 \leq \gamma \leq 1$,

$$\gamma = (P - Q)/(P + Q)$$

with asymptotic variance

$$16\sum_i \sum_j n_{ij}(QA_{ij} - PD_{ij})^2/(P+Q)^4$$

Kendall's τ_b (Kendall 1945; also see Agresti 2010, 188–189), $-1 \leq \tau_b \leq 1$, is similar to gamma, except that it uses a correction for ties,

$$\tau_b = (P - Q)/(w_r w_c)^{1/2}$$

with asymptotic variance

$$\frac{\sum_i \sum_j n_{ij}(2w_r w_c d_{ij} + \tau_b v_{ij})^2 - n^3 \tau_b^2 (w_r + w_c)^2}{(w_r w_c)^4}$$

where

$$w_r = n^2 - \sum_i n_{i.}^2$$
$$w_c = n^2 - \sum_j n_{.j}^2$$
$$d_{ij} = A_{ij} - D_{ij}$$
$$v_{ij} = n_{i.} w_c + n_{.j} w_r$$

Fisher's exact test (Fisher 1935; Finney 1948; see Zelterman and Louis [1992, 293–301] for the 2×2 case) yields the probability of observing a table that gives at least as much evidence of association as the one actually observed under the assumption of no association. Holding row and column marginals fixed, the hypergeometric probability P of every possible table A is computed, and the

$$P = \sum_{T \in A} \Pr(T)$$

where A is the set of all tables with the same marginals as the observed table, T^*, such that $\Pr(T) \leq \Pr(T^*)$. For 2×2 tables, the one-sided probability is calculated by further restricting A to tables in the same tail as T^*. The first algorithm extending this calculation to $r \times c$ tables was Pagano and Halvorsen (1981); the one implemented here is the FEXACT algorithm by Mehta and Patel (1986). This is a search-tree clipping method originally published by Mehta and Patel (1983) with further refinements by Joe (1988) and Clarkson, Fan, and Joe (1993). Fisher's exact test is a permutation test. For more information on permutation tests, see Good (2005 and 2006) and Pesarin (2001).

Title

tabulate, summarize() — One- and two-way tables of summary statistics

Syntax Menu Description Options
Remarks and examples Also see

Syntax

`tabulate` *varname*$_1$ [*varname*$_2$] [*if*] [*in*] [*weight*] [, *options*]

options	Description
Main	
`summarize(`*varname*$_3$`)`	report summary statistics for *varname*$_3$
[`no`]`means`	include or suppress means
[`no`]`standard`	include or suppress standard deviations
[`no`]`freq`	include or suppress frequencies
[`no`]`obs`	include or suppress number of observations
`nolabel`	show numeric codes, not labels
`wrap`	do not break wide tables
`missing`	treat missing values of *varname*$_1$ and *varname*$_2$ as categories

`by` is allowed; see [D] **by**.

`aweights` and `fweights` are allowed; see [U] **11.1.6 weight**.

Menu

Statistics > Summaries, tables, and tests > Other tables > Table of means, std. dev., and frequencies

Description

`tabulate, summarize()` produces one- and two-way tables (breakdowns) of means and standard deviations. See [R] **tabulate oneway** and [R] **tabulate twoway** for one- and two-way frequency tables. See [R] **table** for a more flexible command that produces one-, two-, and n-way tables of frequencies and a wide variety of summary statistics. `table` is better, but `tabulate, summarize()` is faster. Also see [R] **tabstat** for yet another alternative.

Options

Main

`summarize(`*varname*$_3$`)` identifies the name of the variable for which summary statistics are to be reported. If you do not specify this option, a table of frequencies is produced; see [R] **tabulate oneway** and [R] **tabulate twoway**. The description here concerns `tabulate` when this option is specified.

[no]means includes or suppresses only the means from the table.

The summarize() table normally includes the mean, standard deviation, frequency, and, if the data are weighted, number of observations. Individual elements of the table may be included or suppressed by the [no]means, [no]standard, [no]freq, and [no]obs options. For example, typing

```
. tabulate category, summarize(myvar) means standard
```

produces a summary table by category containing only the means and standard deviations of myvar. You could also achieve the same result by typing

```
. tabulate category, summarize(myvar) nofreq
```

[no]standard includes or suppresses only the standard deviations from the table; see [no]means option above.

[no]freq includes or suppresses only the frequencies from the table; see [no]means option above.

[no]obs includes or suppresses only the reported number of observations from the table. If the data are not weighted, the number of observations is identical to the frequency, and by default only the frequency is reported. If the data are weighted, the frequency refers to the sum of the weights. See [no]means option above.

nolabel causes the numeric codes to be displayed rather than the label values.

wrap requests that no action be taken on wide tables to make them readable. Unless wrap is specified, wide tables are broken into pieces to enhance readability.

missing requests that missing values of *varname*$_1$ and *varname*$_2$ be treated as categories rather than as observations to be omitted from the analysis.

Remarks and examples

tabulate with the summarize() option produces one- and two-way tables of summary statistics. When combined with the by prefix, it can produce n-way tables as well.

Remarks are presented under the following headings:

One-way tables
Two-way tables

One-way tables

▷ Example 1

We have data on 74 automobiles. Included in our dataset are the variables foreign, which marks domestic and foreign cars, and mpg, the car's mileage rating. Typing tabulate foreign displays a breakdown of the number of observations we have by the values of the foreign variable.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. tabulate foreign
```

Car type	Freq.	Percent	Cum.
Domestic	52	70.27	70.27
Foreign	22	29.73	100.00
Total	74	100.00	

We discover that we have 52 domestic cars and 22 foreign cars in our dataset. If we add the `summarize(`*varname*`)` option, however, `tabulate` produces a table of summary statistics for *varname*:

```
. tabulate foreign, summarize(mpg)
```

Car type	Summary of Mileage (mpg) Mean	Std. Dev.	Freq.
Domestic	19.826923	4.7432972	52
Foreign	24.772727	6.6111869	22
Total	21.297297	5.7855032	74

We also discover that the average gas mileage for domestic cars is about 20 mpg and the average foreign is almost 25 mpg. Overall, the average is 21 mpg in our dataset.

◁

❑ Technical note

We might now wonder if the difference in gas mileage between foreign and domestic cars is statistically significant. We can use the `oneway` command to find out; see [R] **oneway**. To obtain an analysis-of-variance table of `mpg` on `foreign`, we type

```
. oneway mpg foreign
```

Source	Analysis of Variance SS	df	MS	F	Prob > F
Between groups	378.153515	1	378.153515	13.18	0.0005
Within groups	2065.30594	72	28.6848048		
Total	2443.45946	73	33.4720474		

```
Bartlett's test for equal variances:  chi2(1) =   3.4818  Prob>chi2 = 0.062
```

The F statistic is 13.18, and the difference between foreign and domestic cars' mileage ratings is significant at the 0.05% level.

There are several ways that we could have statistically compared mileage ratings—see, for instance, [R] **anova**, [R] **oneway**, [R] **regress**, and [R] **ttest**—but `oneway` seemed the most convenient.

❑

Two-way tables

▷ Example 2

`tabulate, summarize` can be used to obtain two-way as well as one-way breakdowns. For instance, we obtained summary statistics on `mpg` decomposed by `foreign` by typing `tabulate foreign, summarize(mpg)`. We can specify up to two variables before the comma:

```
. generate wgtcat = autocode(weight,4,1760,4840)
. tabulate wgtcat foreign, summarize(mpg)
        Means, Standard Deviations and Frequencies of Mileage (mpg)
```

wgtcat	Car type Domestic	Foreign	Total
2530	28.285714	27.0625	27.434783
	3.0937725	5.9829619	5.2295149
	7	16	23
3300	21.75	19.6	21.238095
	2.4083189	3.4351128	2.7550819
	16	5	21
4070	17.26087	14	17.125
	1.8639497	0	1.9406969
	23	1	24
4840	14.666667	.	14.666667
	3.32666	.	3.32666
	6	0	6
Total	19.826923	24.772727	21.297297
	4.7432972	6.6111869	5.7855032
	52	22	74

In addition to the means, standard deviations, and frequencies for each weight–mileage cell, also reported are the summary statistics by weight, by mileage, and overall. For instance, the last row of the table reveals that the average mileage of domestic cars is 19.83 and that of foreign cars is 24.77—domestic cars yield poorer mileage than foreign cars. But we now see that domestic cars yield better gas mileage within weight class—the reason domestic cars yield poorer gas mileage is because they are, on average, heavier.

◁

▷ Example 3

If we do not specify the statistics to be included in a table, `tabulate` reports the mean, standard deviation, and frequency. We can specify the statistics that we want to see using the `means`, `standard`, and `freq` options:

```
. tabulate wgtcat foreign, summarize(mpg) means
                        Means of Mileage (mpg)
```

wgtcat	Car type Domestic	Foreign	Total
2530	28.285714	27.0625	27.434783
3300	21.75	19.6	21.238095
4070	17.26087	14	17.125
4840	14.666667	.	14.666667
Total	19.826923	24.772727	21.297297

When we specify one or more of the `means`, `standard`, and `freq` options, only those statistics are displayed. Thus we could obtain a table containing just the means and standard deviations by typing `means standard` after the `summarize(mpg)` option. We can also suppress selected statistics by placing `no` in front of the option name. Another way of obtaining only the means and standard deviations is to add the `nofreq` option:

```
. tabulate wgtcat foreign, summarize(mpg) nofreq
```

Means and Standard Deviations of Mileage (mpg)

wgtcat	Car type Domestic	Foreign	Total
2530	28.285714 3.0937725	27.0625 5.9829619	27.434783 5.2295149
3300	21.75 2.4083189	19.6 3.4351128	21.238095 2.7550819
4070	17.26087 1.8639497	14 0	17.125 1.9406969
4840	14.666667 3.32666	. .	14.666667 3.32666
Total	19.826923 4.7432972	24.772727 6.6111869	21.297297 5.7855032

Title

test — Test linear hypotheses after estimation

Syntax | Menu | Description | Options for testparm
Options for test | Remarks and examples | Stored results | Methods and formulas
Acknowledgment | References | Also see

Syntax

Basic syntax

`test` *coeflist* (*Syntax 1*)

`test` *exp*`=`*exp*`[=...]` (*Syntax 2*)

`test [`*eqno*`]` `[:` *coeflist*`]` (*Syntax 3*)

`test [`*eqno*`=`*eqno*`[=...]] [:` *coeflist*`]` (*Syntax 4*)

`testparm` *varlist* `[, equal equation(`*eqno*`)]`

Full syntax

`test (`*spec*`) [(`*spec*`) ...] [,` *test_options*`]`

test_options	Description
Options	
`mtest[(`*opt*`)]`	test each condition separately
`coef`	report estimated constrained coefficients
`accumulate`	test hypothesis jointly with previously tested hypotheses
`notest`	suppress the output
`common`	test only variables common to all the equations
`constant`	include the constant in coefficients to be tested
`nosvyadjust`	compute unadjusted Wald tests for survey results
`minimum`	perform test with the constant, drop terms until the test becomes nonsingular, and test without the constant on the remaining terms; highly technical
`matvlc(`*matname*`)`	save the variance–covariance matrix; programmer's option

coeflist and *varlist* may contain factor variables and time-series operators; see **[U] 11.4.3 Factor variables** and **[U] 11.4.4 Time-series varlists**.

`matvlc(`*matname*`)` does not appear in the dialog box.

Syntax 1 tests that coefficients are 0.

Syntax 2 tests that linear expressions are equal.

Syntax 3 tests that coefficients in *eqno* are 0.

Syntax 4 tests equality of coefficients between equations.

spec is one of

coeflist
exp=*exp* [=*exp*]
[*eqno*] [: *coeflist*]
[*eqno*$_1$=*eqno*$_2$ [=...]] [: *coeflist*]

coeflist is

coef [*coef* ...]
[*eqno*]*coef* [[*eqno*]*coef*...]
[*eqno*] _b[*coef*] [[*eqno*] _b[*coef*]...]

exp is a linear expression containing

coef
_b[*coef*]
_b[*eqno*:*coef*]
[*eqno*]*coef*
[*eqno*] _b[*coef*]

eqno is

##
name

coef identifies a coefficient in the model. *coef* is typically a variable name, a level indicator, an interaction indicator, or an interaction involving continuous variables. Level indicators identify one level of a factor variable and interaction indicators identify one combination of levels of an interaction; see [U] **11.4.3 Factor variables**. *coef* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

Distinguish between `[]`, which are to be typed, and [ ], which indicate optional arguments.

Although not shown in the syntax diagram, parentheses around *spec* are required only with multiple specifications. Also, the diagram does not show that `test` may be called without arguments to redisplay the results from the last `test`.

`anova` and `manova` (see [R] **anova** and [MV] **manova**) allow the `test` syntax above plus more (see [R] **anova postestimation** for `test` after `anova`; see [MV] **manova postestimation** for `test` after `manova`).

Menu

test

Statistics > Postestimation > Tests > Test linear hypotheses

testparm

Statistics > Postestimation > Tests > Test parameters

Description

test performs Wald tests of simple and composite linear hypotheses about the parameters of the most recently fit model.

test supports svy estimators (see [SVY] **svy estimation**), carrying out an adjusted Wald test by default in such cases. test can be used with svy estimation results, see [SVY] **svy postestimation**.

testparm provides a useful alternative to test that permits *varlist* rather than a list of coefficients (which is often nothing more than a list of variables), allowing the use of standard Stata notation, including '-' and '*', which are given the *exp*ression interpretation by test.

test and testparm perform Wald tests. For likelihood-ratio tests, see [R] **lrtest**. For Wald-type tests of nonlinear hypotheses, see [R] **testnl**. To display estimates for one-dimensional linear or nonlinear expressions of coefficients, see [R] **lincom** and [R] **nlcom**.

See [R] **anova postestimation** for additional test syntax allowed after anova.

See [MV] **manova postestimation** for additional test syntax allowed after manova.

Options for testparm

equal tests that the variables appearing in *varlist*, which also appear in the previously fit model, are equal to each other rather than jointly equal to zero.

equation(*eqno*) is relevant only for multiple-equation models, such as mvreg, mlogit, and heckman. It specifies the equation for which the all-zero or all-equal hypothesis is tested. equation(#1) specifies that the test be conducted regarding the first equation #1. equation(price) specifies that the test concern the equation named price.

Options for test

Options

mtest[(*opt*)] specifies that tests be performed for each condition separately. *opt* specifies the method for adjusting p-values for multiple testing. Valid values for *opt* are

bonferroni	Bonferroni's method
holm	Holm's method
sidak	Šidák's method
noadjust	no adjustment is to be made

Specifying mtest without an argument is equivalent to mtest(noadjust).

coef specifies that the constrained coefficients be displayed.

accumulate allows a hypothesis to be tested jointly with the previously tested hypotheses.

notest suppresses the output. This option is useful when you are interested only in the joint test of several hypotheses, specified in a subsequent call of test, accumulate.

common specifies that when you use the [*eqno*$_1$=*eqno*$_2$[=...]] form of *spec*, the variables common to the equations *eqno*$_1$, *eqno*$_2$, etc., be tested. The default action is to complain if the equations have variables not in common.

constant specifies that _cons be included in the list of coefficients to be tested when using the [*eqno*$_1$=*eqno*$_2$[=...]] or [*eqno*] forms of *spec*. The default is not to include _cons.

`nosvyadjust` is for use with `svy` estimation commands; see [SVY] **svy estimation**. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is, the test is carried out as $W/k \sim F(k,d)$ rather than as $(d-k+1)W/(kd) \sim F(k,d-k+1)$, where k = the dimension of the test and d = the total number of sampled PSUs minus the total number of strata.

`minimum` is a highly technical option. It first performs the test with the constant added. If this test is singular, coefficients are dropped until the test becomes nonsingular. Then the test without the constant is performed with the remaining terms.

The following option is available with `test` but is not shown in the dialog box:

`matvlc(`*matname*`)`, a programmer's option, saves the variance–covariance matrix of the linear combinations involved in the suite of tests. For the test of the linear constraints $Lb = c$, *matname* contains $L\mathbf{V}L'$, where $\mathbf{V}$ is the estimated variance–covariance matrix of b.

Remarks and examples

Remarks are presented under the following headings:

Introductory examples
Special syntaxes after multiple-equation estimation
Constrained coefficients
Multiple testing

Introductory examples

`test` performs F or χ^2 tests of linear restrictions applied to the most recently fit model (for example, `regress` or `svy: regress` in the linear regression case; `logit`, `stcox`, `svy: logit`, ... in the single-equation maximum-likelihood case; and `mlogit`, `mvreg`, `streg`, ... in the multiple-equation maximum-likelihood case). `test` may be used after *any* estimation command, although for maximum likelihood techniques, `test` produces a Wald test that depends only on the estimate of the covariance matrix—you may prefer to use the more computationally expensive likelihood-ratio test; see [U] **20 Estimation and postestimation commands** and [R] **lrtest**.

There are several variations on the syntax for `test`. The second syntax,

`test` *exp*=*exp*[`=`...]

is allowed after any form of estimation. After fitting a model of *depvar* on `x1`, `x2`, and `x3`, typing `test x1+x2=x3` tests the restriction that the coefficients on `x1` and `x2` sum to the coefficient on `x3`. The expressions can be arbitrarily complicated; for instance, typing `test x1+2*(x2+x3)=x2+3*x3` is the same as typing `test x1+x2=x3`.

As a convenient shorthand, `test` also allows you to specify equality for multiple expressions; for example, `test x1+x2 = x3+x4 = x5+x6` tests that the three specified pairwise sums of coefficients are equal.

`test` understands that when you type `x1`, you are referring to the coefficient on `x1`. You could also more explicitly type `test _b[x1]+_b[x2]=_b[x3]`; or you could `test _coef[x1]+_coef[x2]=_coef[x3]`, or `test [#1]x1+[#1]x2=[#1]x3`, or many other things because there is more than one way to refer to an estimated coefficient; see [U] **13.5 Accessing coefficients and standard errors**. The shorthand involves less typing. On the other hand, you must be more explicit

after estimation of multiple-equation models because there may be more than one coefficient associated with an independent variable. You might type, for instance, `test [#2]x1+[#2]x2=[#2]x3` to test the constraint in equation 2 or, more readably, `test [ford]x1+[ford]x2=[ford]x3`, meaning that Stata will test the constraint on the equation corresponding to `ford`, which might be equation 2. `ford` would be an equation name after, say, `sureg`, or, after `mlogit`, `ford` would be one of the outcomes. For `mlogit`, you could also type `test [2]x1+[2]x2=[2]x3`—note the lack of the `#`—meaning not equation 2, but the equation corresponding to the numeric outcome 2. You can even test constraints across equations: `test [ford]x1+[ford]x2=[buick]x3`.

The syntax

`test` *coeflist*

is available after all estimation commands and is a convenient way to test that multiple coefficients are zero following estimation. A *coeflist* can simply be a list of variable names,

`test` *varname* [*varname* ...]

and it is most often specified that way. After you have fit a model of `depvar` on `x1`, `x2`, and `x3`, typing `test x1 x3` tests that the coefficients on `x1` and `x3` are jointly zero. After multiple-equation estimation, this would test that the coefficients on `x1` and `x3` are zero in all equations that contain them. You can also be more explicit and type, for instance, `test [ford]x1 [ford]x3` to test that the coefficients on `x1` and `x3` are zero in the equation for `ford`.

In the multiple-equation case, there are more alternatives. You could also test that the coefficients on `x1` and `x3` are zero in the equation for `ford` by typing `test [ford]: x1 x3`. You could test that all coefficients except the coefficient on the constant are zero in the equation for `ford` by typing `test [ford]`. You could test that the coefficients on `x1` and `x3` in the equation for `ford` are equal to the corresponding coefficients in the equation corresponding to `buick` by typing `test[ford=buick]: x1 x3`. You could test that all the corresponding coefficients except the constant in three equations are equal by typing `test [ford=buick=volvo]`.

`testparm` is much like the first syntax of `test`. Its usefulness will be demonstrated below.

The examples below use `regress`, but what is said applies equally after any single-equation estimation command (such as `logistic`). It also applies after multiple-equation estimation commands as long as references to coefficients are qualified with an equation name or number in square brackets placed before them. The convenient syntaxes for dealing with tests of many coefficients in multiple-equation models are demonstrated in *Special syntaxes after multiple-equation estimation* below.

▷ Example 1: Testing for a single coefficient against zero

We have 1980 census data on the 50 states recording the birth rate in each state (`brate`), the median age (`medage`), and the region of the country in which each state is located.

The `region` variable is 1 if the state is in the Northeast, 2 if the state is in the North Central, 3 if the state is in the South, and 4 if the state is in the West. We estimate the following regression:

```
. use http://www.stata-press.com/data/r13/census3
(1980 Census data by state)
. regress brate medage c.medage#c.medage i.region
      Source |       SS       df       MS              Number of obs =      50
-------------+------------------------------           F(  5,    44) =  100.63
       Model |  38803.4208     5  7760.68416            Prob > F      =  0.0000
    Residual |  3393.39921    44  77.1227094            R-squared     =  0.9196
-------------+------------------------------           Adj R-squared =  0.9104
       Total |   42196.82    49  861.159592            Root MSE      =   8.782

------------------------------------------------------------------------------
       brate |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
      medage |  -109.0958   13.52452    -8.07   0.000    -136.3527   -81.83892
             |
    c.medage#|
    c.medage |   1.635209   .2290536     7.14   0.000     1.173582    2.096836
             |
      region |
   N Cntrl   |   15.00283   4.252067     3.53   0.001     6.433353    23.57231
       South |   7.366445   3.953335     1.86   0.069    -.6009775    15.33387
        West |   21.39679   4.650601     4.60   0.000     12.02412    30.76946
             |
       _cons |   1947.611   199.8405     9.75   0.000     1544.859    2350.363
------------------------------------------------------------------------------
```

`test` can now be used to perform a variety of statistical tests. Specify the `coeflegend` option with your estimation command to see a legend of the coefficients and how to specify them; see [R] **estimation options**. We can test the hypothesis that the coefficient on `3.region` is zero by typing

```
. test 3.region=0
 ( 1)  3.region = 0
       F(  1,    44) =    3.47
            Prob > F =    0.0691
```

The F statistic with 1 numerator and 44 denominator degrees of freedom is 3.47. The significance level of the test is 6.91%—we can reject the hypothesis at the 10% level but not at the 5% level.

This result from `test` is identical to one presented in the output from `regress`, which indicates that the t statistic on the `3.region` coefficient is 1.863 and that its significance level is 0.069. The t statistic presented in the output can be used to test the hypothesis that the corresponding coefficient is zero, although it states the test in slightly different terms. The F distribution with 1 numerator degree of freedom is, however, identical to the t^2 distribution. We note that $1.863^2 \approx 3.47$ and that the significance levels in each test agree, although one extra digit is presented by the `test` command.

◁

❑ Technical note

After all estimation commands, including those that use the maximum likelihood method, the test that one variable is zero is identical to that reported by the command's output. The tests are performed in the same way—using the estimated covariance matrix—and are known as Wald tests. If the estimation command reports significance levels and confidence intervals using z rather than t statistics, `test` reports results using the χ^2 rather than the F statistic.

❑

▷ Example 2: Testing the value of a single coefficient

If that were all `test` could do, it would be useless. We can use `test`, however, to perform other tests. For instance, we can `test` the hypothesis that the coefficient on `2.region` is 21 by typing

```
. test 2.region=21
 ( 1)  2.region = 21
       F(  1,    44) =    1.99
            Prob > F =    0.1654
```

We find that we cannot reject that hypothesis, or at least we cannot reject it at any significance level below 16.5%.

◁

▷ Example 3: Testing the equality of two coefficients

The previous test is useful, but we could almost as easily perform it by hand using the results presented in the regression output if we were well read on our statistics. We could type

```
. display Ftail(1,44,((_coef[2.region]-21)/4.252068)^2)
.16544873
```

So, now let's `test` something a bit more difficult: whether the coefficient on `2.region` is the same as the coefficient on `4.region`:

```
. test 2.region=4.region
 ( 1)  2.region - 4.region = 0
       F(  1,    44) =    2.84
            Prob > F =    0.0989
```

We find that we cannot reject the equality hypothesis at the 5% level, but we can at the 10% level.

◁

▷ Example 4

When we tested the equality of the `2.region` and `4.region` coefficients, Stata rearranged our algebra. When Stata displayed its interpretation of the specified test, it indicated that we were testing whether `2.region` *minus* `4.region` is zero. The rearrangement is innocuous and, in fact, allows Stata to perform much more complicated algebra, for instance,

```
. test 2*(2.region-3*(3.region-4.region))=3.region+2.region+6*(4.region-3.region)
 ( 1)  2.region - 3.region = 0
       F(  1,    44) =    5.06
            Prob > F =    0.0295
```

Although we requested what appeared to be a lengthy hypothesis, once Stata simplified the algebra, it realized that all we wanted to do was test whether the coefficient on `2.region` is the same as the coefficient on `3.region`.

◁

❑ Technical note

Stata's ability to simplify and test complex hypotheses is limited to *linear* hypotheses. If you attempt to `test` a nonlinear hypothesis, you will be told that it is not possible:

```
. test 2.region/3.region=2.region+3.region
not possible with test
r(131);
```

To test a nonlinear hypothesis, see [R] **testnl**.

❑

▷ Example 5: Testing joint hypotheses

The real power of `test` is demonstrated when we test *joint* hypotheses. Perhaps we wish to test whether the region variables, taken as a whole, are significant by testing whether the coefficients on `2.region`, `3.region`, and `4.region` are simultaneously zero. `test` allows us to specify multiple conditions to be tested, each embedded within parentheses.

```
. test (2.region=0) (3.region=0) (4.region=0)
 ( 1)  2.region = 0
 ( 2)  3.region = 0
 ( 3)  4.region = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

`test` displays the set of conditions and reports an F statistic of 8.85. `test` also reports the degrees of freedom of the test to be 3, the "dimension" of the hypothesis, and the residual degrees of freedom, 44. The significance level of the test is close to 0, so we can strongly reject the hypothesis of no difference between the regions.

An alternative method to specify simultaneous hypotheses uses the convenient shorthand of conditions with multiple equality operators.

```
. test 2.region=3.region=4.region=0
 ( 1)  2.region - 3.region = 0
 ( 2)  2.region - 4.region = 0
 ( 3)  2.region = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

◁

❑ Technical note

Another method to test simultaneous hypotheses is to specify a `test` for each constraint and `accumulate` it with the previous constraints:

```
. test 2.region=0
 ( 1)  2.region = 0
       F(  1,    44) =   12.45
            Prob > F =    0.0010
. test 3.region=0, accumulate
 ( 1)  2.region = 0
 ( 2)  3.region = 0
       F(  2,    44) =    6.42
            Prob > F =    0.0036
. test 4.region=0, accumulate
 ( 1)  2.region = 0
 ( 2)  3.region = 0
 ( 3)  4.region = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

We tested the hypothesis that the coefficient on `2.region` was zero by typing `test 2.region=0`. We then tested whether the coefficient on `3.region` was also zero by typing `test 3.region=0, accumulate`. The `accumulate` option told Stata that this was not the start of a new test but a continuation of a previous one. Stata responded by showing us the two equations and reporting an F statistic of 6.42. The significance level associated with those two coefficients being zero is 0.36%.

When we added the last constraint `test 4.region=0, accumulate`, we discovered that the three region variables are significant. If all we wanted was the overall significance and we did not want to bother seeing the interim results, we could have used the `notest` option:

```
. test 2.region=0, notest
 ( 1)  2.region = 0
. test 3.region=0, accumulate notest
 ( 1)  2.region = 0
 ( 2)  3.region = 0
. test 4.region=0, accumulate
 ( 1)  2.region = 0
 ( 2)  3.region = 0
 ( 3)  4.region = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

❑

▷ Example 6: Quickly testing coefficients against zero

Because tests that coefficients are zero are so common in applied statistics, the `test` command has a more convenient syntax to accommodate this case:

```
. test 2.region 3.region 4.region
 ( 1)  2.region = 0
 ( 2)  3.region = 0
 ( 3)  4.region = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

◁

▷ Example 7: Specifying varlists

We will now show how to use `testparm`. In its first syntax, `test` accepts a list of variable names but not a *varlist*.

```
. test i(2/4).region
i not found
r(111);
```

In the varlist, `i(2/4).region` means all the level variables from `2.region` through `4.region`, yet we received an error. `test` does not actually understand varlists, but `testparm` does. In fact, it understands only varlists.

```
. testparm i(2/4).region
 ( 1)  2.region = 0
 ( 2)  3.region = 0
 ( 3)  4.region = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

Another way to test all the `region` variables is to type `testparm i.region`.

That `testparm` accepts varlists has other advantages that do not involve factor variables. Suppose that we have a dataset that has dummy variables `reg2`, `reg3`, and `reg4`, rather than the categorical variable `region`.

```
. use http://www.stata-press.com/data/r13/census4
(birth rate, median age)
. regress brate medage c.medage#c.medage reg2 reg3 reg4
  (output omitted)
. test reg2-reg4
- not found
r(111);
```

In a varlist, `reg2-reg4` means variables `reg2` and `reg4` and all the variables between, yet we received an error. `test` is confused because the `-` has two meanings: it means subtraction in an expression and "through" in a *varlist*. Similarly, '`*`' means "any set of characters" in a *varlist* and multiplication in an expression. `testparm` avoids this confusion—it allows only a *varlist*.

```
. testparm reg2-reg4
 ( 1)  reg2 = 0
 ( 2)  reg3 = 0
 ( 3)  reg4 = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

`testparm` has another advantage. We have five variables in our dataset that start with the characters `reg`: `region`, `reg1`, `reg2`, `reg3`, and `reg4`. `reg*` thus means those five variables:

```
. describe reg*
              storage   display    value
variable name   type    format     label      variable label
------------------------------------------------------------------------------
region          int     %8.0g      region     Census Region
reg1            byte    %9.0g                 region==NE
reg2            byte    %9.0g                 region==N Cntrl
reg3            byte    %9.0g                 region==South
reg4            byte    %9.0g                 region==West
```

We cannot type `test reg*` because, in an expression, '`*`' means multiplication, but here is what would happen if we attempted to test all the variables that begin with `reg`:

```
. test region reg1 reg2 reg3 reg4
region not found
r(111);
```

The variable `region` was not included in our model, so it was not found. However, with `testparm`,

```
. testparm reg*
 ( 1)  reg2 = 0
 ( 2)  reg3 = 0
 ( 3)  reg4 = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

That is, `testparm` took `reg*` to mean all variables that start with `reg` that were in our model.

◁

❑ Technical note

Actually, `reg*` means what it always does—all variables in our dataset that begin with `reg`—in this case, `region reg1 reg2 reg3 reg4`. `testparm` just ignores any variables you specify that are not in the model.

❑

▷ Example 8: Replaying the previous test

We just used `test` (`testparm`, actually, but it does not matter) to test the hypothesis that `reg2`, `reg3`, and `reg4` are jointly zero. We can review the results of our last test by typing `test` without arguments:

```
. test
 ( 1)  reg2 = 0
 ( 2)  reg3 = 0
 ( 3)  reg4 = 0
       F(  3,    44) =    8.85
            Prob > F =    0.0001
```

◁

❑ Technical note

`test` does not care how we build joint hypotheses; we may freely mix different forms of syntax. (We can even start with `testparm`, but we cannot use it thereafter because it does not have an `accumulate` option.)

Say that we type `test reg2 reg3 reg4` to test that the coefficients on our region dummies are jointly zero. We could then add a fourth constraint, say, that `medage` = 100, by typing `test medage=100, accumulate`. Or, if we had introduced the `medage` constraint first (our first `test` command had been `test medage=100`), we could then add the region dummy test by typing `test reg2 reg3 reg4, accumulate` or `test (reg2=0) (reg3=0) (reg4=0), accumulate`.

Remember that all previous tests are cleared when we do not specify the `accumulate` option. No matter what tests we performed in the past, if we type `test medage c.medage#c.medage`, omitting the `accumulate` option, we would test that `medage` and `c.medage#c.medage` are jointly zero.

❑

▷ Example 9: Testing the equality of multiple coefficients

Let's return to our `census3.dta` dataset and test the hypothesis that all the included regions have the *same* coefficient—that the Northeast is significantly different from the rest of the nation:

```
. use http://www.stata-press.com/data/r13/census3
(1980 Census data by state)
. regress brate medage c.medage#c.medage i.region
  (output omitted)
. test 2.region=3.region=4.region
 ( 1)  2.region - 3.region = 0
 ( 2)  2.region - 4.region = 0
       F(  2,    44) =    8.23
            Prob > F =    0.0009
```

We find that they are not all the same. The syntax `2.region=3.region=4.region` with multiple `=` operators is just a convenient shorthand for typing that the first expression equals the second expression and that the first expression equals the third expression,

```
. test (2.region=3.region) (2.region=4.region)
```

We performed the test for equality of the three regions by imposing two constraints: region 2 has the same coefficient as region 3, and region 2 has the same coefficient as region 4. Alternatively, we could have tested that the coefficients on regions 2 and 3 are the same and that the coefficients on regions 3 and 4 are the same. We would obtain the same results in either case.

To test for equality of the three regions, we might, likely by mistake, type equality constraints for *all* pairs of regions:

```
. test (2.region=3.region) (2.region=4.region) (3.region=4.region)
 ( 1)  2.region - 3.region = 0
 ( 2)  2.region - 4.region = 0
 ( 3)  3.region - 4.region = 0
       Constraint 3 dropped
       F(  2,    44) =    8.23
            Prob > F =    0.0009
```

Equality of regions 2 and 3 and of regions 2 and 4, however, implies equality of regions 3 and 4. `test` recognized that the last constraint is implied by the other constraints and hence dropped it.

◁

❑ Technical note

Generally, Stata uses `=` for assignment, as in `gen` *newvar* `=` *exp*, and `==` as the operator for testing equality in expressions. For your convenience, `test` allows both `=` and `==` to be used.

❑

▷ Example 10

The test for the equality of the regions is also possible with the `testparm` command. When we include the `equal` option, `testparm` tests that the coefficients of all the variables specified are equal:

```
. testparm i(2/4).region, equal
 ( 1)  - 2.region + 3.region = 0
 ( 2)  - 2.region + 4.region = 0
       F(  2,    44) =    8.23
            Prob > F =    0.0009
```

We can also obtain the equality test by accumulating single equality tests.

```
. test 2.region=3.region, notest
 ( 1)  2.region - 3.region = 0
. test 2.region=4.region, accum
 ( 1)  2.region - 3.region = 0
 ( 2)  2.region - 4.region = 0
       F(  2,    44) =    8.23
            Prob > F =    0.0009
```

◁

❑ Technical note

If we specify a set of inconsistent constraints, `test` will tell us by dropping the constraint or constraints that led to the inconsistency. For instance, let's `test` that the coefficients on region 2 and region 4 are the same, add the test that the coefficient on region 2 is 20, and finally add the test that the coefficient on region 4 is 21:

```
. test (2.region=4.region) (2.region=20) (4.region=21)
 ( 1)  2.region - 4.region = 0
 ( 2)  2.region = 20
 ( 3)  4.region = 21
       Constraint 1 dropped
       F(  2,    44) =    1.29
            Prob > F =    0.2868
```

`test` informed us that it was dropping constraint 1. All three equations cannot be simultaneously true, so `test` drops whatever it takes to get back to something that makes sense.

❑

Special syntaxes after multiple-equation estimation

Everything said above about tests after single-equation estimation applies to tests after multiple-equation estimation, as long as you remember to specify the equation name. To demonstrate, let's estimate a seemingly unrelated regression by using `sureg`; see [R] **sureg**.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. sureg (price foreign mpg displ) (weight foreign length)
Seemingly unrelated regression
```

Equation	Obs	Parms	RMSE	"R-sq"	chi2	P
price	74	3	2165.321	0.4537	49.64	0.0000
weight	74	2	245.2916	0.8990	661.84	0.0000

	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
price						
foreign	3058.25	685.7357	4.46	0.000	1714.233	4402.267
mpg	-104.9591	58.47209	-1.80	0.073	-219.5623	9.644042
displacement	18.18098	4.286372	4.24	0.000	9.779842	26.58211
_cons	3904.336	1966.521	1.99	0.047	50.0263	7758.645
weight						
foreign	-147.3481	75.44314	-1.95	0.051	-295.2139	.517755
length	30.94905	1.539895	20.10	0.000	27.93091	33.96718
_cons	-2753.064	303.9336	-9.06	0.000	-3348.763	-2157.365

To test the significance of `foreign` in the `price` equation, we could type

```
. test [price]foreign
 ( 1)  [price]foreign = 0
           chi2(  1) =   19.89
         Prob > chi2 =    0.0000
```

which is the same result reported by `sureg`: $4.460^2 \approx 19.89$. To test `foreign` in both equations, we could type

```
. test [price]foreign [weight]foreign
 ( 1)  [price]foreign = 0
 ( 2)  [weight]foreign = 0
           chi2(  2) =   31.61
         Prob > chi2 =    0.0000
```

or

```
. test foreign
 ( 1)  [price]foreign = 0
 ( 2)  [weight]foreign = 0
           chi2(  2) =   31.61
         Prob > chi2 =    0.0000
```

This last syntax—typing the variable name by itself—tests the coefficients in all equations in which they appear. The variable `length` appears in only the `weight` equation, so typing

```
. test length
 ( 1)  [weight]length = 0
           chi2(  1) =  403.94
         Prob > chi2 =    0.0000
```

yields the same result as typing `test [weight]length`. We may also specify a linear expression rather than a list of coefficients:

```
. test mpg=displ
 ( 1)  [price]mpg - [price]displacement = 0
           chi2(  1) =    4.85
         Prob > chi2 =    0.0277
```

or

```
. test [price]mpg = [price]displ
 ( 1)  [price]mpg - [price]displacement = 0
           chi2(  1) =    4.85
         Prob > chi2 =    0.0277
```

A variation on this syntax can be used to test cross-equation constraints:

```
. test [price]foreign = [weight]foreign
 ( 1)  [price]foreign - [weight]foreign = 0
           chi2(  1) =   23.07
         Prob > chi2 =    0.0000
```

Typing an equation name in square brackets by itself tests all the coefficients except the intercept in that equation:

```
. test [price]
 ( 1)  [price]foreign = 0
 ( 2)  [price]mpg = 0
 ( 3)  [price]displacement = 0
           chi2(  3) =   49.64
         Prob > chi2 =    0.0000
```

Typing an equation name in square brackets, a colon, and a list of variable names tests those variables in the specified equation:

```
. test [price]: foreign displ
 ( 1)  [price]foreign = 0
 ( 2)  [price]displacement = 0
           chi2(  2) =   25.19
         Prob > chi2 =    0.0000
```

`test` [*eqname*$_1$=*eqname*$_2$] tests that all the coefficients in the two equations are equal. We cannot use that syntax here because there are different variables in the model:

```
. test [price=weight]
variables differ between equations
(to test equality of coefficients in common, specify option common)
r(111);
```

The `common` option specifies a test of the equality coefficients common to the equations `price` and `weight`,

```
. test [price=weight], common
 ( 1)  [price]foreign - [weight]foreign = 0
           chi2(  1) =   23.07
         Prob > chi2 =    0.0000
```

By default, `test` does not include the constant, the coefficient of the constant variable `_cons`, in the test. The `cons` option specifies that the constant be included.

```
. test [price=weight], common cons
 ( 1)  [price]foreign - [weight]foreign = 0
 ( 2)  [price]_cons - [weight]_cons = 0
           chi2(  2) =   51.23
         Prob > chi2 =    0.0000
```

We can also use a modification of this syntax with the model if we also type a colon and the names of the variables we want to test:

```
. test [price=weight]: foreign
 ( 1)  [price]foreign - [weight]foreign = 0
           chi2(  1) =   23.07
         Prob > chi2 =    0.0000
```

We have only one variable in common between the two equations, but if there had been more, we could have listed them.

Finally, a simultaneous test of multiple constraints may be specified just as after single-equation estimation.

```
. test ([price]: foreign) ([weight]: foreign)
 ( 1)  [price]foreign = 0
 ( 2)  [weight]foreign = 0
           chi2(  2) =   31.61
         Prob > chi2 =    0.0000
```

`test` can also test for equality of coefficients across more than two equations. For instance, `test [eq1=eq2=eq3]` specifies a test that the coefficients in the three equations `eq1`, `eq2`, and `eq3` are equal. This requires that the same variables be included in the three equations. If some variables are entered only in some of the equations, you can type `test [eq1=eq2=eq3], common` to test that the coefficients of the variables common to all three equations are equal. Alternatively, you can explicitly list the variables for which equality of coefficients across the equations is to be tested. For instance, `test [eq1=eq2=eq3]: time money` tests that the coefficients of the variables `time` and `money` do not differ between the equations.

❑ Technical note

`test [eq1=eq2=eq3], common` tests the equality of the coefficients common to all equations, but it does *not* test the equality of all common coefficients. Consider the case where

`eq1`	contains the variables `var1 var2 var3`
`eq2`	contains the variables `var1 var2 var4`
`eq3`	contains the variables `var1 var3 var4`

Obviously, only `var1` is common to all three equations. Thus `test [eq1=eq2=eq3], common` tests that the coefficients of `var1` do not vary across the equations, so it is equivalent to `test [eq1=eq2=eq3]: var1`. To perform a test of the coefficients of variables common to two equations, you could explicitly list the constraints to be tested,

```
. test ([eq1=eq2=eq3]:var1) ([eq1=eq2]:var2) ([eq1=eq3]:var3) ([eq2=eq3]:var4)
```

or use `test` with the `accumulate` option, and maybe also with the `notest` option, to form the appropriate joint hypothesis:

```
. test [eq1=eq2], common notest
. test [eq1=eq3], common accumulate notest
. test [eq2=eq3], common accumulate
```

❑

Constrained coefficients

If the test indicates that the data do not allow you to conclude that the constraints are not satisfied, you may want to inspect the constrained coefficients. The `coef` option specified that the constrained results, estimated by GLS, are shown.

```
. test [price=weight], common coef
 ( 1)  [price]foreign - [weight]foreign = 0
           chi2(  1) =   23.07
         Prob > chi2 =    0.0000

Constrained coefficients
```

	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
price						
foreign	-216.4015	74.06083	-2.92	0.003	-361.558	-71.2449
mpg	-121.5717	58.36972	-2.08	0.037	-235.9742	-7.169116
displacement	7.632566	3.681114	2.07	0.038	.4177148	14.84742
_cons	7312.856	1834.034	3.99	0.000	3718.215	10907.5
weight						
foreign	-216.4015	74.06083	-2.92	0.003	-361.558	-71.2449
length	30.34875	1.534815	19.77	0.000	27.34057	33.35693
_cons	-2619.719	302.6632	-8.66	0.000	-3212.928	-2026.51

The constrained coefficient of `foreign` is -216.40 with standard error 74.06 in equations `price` and `weight`. The other coefficients and their standard errors are affected by imposing the equality constraint of the two coefficients of `foreign` because the unconstrained estimates of these two coefficients were correlated with the estimates of the other coefficients.

❑ Technical note

The two-step constrained coefficients b_c displayed by `test, coef` are asymptotically equivalent to the one-stage constrained estimates that are computed by specifying the constraints during estimation using the `constraint()` option of estimation commands (Gourieroux and Monfort 1995, chap. 10). Generally, one-step constrained estimates have better small-sample properties. For inspection and interpretation, however, two-step constrained estimates are a convenient alternative. Moreover, some estimation commands (for example, `stcox`, many `xt` estimators) do not have a `constraint()` option.

❑

Multiple testing

When performing the test of a joint hypothesis, you might want to inspect the underlying 1-degree-of-freedom hypotheses. Which constraint "is to blame"? `test` displays the univariate as well as the simultaneous test if the `mtest` option is specified. For example,

```
. test [price=weight], common cons mtest
 ( 1)  [price]foreign - [weight]foreign = 0
 ( 2)  [price]_cons - [weight]_cons = 0

------------------------------------------------------------------------------
             |      chi2     df       p
-------------+----------------------------------------------------------------
         (1) |      23.07      1     0.0000 #
         (2) |      11.17      1     0.0008 #
-------------+----------------------------------------------------------------
         all |      51.23      2     0.0000
------------------------------------------------------------------------------
                                  # unadjusted p-values
```

Both coefficients seem to contribute to the highly significant result. The 1-degree-of-freedom test shown here is identical to those if `test` had been invoked to test just this simple hypotheses. There is, of course, a real risk in inspecting these simple hypotheses. Especially in high-dimensional hypotheses, you may easily find one hypothesis that happens to be significant. Multiple testing procedures are designed to provide some safeguard against this risk. p-values of the univariate hypotheses are modified so that the probability of falsely rejecting one of the null hypotheses is bounded. `test` provides the methods based on Bonferroni, Šidák, and Holm.

```
. test [price=weight], common cons mtest(b)
 ( 1)  [price]foreign - [weight]foreign = 0
 ( 2)  [price]_cons - [weight]_cons = 0

------------------------------------------------------------------------------
             |      chi2     df       p
-------------+----------------------------------------------------------------
         (1) |      23.07      1     0.0000 #
         (2) |      11.17      1     0.0017 #
-------------+----------------------------------------------------------------
         all |      51.23      2     0.0000
------------------------------------------------------------------------------
                        # Bonferroni-adjusted p-values
```

Stored results

`test` and `testparm` store the following in `r()`:

Scalars

`r(p)`	two-sided p-value	`r(chi2)`	χ^2
`r(F)`	F statistic	`r(ss)`	sum of squares (test)
`r(df)`	test constraints degrees of freedom	`r(rss)`	residual sum of squares
`r(df_r)`	residual degrees of freedom	`r(drop)`	1 if constraints were dropped, 0 otherwise
`r(dropped_i)`	index of ith constraint dropped		

Macros

`r(mtmethod)`	method of adjustment for multiple testing

Matrices

`r(mtest)`	multiple test results

`r(ss)` and `r(rss)` are defined only when `test` is used for testing effects after `anova`.

Methods and formulas

`test` and `testparm` perform Wald tests. Let the estimated coefficient vector be $\mathbf{b}$ and the estimated variance–covariance matrix be $\mathbf{V}$. Let $\mathbf{Rb} = \mathbf{r}$ denote the set of q linear hypotheses to be tested jointly.

The Wald test statistic is (Judge et al. 1985, 20–28)

$$W = (\mathbf{Rb} - \mathbf{r})'(\mathbf{RVR}')^{-1}(\mathbf{Rb} - \mathbf{r})$$

If the estimation command reports its significance levels using Z statistics, a chi-squared distribution with q degrees of freedom,

$$W \sim \chi^2_q$$

is used for computation of the significance level of the hypothesis test.

If the estimation command reports its significance levels using t statistics with d degrees of freedom, an F statistic,

$$F = \frac{1}{q}W$$

is computed, and an F distribution with q numerator degrees of freedom and d denominator degrees of freedom computes the significance level of the hypothesis test.

The two-step constrained estimates b_c displayed by `test` with the `coef` option are the GLS estimates of the unconstrained estimates b subject to the specified constraints $Rb = c$ (Gourieroux and Monfort 1995, chap. 10),

$$\mathbf{b_c} = \mathbf{b} - \mathbf{R}'(\mathbf{RVR}')^{-1}\mathbf{R}(\mathbf{Rb} - \mathbf{r})$$

with variance–covariance matrix

$$\mathbf{V_c} = \mathbf{V} - \mathbf{VR}'(\mathbf{RVR}')^{-1}\mathbf{RV}$$

If `test` displays a Wald test for joint (simultaneous) hypotheses, it can also display all 1-degree-of-freedom tests, with p-values adjusted for multiple testing. Let $p_1, p_2, \ldots, p_k$ be the unadjusted p-values of these 1-degree-of-freedom tests. The Bonferroni-adjusted p-values are defined as $p^b_i = \min(1, kp_i)$. The Šidák-adjusted p-values are $p^s_i = 1 - (1 - p_i)^k$. Holm's method for adjusting p-values is defined as $p^h_i = \min(1, k_i p_i)$, where k_i is the number of p-values at least as large as p_i. Note that $p^h_i < p^b_i$, reflecting that Holm's method is strictly less conservative than the widely used Bonferroni method.

If `test` is used after a `svy` command, it carries out an adjusted Wald test—this adjustment should not be confused with the adjustment for multiple testing. Both adjustments may actually be combined. Specifically, the survey adjustment uses an approximate F statistic $(d-k+1)W/(kd)$, where W is the Wald test statistic, k is the dimension of the hypothesis test, and d = the total number of sampled PSUs minus the total number of strata. Under the null hypothesis, $(d-k+1)F/(kd) \sim F(k, d-k+1)$, where $F(k, d-k+1)$ is an F distribution with k numerator degrees of freedom and $d-k+1$ denominator degrees of freedom. If `nosvyadjust` is specified, the p-value is computed using $W/k \sim F(k, d)$.

See Korn and Graubard (1990) for a detailed description of the Bonferroni adjustment technique and for a discussion of the relative merits of it and of the adjusted and unadjusted Wald tests.

Acknowledgment

The svy adjustment code was adopted from another command developed in collaboration with John L. Eltinge of the Bureau of Labor Statistics.

Title

testnl — Test nonlinear hypotheses after estimation

Syntax | Menu | Description | Options
Remarks and examples | Stored results | Methods and formulas | References
Also see

Syntax

```
testnl exp = exp [= exp ...] [, options]

testnl (exp = exp [= exp ...]) [(exp = exp [= exp ...]) ...] [, options]
```

options	Description
`mtest[(opt)]`	test each condition separately
`iterate(#)`	use maximum # of iterations to find the optimal step size
`df(#)`	use F distribution with # denominator degrees of freedom for the reference distribution of the test statistic
`nosvyadjust`	carry out the Wald test as $W/k \sim F(k,d)$; for use with `svy` estimation commands when the `df()` option is also specified

`df(#)` and `nosvyadjust` do not appear in the dialog box.

The second syntax means that if more than one expression is specified, each must be surrounded by parentheses.

exp is a possibly nonlinear expression containing

```
_b[coef]
_b[eqno:coef]
[eqno]coef
[eqno]_b[coef]
```

eqno is

```
##
name
```

coef identifies a coefficient in the model. *coef* is typically a variable name, a level indicator, an interaction indicator, or an interaction involving continuous variables. Level indicators identify one level of a factor variable and interaction indicators identify one combination of levels of an interaction; see **[U] 11.4.3 Factor variables**. *coef* may contain time-series operators; see **[U] 11.4.4 Time-series varlists**.

Distinguish between `[]`, which are to be typed, and [ ], which indicate optional arguments.

Menu

Statistics > Postestimation > Tests > Test nonlinear hypotheses

Description

`testnl` tests (linear or nonlinear) hypotheses about the estimated parameters from the most recently fit model.

`testnl` produces Wald-type tests of smooth nonlinear (or linear) hypotheses about the estimated parameters from the most recently fit model. The p-values are based on the delta method, an approximation appropriate in large samples.

`testnl` can be used with `svy` estimation results; see [SVY] **svy postestimation**.

The format `(`*exp*$_1$`=`*exp*$_2$`=`*exp*$_3$`...)` for a simultaneous-equality hypothesis is just a convenient shorthand for a list `(`*exp*$_1$`=`*exp*$_2$`)` `(`*exp*$_1$`=`*exp*$_3$`)`, etc.

`testnl` may also be used to test linear hypotheses. `test` is faster if you want to test only linear hypotheses; see [R] **test**. `testnl` is the only option for testing linear and nonlinear hypotheses simultaneously.

Options

`mtest`$\left[\texttt{(}opt\texttt{)}\right]$ specifies that tests be performed for each condition separately. *opt* specifies the method for adjusting p-values for multiple testing. Valid values for *opt* are

`bonferroni`	Bonferroni's method
`holm`	Holm's method
`sidak`	Šidák's method
`noadjust`	no adjustment is to be made

Specifying `mtest` without an argument is equivalent to specifying `mtest(noadjust)`.

`iterate(#)` specifies the maximum number of iterations used to find the optimal step size in the calculation of numerical derivatives of the test expressions. By default, the maximum number of iterations is 100, but convergence is usually achieved after only a few iterations. You should rarely have to use this option.

The following options are available with `testnl` but are not shown in the dialog box:

`df(#)` specifies that the F distribution with # denominator degrees of freedom be used for the reference distribution of the test statistic. With survey data, # is the design degrees unless `nosvyadjust` is specified.

`nosvyadjust` is for use with `svy` estimation commands when the `df()` option is also specified; see [SVY] **svy estimation**. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is, the test is carried out as $W/k \sim F(k,d)$ rather than as $(d-k+1)W/(kd) \sim F(k,d-k+1)$, where $k =$ the dimension of the test and $d =$ the design degrees of freedom specified in the `df()` option.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Using testnl to perform linear tests
Specifying constraints
Dropped constraints
Multiple constraints
Manipulability

Introduction

▷ Example 1

We have just estimated the parameters of an earnings model on cross-sectional time-series data using one of Stata's more sophisticated estimators:

```
. use http://www.stata-press.com/data/r13/earnings
(NLS Women 14-24 in 1968)
. xtgee ln_w grade age c.age#c.age, corr(exchangeable) nolog
GEE population-averaged model                   Number of obs      =      1326
Group variable:                      idcode     Number of groups   =       269
Link:                              identity     Obs per group: min =         1
Family:                            Gaussian                    avg =       4.9
Correlation:                   exchangeable                    max =         9
                                                Wald chi2(3)       =    327.33
Scale parameter:                   .0976738     Prob > chi2        =    0.0000
```

ln_wage	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
grade	.0749686	.0066111	11.34	0.000	.062011	.0879261
age	.1080806	.0235861	4.58	0.000	.0618526	.1543086
c.age#c.age	-.0016253	.0004739	-3.43	0.001	-.0025541	-.0006966
_cons	-.8788933	.2830899	-3.10	0.002	-1.433739	-.3240473

An implication of this model is that peak earnings occur at age `-_b[age]/(2*_b[c.age#c.age])`, which here is equal to 33.2. Say that we have a theory that peak earnings should occur at age `16 + 1/_b[grade]`.

```
. testnl -_b[age]/(2*_b[c.age#c.age]) = 16 + 1/_b[grade]
  (1)  -_b[age]/(2*_b[c.age#c.age]) = 16 + 1/_b[grade]
               chi2(1) =        1.71
           Prob > chi2 =        0.1914
```

These data do not reject our theory. ◁

Using testnl to perform linear tests

`testnl` may be used to test linear constraints, but `test` is faster; see [R] **test**. You could type

```
. testnl _b[x4] = _b[x1]
```

but it would take less computer time if you typed

```
. test _b[x4] = _b[x1]
```

Specifying constraints

The constraints to be tested can be formulated in many different ways. You could type

```
. testnl _b[mpg]*_b[weight] = 1
```

or

```
. testnl _b[mpg] = 1/_b[weight]
```

or you could express the constraint any other way you wished. (To say that `testnl` allows constraints to be specified in different ways does not mean that the test itself does not depend on the formulation. This point is briefly discussed later.) In formulating the constraints, you must, however, exercise one caution: users of `test` often refer to the coefficient on a variable by specifying the variable name. For example,

```
. test mpg = 0
```

More formally, they should type

```
. test _b[mpg] = 0
```

but `test` allows the `_b[]` surrounding the variable name to be omitted. `testnl` does not allow this shorthand. Typing

```
. testnl mpg=0
```

specifies the constraint that the value of variable `mpg` in the first observation is zero. If you make this mistake, sometimes `testnl` will catch it:

```
. testnl mpg=0
equation (1) contains reference to X rather than _b[X]
r(198);
```

In other cases, `testnl` may not catch the mistake; then the constraint will be dropped because it does not make sense:

```
. testnl mpg=0
  Constraint (1) dropped
```

(There are reasons other than this for constraints being dropped.) The worst case, however, is

```
. testnl _b[weight]*mpg = 1
```

when what you mean is not that `_b[weight]` equals the reciprocal of the value of `mpg` in the first observation, but rather that

```
. testnl _b[weight]*_b[mpg] = 1
```

Sometimes this mistake will be caught by the "contains reference to X rather than _b[X]" error, and sometimes it will not. Be careful.

`testnl`, like `test`, can be used after any Stata estimation command, including the survey estimators. When you use it after a multiple-equation command, such as `mlogit` or `heckman`, you refer to coefficients by using Stata's standard syntax: `[`*eqname*`]_b[`*varname*`]`.

Stata's single-equation estimation output looks like this:

```
             |    Coef   ...
-------------+----------------------------------------------------------------
      weight |   12.27   ...    <-  coefficient is  _b[weight]
         mpg |    3.21   ...
-------------+----------------------------------------------------------------
```

Stata's multiple-equation output looks like this:

```
             |    Coef   ...
-------------+----------------------------------------------------------------
cat1         |           ...
      weight |   12.27   ...    <-  coefficient is  [cat1]_b[weight]
         mpg |    3.21   ...
-------------+----------------------------------------------------------------
8            |           ...
      weight |    5.83   ...    <-  coefficient is  [8]_b[weight]
         mpg |    7.43   ...
-------------+----------------------------------------------------------------
```

Dropped constraints

`testnl` automatically drops constraints when

- They are nonbinding, for example, `_b[mpg]=_b[mpg]`. More subtle cases include

```
_b[mpg]*_b[weight] = 4
_b[weight] = 2
_b[mpg] = 2
```

  In this example, the third constraint is nonbinding because it is implied by the first two.

- They are contradictory, for example, `_b[mpg]=2 and _b[mpg]=3`. More subtle cases include

```
_b[mpg]*_b[weight] = 4
_b[weight] = 2
_b[mpg] = 3
```

  The third constraint contradicts the first two.

Multiple constraints

▷ Example 2

We illustrate the simultaneous test of a series of constraints using simulated data on labor-market promotion in a given year. We fit a probit model with separate effects for education, experience, and experience-squared for men and women.

```
. use http://www.stata-press.com/data/r13/promotion
. probit promo male male#c.(yedu yexp yexp2), nolog
Probit regression                                 Number of obs   =        775
                                                  LR chi2(7)      =     424.42
                                                  Prob > chi2     =     0.0000
Log likelihood = -245.42768                       Pseudo R2       =     0.4637
```

promo	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
male	.6489974	.203739	3.19	0.001	.2496763	1.048318
male#c.yedu						
0	.9730237	.1056136	9.21	0.000	.7660248	1.180023
1	1.390517	.1527288	9.10	0.000	1.091174	1.68986
male#c.yexp						
0	.4559544	.0901169	5.06	0.000	.2793285	.6325803
1	1.422539	.1544255	9.21	0.000	1.11987	1.725207
male#c.yexp2						
0	-.1027149	.0573059	-1.79	0.073	-.2150325	.0096026
1	-.3749457	.1160113	-3.23	0.001	-.6023236	-.1475677
_cons	.9872018	.1148215	8.60	0.000	.7621559	1.212248

```
Note: 1 failure and 2 successes completely determined.
```

The effects of human capital seem to differ between men and women. A formal test confirms this.

```
. test (yedu#0.male = yedu#1.male) (yexp#0.male = yexp#1.male)
> (yexp2#0.male = yexp2#1.male)
 ( 1)  [promo]0b.male#c.yedu - [promo]1.male#c.yedu = 0
 ( 2)  [promo]0b.male#c.yexp - [promo]1.male#c.yexp = 0
 ( 3)  [promo]0b.male#c.yexp2 - [promo]1.male#c.yexp2 = 0
           chi2(  3) =   35.43
         Prob > chi2 =    0.0000
```

How do we interpret this gender difference? It has repeatedly been stressed (see, for example, Long [1997, 47–50]; Allison [1999]) that comparison of groups in binary response models, and similarly in other latent-variable models, is hampered by an identification problem: with β the regression coefficients for the latent variable and σ the standard deviation of the latent residual, only the β/σ are identified. In fact, in terms of the latent regression, the probit coefficients should be interpreted as β/σ, not as the β. If we cannot claim convincingly that the residual standard deviation σ does not vary between the sexes, equality of the regression coefficients β implies that the coefficients of the probit model for men and women are *proportional* but not necessarily equal. This is a nonlinear hypothesis in terms of the probit coefficients, not a linear one.

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
> = _b[yexp2#1.male]/_b[yexp2#0.male]
  (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
  (2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]
               chi2(2) =        9.21
             Prob > chi2 =        0.0100
```

We conclude that we find fairly strong evidence against the proportionality of the coefficients, and hence we have to conclude that success in the labor market is produced in different ways by men and women. (But remember, these were simulated data.)

◁

▷ Example 3

The syntax for specifying the equality of multiple expressions is just a convenient shorthand for specifying a series of constraints, namely, that the first expression equals the second expression, the first expression also equals the third expression, etc. The Wald test performed and the output of `testnl` are the same whether we use the shorthand or we specify the series of constraints. The lengthy specification as a series of constraints can be simplified using the continuation symbols `///`.

```
. testnl (_b[yedu#1.male]/_b[yedu#0.male] = ///
>         _b[yexp#1.male]/_b[yexp#0.male])  ///
>        (_b[yedu#1.male]/_b[yedu#0.male] = ///
>         _b[yexp2#1.male]/_b[yexp2#0.male])
  (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
  (2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]

           chi2(2) =        9.21
         Prob > chi2 =        0.0100
```

Having established differences between men and women, we would like to do multiple testing between the ratios. Because we did not specify hypotheses in advance, we prefer to adjust the p-values of tests using, here, Bonferroni's method.

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = ///
>        _b[yexp#1.male]/_b[yexp#0.male] = ///
>        _b[yexp2#1.male]/_b[yexp2#0.male], mtest(b)
  (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
  (2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]
```

	chi2	df	p
(1)	6.89	1	0.0173 #
(2)	0.93	1	0.6713 #
all	9.21	2	0.0100

 # Bonferroni-adjusted p-values

◁

Manipulability

Although `testnl` allows you to specify constraints in different ways that are mathematically equivalent, as noted above, this does not mean that the tests are the same. This difference is known as the manipulability of the Wald test for nonlinear hypotheses; also see [R] **boxcox**. The test might even be significant for one formulation but not significant for another formulation that is mathematically equivalent. Trying out different specifications to find a formulation with the desired p-value is totally inappropriate, though it may actually be fun to try. There is no variance under representation because the nonlinear Wald test is actually a standard Wald test for a linearization of the constraint, which depends on the particular specification. We note that the likelihood-ratio test is not manipulable in this sense.

From a statistical point of view, it is best to choose a specification of the constraints that is as linear is possible. Doing so usually improves the accuracy of the approximation of the null-distribution of the test by a χ^2 or an F distribution. The example above used the nonlinear Wald test to test whether the coefficients of human capital variables for men were proportional to those of women. A specification of proportionality of coefficients in terms of ratios of coefficients is fairly nonlinear if the coefficients in the denominator are close to 0. A more linear version of the test results from a bilinear formulation. Thus instead of

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
  (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
               chi2(1) =        6.89
             Prob > chi2 =        0.0087
```

perhaps

```
. testnl _b[yedu#1.male]*_b[yexp#0.male] = _b[yedu#0.male]*_b[yexp#1.male]
  (1)  _b[yedu#1.male]*_b[yexp#0.male] = _b[yedu#0.male]*_b[yexp#1.male]
               chi2(1) =       13.95
             Prob > chi2 =        0.0002
```

is better, and in fact it has been suggested that the latter version of the test is more reliable. This assertion is confirmed by performing simulations and is in line with theoretical results of Phillips and Park (1988). There is strong evidence against the proportionality of human capital effects between men and women, implying for this example that differences in the residual variances between the sexes can be ruled out as the explanation of the sex differences in the analysis of labor market participation.

Stored results

`testnl` stores the following in `r()`:

Scalars

`r(df)`	degrees of freedom
`r(df_r)`	residual degrees of freedom
`r(chi2)`	χ^2
`r(p)`	significance
`r(F)`	F statistic

Macros

`r(mtmethod)`	method specified in `mtest()`

Matrices

`r(G)`	derivatives of $R(\mathbf{b})$ with respect to $\mathbf{b}$; see *Methods and formulas* below
`r(R)`	$R(\mathbf{b})-\mathbf{q}$; see *Methods and formulas* below
`r(mtest)`	multiple test results

Methods and formulas

After fitting a model, define $\mathbf{b}$ as the resulting $1 \times k$ parameter vector and $\mathbf{V}$ as the $k \times k$ covariance matrix. The (linear or nonlinear) hypothesis is given by $R(\mathbf{b}) = \mathbf{q}$, where R is a function returning a $j \times 1$ vector. The Wald test formula is (Greene 2012, 528)

$$W = \Big\{R(\mathbf{b}) - \mathbf{q}\Big\}' \Big(\mathbf{G}\mathbf{V}\mathbf{G}'\Big)^{-1} \Big\{R(\mathbf{b}) - \mathbf{q}\Big\}$$

where $\mathbf{G}$ is the derivative matrix of $R(\mathbf{b})$ with respect to $\mathbf{b}$. W is distributed as χ^2 if $\mathbf{V}$ is an asymptotic covariance matrix. $F = W/j$ is distributed as F for linear regression.

The adjustment methods for multiple testing are described in [R] **test**. The adjustment for survey design effects is described in [SVY] **svy postestimation**.

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Tetrachoric correlations

Description

`tetrachoric` computes estimates of the tetrachoric correlation coefficients of the binary variables in *varlist*. All of these variables should be 0, 1, or missing values.

Tetrachoric correlations assume a latent bivariate normal distribution (X_1,X_2) for each pair of variables (v_1,v_2), with a threshold model for the manifest variables, $v_i = 1$ if and only if $X_i > 0$. The means and variances of the latent variables are not identified, but the correlation, r, of X_1 and X_2 can be estimated from the joint distribution of v_1 and v_2 and is called the tetrachoric correlation coefficient.

`tetrachoric` computes pairwise estimates of the tetrachoric correlations by the (iterative) maximum likelihood estimator obtained from bivariate probit without explanatory variables (see [R] **biprobit**) by using the Edwards and Edwards (1984) noniterative estimator as the initial value.

The pairwise correlation matrix is returned as `r(Rho)` and can be used to perform a factor analysis or a principal component analysis of binary variables by using the `factormat` or `pcamat` commands; see [MV] **factor** and [MV] **pca**.

Options

Main

`stats(`*statlist*`)` specifies the statistics to be displayed in the matrix of output. `stats(rho)` is the default. Up to four statistics may be specified. `stats(rho se p obs)` would display the tetrachoric correlation coefficient, its standard error, the significance level, and the number of observations. If *varlist* contains only two variables, all statistics are shown in tabular form. `stats()`, `print()`, and `star()` have no effect unless the `matrix` option is also specified.

`edwards` specifies that the noniterative Edwards and Edwards estimator be used. The default is the maximum likelihood estimator. If you analyze many binary variables, you may want to use the fast noniterative estimator proposed by Edwards and Edwards (1984). However, if you have skewed variables, the approximation does not perform well.

`print(#)` specifies the maximum significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing `tetrachoric ..., print(.10)` would list only those correlation coefficients that are significant at the 10% level or lower.

`star(#)` specifies the maximum significance level of correlation coefficients to be marked with a star. Typing `tetrachoric ..., star(.05)` would "star" all correlation coefficients significant at the 5% level or lower.

`bonferroni` makes the Bonferroni adjustment to calculated significance levels. This option affects printed significance levels and the `print()` and `star()` options. Thus `tetrachoric ..., print(.05) bonferroni` prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

`sidak` makes the Šidák adjustment to calculated significance levels. This option affects printed significance levels and the `print()` and `star()` options. Thus `tetrachoric ..., print(.05) sidak` prints coefficients with Šidák-adjusted significance levels of 0.05 or less.

`pw` specifies that the tetrachoric correlation be calculated by using all available data. By default, `tetrachoric` uses casewise deletion, where observations are ignored if any of the specified variables in *varlist* are missing.

`zeroadjust` specifies that when one of the cells has a zero count, a frequency adjustment be applied in such a way as to increase the zero to one-half and maintain row and column totals.

`matrix` forces `tetrachoric` to display the statistics as a matrix, even if *varlist* contains only two variables. `matrix` is implied if more than two variables are specified.

`notable` suppresses the output.

`posdef` modifies the correlation matrix so that it is positive semidefinite, that is, a proper correlation matrix. The modified result is the correlation matrix associated with the least-squares approximation of the tetrachoric correlation matrix by a positive-semidefinite matrix. If the correlation matrix is modified, the standard errors and significance levels are not displayed and are returned in `r()`.

Remarks and examples

Remarks are presented under the following headings:

Association in 2-by-2 tables
Factor analysis of dichotomous variables
Tetrachoric correlations with simulated data

Association in 2-by-2 tables

Although a wide variety of measures of association in cross tabulations have been proposed, such measures are essentially equivalent (monotonically related) in the special case of 2×2 tables—there is only 1 degree of freedom for nonindependence. Still, some measures have more desirable properties than others. Here we compare two measures: the standard Pearson correlation coefficient and the tetrachoric correlation coefficient. Given asymmetric row or column margins, Pearson correlations are limited to a range smaller than -1 to 1, although tetrachoric correlations can still span the range from -1 to 1. To illustrate, consider the following set of tables for two binary variables, X and Z:

	Z = 0	Z = 1	
X = 0	$20 - a$	$10 + a$	30
X = 1	a	$10 - a$	10
	20	20	40

For a equal to 0, 1, 2, 5, 8, 9, and 10, the Pearson and tetrachoric correlations for the above table are

a	0	1	2	5	8	9	10
Pearson	0.577	0.462	0.346	0	−0.346	−0.462	−0.577
Tetrachoric	1.000	0.792	0.607	0	−0.607	−0.792	−1.000

The restricted range for the Pearson correlation is especially unfortunate when you try to analyze the association between binary variables by using models developed for continuous data, such as factor analysis and principal component analysis.

The tetrachoric correlation of two variables (Y_1, Y_2) can be thought of as the Pearson correlation of two latent bivariate normal distributed variables (Y_1^*, Y_2^*) with threshold measurement models $Y_i = (Y_i^* > c_i)$ for unknown cutpoints c_i. Or equivalently, $Y_i = (Y_i^{**} > 0)$ where the latent bivariate normal (Y_1^{**}, Y_2^{**}) are shifted versions of (Y_1^*, Y_2^*) so that the cutpoints are zero. Obviously, you must judge whether assuming underlying latent variables is meaningful for the data. If this assumption is justified, tetrachoric correlations have two advantages. First, you have an intuitive understanding of

the size of correlations that are substantively interesting in your field of research, and this intuition is based on correlations that range from −1 to 1. Second, because the tetrachoric correlation for binary variables estimates the Pearson correlation of the latent continuous variables (assumed multivariate normal distributed), you can use the tetrachoric correlations to analyze multivariate relationships between the dichotomous variables. When doing so, remember that you must interpret the model in terms of the underlying continuous variables.

▷ Example 1

To illustrate tetrachoric correlations, we examine three binary variables from the `familyvalues` dataset (described in example 2).

```
. use http://www.stata-press.com/data/r13/familyvalues

```

As usual, the tetrachoric correlation coefficients are larger (in absolute value) and more dispersed than the Pearson correlations.

◁

Factor analysis of dichotomous variables

▷ Example 2

Factor analysis is a popular model for measuring latent continuous traits. The standard estimators are appropriate only for continuous unimodal data. Because of the skewness implied by Bernoulli-distributed variables (especially when the probability is distributed unevenly), a factor analysis of a Pearson correlation matrix can be rather misleading when used in this context. A factor analysis of a matrix of tetrachoric correlations is more appropriate under these conditions (Uebersax 2000). We illustrate this with data on gender, relationship, and family attitudes of spouses using the Households in The Netherlands survey 1995 (Weesie et al. 1995). For attitude variables, it seems reasonable to assume that agreement or disagreement is just a coarse measurement of more nuanced underlying attitudes.

To demonstrate, we examine a few of the variables from the `familyvalues` dataset.

```

	RS063
RS063	1.0000

Again we see that the tetrachoric correlations are generally larger in absolute value than the Pearson correlations. The bivariate probit and Edwards and Edwards estimators (the `edwards` option) implemented in `tetrachoric` may return a correlation matrix that is not positive semidefinite—a mathematical property of any real correlation matrix. Positive definiteness is required by commands for analyses of correlation matrices, such as `factormat` and `pcamat`; see [MV] **factor** and [MV] **pca**. The `posdef` option of `tetrachoric` tests for positive definiteness and projects the estimated correlation matrix to a positive-semidefinite matrix if needed.

```
. tetrachoric RS056-RS063, notable posdef
. matrix C = r(corr)
```

This time, we suppressed the display of the correlations with the `notable` option and requested that the correlation matrix be positive semidefinite with the `posdef` option. Had the correlation matrix not been positive definite, `tetrachoric` would have displayed a warning message and then adjusted the matrix to be positive semidefinite. We placed the resulting tetrachoric correlation matrix into a matrix, `C`, so that we can perform a factor analysis upon it.

`tetrachoric` with the `posdef` option asserted that `C` was positive definite because no warning message was displayed. We can verify this by using a familiar characterization of symmetric positive-definite matrices: all eigenvalues are real and positive.

```
. matrix symeigen eigenvectors eigenvalues = C
. matrix list eigenvalues
eigenvalues[1,8]
           e1         e2         e3         e4         e5         e6         e7
r1  2.5974789  1.3544664  1.0532476  .77980391  .73462018  .57984565  .54754512
           e8
r1  .35299228
```

We can proceed with a factor analysis on the matrix `C`. We use `factormat` and select iterated principal factors as the estimation method; see [MV] **factor**.

```
. factormat C, n(3221) ipf factor(2)

  +-------------------------------------------------------------------------+
: end
-------------------------------------------------------------------------------
```

The estimated tetrachoric correlation matrix is rank-2 deficient. With this `C2` matrix, we can only use models of correlation that allow for singular cases.

◁

Tetrachoric correlations with simulated data

▷ Example 4

We use `drawnorm` (see [D] **drawnorm**) to generate a sample of 1,000 observations from a bivariate normal distribution with means -1 and 1, unit variances, and correlation 0.4.

```
. clear
. set seed 11000
. matrix m = (1, -1)
. matrix V = (1, 0.4 \ 0.4, 1)
. drawnorm c1 c2, n(1000) means(m) cov(V)
(obs 1000)
```

Now consider the measurement model assumed by the tetrachoric correlations. We observe only whether `c1` and `c2` are greater than zero,

```
. generate d1 = (c1 > 0)
. generate d2 = (c2 > 0)
. tabulate d1 d2
```

d1	d2 = 0	d2 = 1	Total
0	176	6	182
1	656	162	818
Total	832	168	1,000

We want to estimate the correlation of `c1` and `c2` from the binary variables `d1` and `d2`. Pearson's correlation of the binary variables `d1` and `d2` is 0.170—a seriously biased estimate of the underlying correlation $\rho = 0.4$.

```
. correlate d1 d2
(obs=1000)
             |       d1       d2
-------------+------------------
          d1 |   1.0000
          d2 |   0.1704   1.0000
```

The tetrachoric correlation coefficient of d1 and d2 estimates the Pearson correlation of the latent continuous variables, c1 and c2.

```
. tetrachoric d1 d2
   Number of obs =    1000
 Tetrachoric rho =       0.4790
       Std error =       0.0700
Test of Ho: d1 and d2 are independent
 2-sided exact P =       0.0000
```

The estimate of the tetrachoric correlation of d1 and d2, 0.4790, is much closer to the underlying correlation, 0.4, between c1 and c2.

◁

Stored results

tetrachoric stores the following in r():

Scalars

r(rho)	tetrachoric correlation coefficient between variables 1 and 2
r(N)	number of observations
r(nneg)	number of negative eigenvalues (posdef only)
r(se_rho)	standard error of r(rho)
r(p)	exact two-sided significance level

Macros

r(method)	estimator used

Matrices

r(Rho)	tetrachoric correlation matrix
r(Se_Rho)	standard errors of r(Rho)
r(Nobs)	number of observations used in computing correlation
r(P)	exact two-sided significance level matrix

Methods and formulas

tetrachoric provides two estimators for the tetrachoric correlation ρ of two binary variables with the frequencies n_{ij}, $i, j = 0, 1$. tetrachoric defaults to the slower (iterative) maximum likelihood estimator obtained from bivariate probit without explanatory variables (see [R] **biprobit**) by using the Edwards and Edwards noniterative estimator as the initial value. A fast (noniterative) estimator is also available by specifying the edwards option (Edwards and Edwards 1984; Digby 1983)

$$\widehat{\rho} = \frac{\alpha - 1}{\alpha + 1}$$

where

$$\alpha = \left(\frac{n_{00}n_{11}}{n_{01}n_{10}}\right)^{\pi/4} \quad (\pi = 3.14\ldots)$$

if all $n_{ij} > 0$. If $n_{00} = 0$ or $n_{11} = 0$, $\widehat{\rho} = -1$; if $n_{01} = 0$ or $n_{10} = 0$, $\widehat{\rho} = 1$.

The asymptotic variance of the Edwards and Edwards estimator of the tetrachoric correlation is easily obtained by the delta method,

$$\text{avar}(\widehat{\rho}) = \left(\frac{\pi\alpha}{2(1+\alpha)^2}\right)^2 \left(\frac{1}{n_{00}} + \frac{1}{n_{01}} + \frac{1}{n_{10}} + \frac{1}{n_{11}}\right)$$

provided all $n_{ij} > 0$, otherwise it is left undefined (missing). The Edwards and Edwards estimator is fast, but may be inaccurate if the margins are very skewed.

`tetrachoric` reports exact p-values for statistical independence, computed by the `exact` option of [R] **tabulate twoway**.

options	Description
Model	
`noconstant`	suppress constant term
`ll(#|`*varname*`)`	truncation point; default value is `ll(0)`, zero truncation
`dispersion(mean)`	parameterization of dispersion; the default
`dispersion(constant)`	constant dispersion for all observations
`exposure(`*varname*$_e$`)`	include ln(*varname*$_e$) in model with coefficient constrained to 1
`offset(`*varname*$_o$`)`	include *varname*$_o$ in model with coefficient constrained to 1
`constraints(`*constraints*`)`	apply specified linear constraints
`collinear`	keep collinear variables
SE/Robust	
`vce(`*vcetype*`)`	*vcetype* may be `oim`, `robust`, `cluster` *clustvar*, `opg`, `bootstrap`, or `jackknife`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`nolrtest`	suppress likelihood-ratio test
`irr`	report incidence-rate ratios
`nocnsreport`	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
`coeflegend`	display legend instead of statistics

indepvars may contain factor variables; see [U] **11.4.3 Factor variables**.

depvar and *indepvars* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] **11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] **svy**.

`fweights`, `iweights`, and `pweights` are allowed; see [U] **11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Count outcomes > Truncated negative binomial regression

Description

`tnbreg` estimates the parameters of a truncated negative binomial model by maximum likelihood. The dependent variable *depvar* is regressed on *indepvars*, where *depvar* is a positive count variable whose values are all above the truncation point.

Options

Model

`noconstant`; see [R] **estimation options**.

`ll(#|`*varname*`)` specifies the truncation point, which is a nonnegative integer. The default is zero truncation, `ll(0)`.

`dispersion(mean|constant)` specifies the parameterization of the model. `dispersion(mean)`, the default, yields a model with dispersion equal to $1+\alpha\exp(\mathbf{x}_j\boldsymbol{\beta}+\text{offset}_j)$; that is, the dispersion is a function of the expected mean: $\exp(\mathbf{x}_j\boldsymbol{\beta}+\text{offset}_j)$. `dispersion(constant)` has dispersion equal to $1+\delta$; that is, it is a constant for all observations.

`exposure(`*varname*$_e$`)`, `offset(`*varname*$_o$`)`, `constraints(`*constraints*`)`, `collinear`; see [R] **estimation options**.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

Reporting

`level(#)`; see [R] **estimation options**.

`nolrtest` suppresses fitting the Poisson model. Without this option, a comparison Poisson model is fit, and the likelihood is used in a likelihood-ratio test of the null hypothesis that the dispersion parameter is zero.

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is, e^{β_i} rather than β_i. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

`nocnsreport`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] **maximize**. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

The following option is available with tnbreg but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

Grogger and Carson (1991) showed that overdispersion causes inconsistent estimation of the mean in the truncated Poisson model. To solve this problem, they proposed using the truncated negative binomial model as an alternative. If data are truncated but do not exhibit overdispersion, the truncated Poisson model is more appropriate; see [R] **tpoisson**. For an introduction to negative binomial regression, see Cameron and Trivedi (2005, 2010) and Long and Freese (2014). For an introduction to truncated negative binomial models, see Cameron and Trivedi (2013) and Long (1997, chap. 8).

tnbreg fits the mean-dispersion and the constant-dispersion parameterizations of truncated negative binomial models. These parameterizations extend those implemented in nbreg; see [R] **nbreg**.

▷ Example 1

We illustrate the truncated negative binomial model using the 1997 MedPar dataset (Hilbe 1999). The data are from 1,495 patients in Arizona who were assigned to a diagnostic-related group (DRG) of patients having a ventilator. Length of stay (los), the dependent variable, is a positive integer; it cannot have zero values. The data are truncated because there are no observations on individuals who stayed for zero days.

The objective of this example is to determine whether the length of stay was related to the binary variables: died, hmo, type1, type2, and type3.

The died variable was recorded as a 0 unless the patient died, in which case, it was recorded as a 1. The other variables also adopted this encoding. The hmo variable was set to 1 if the patient belonged to a health maintenance organization (HMO).

The type1–type3 variables indicated the type of admission used for the patient. The type1 variable indicated an emergency admit. The type2 variable indicated an urgent admit—that is, the first available bed. The type3 variable indicated an elective admission. Because type1–type3 were mutually exclusive, only two of the three could be used in the truncated negative binomial regression shown below.

```
. use http://www.stata-press.com/data/r13/medpar
. tnbreg los died hmo type2-type3, vce(cluster provnum) nolog
Truncated negative binomial regression
Truncation point: 0                                Number of obs   =       1495
Dispersion     = mean                              Wald chi2(4)    =      36.01
Log likelihood = -4737.535                         Prob > chi2     =     0.0000
                                  (Std. Err. adjusted for 54 clusters in provnum)
```

los	Coef.	Robust Std. Err.	z	P>|z|	[95% Conf.	Interval]
died	-.2521884	.061533	-4.10	0.000	-.3727908	-.1315859
hmo	-.0754173	.0533132	-1.41	0.157	-.1799091	.0290746
type2	.2685095	.0666474	4.03	0.000	.137883	.3991359
type3	.7668101	.2183505	3.51	0.000	.338851	1.194769
_cons	2.224028	.034727	64.04	0.000	2.155964	2.292091
/lnalpha	-.630108	.0764019			-.779853	-.480363
alpha	.5325343	.0406866			.4584734	.6185588

Because observations within the same hospital (`provnum`) are likely to be correlated, we specified the `vce(cluster provnum)` option. The results show that whether the patient died in the hospital and the type of admission have significant effects on the patient's length of stay.

◁

▷ Example 2

To illustrate truncated negative binomial regression with more complex data than the previous example, similar data were created from 100 hospitals. Each hospital had its own way of tracking patient data. In particular, hospitals only recorded data from patients with a minimum length of stay, denoted by the variable `minstay`.

Definitions for minimum length of stay varied among hospitals, typically, from 5 to 18 days. The objective of this example is the same as before: to determine whether the length of stay, recorded in `los`, was related to the binary variables: `died`, `hmo`, `type1`, `type2`, and `type3`.

The binary variables encode the same information as in example 1 above. The `minstay` variable was used to allow for varying truncation points.

```
. use http://www.stata-press.com/data/r13/medproviders
. tnbreg los died hmo type2-type3, ll(minstay) vce(cluster hospital) nolog
Truncated negative binomial regression
Truncation points: minstay                      Number of obs   =       2144
Dispersion     = mean                           Wald chi2(4)    =      15.22
Log likelihood = -7864.0928                     Prob > chi2     =     0.0043
                              (Std. Err. adjusted for 100 clusters in hospital)
```

los	Coef.	Robust Std. Err.	z	P>|z|	[95% Conf.	Interval]
died	.0781044	.0303596	2.57	0.010	.0186006	.1376081
hmo	-.0731128	.0368897	-1.98	0.047	-.1454152	-.0008104
type2	.0294136	.0390167	0.75	0.451	-.0470578	.1058849
type3	.0626352	.054012	1.16	0.246	-.0432265	.1684969
_cons	3.014964	.0290886	103.65	0.000	2.957951	3.071977
/lnalpha	-.9965131	.082867			-1.158929	-.8340967
alpha	.3691645	.0305916			.313822	.4342666

In this analysis, two variables have a statistically significant relationship with length of stay. On average, patients who died in the hospital had longer lengths of stay ($p = 0.01$). Because the coefficient for HMO is negative, that is, $b_{\text{HMO}} = -0.073$, on average, patients who were insured by an HMO had shorter lengths of stay ($p = 0.047$). The type of admission was not statistically significant ($p > 0.05$).

Stored results

tnbreg stores the following in e():

Scalars

e(N)	number of observations
e(k)	number of parameters
e(k_aux)	number of auxiliary parameters
e(k_eq)	number of equations in e(b)
e(k_eq_model)	number of equations in overall model test
e(k_dv)	number of dependent variables
e(df_m)	model degrees of freedom
e(r2_p)	pseudo-R-squared
e(ll)	log likelihood
e(ll_0)	log likelihood, constant-only model
e(ll_c)	log likelihood, comparison model
e(alpha)	value of alpha
e(N_clust)	number of clusters
e(chi2)	χ^2
e(chi2_c)	χ^2 for comparison test
e(p)	significance
e(rank)	rank of e(V)
e(rank0)	rank of e(V) for constant-only model
e(ic)	number of iterations
e(rc)	return code
e(converged)	1 if converged, 0 otherwise

Macros

e(cmd)	tnbreg
e(cmdline)	command as typed
e(depvar)	name of dependent variable
e(llopt)	contents of ll(), or 0 if not specified
e(wtype)	weight type
e(wexp)	weight expression
e(title)	title in estimation output
e(clustvar)	name of cluster variable
e(offset)	linear offset variable
e(chi2type)	Wald or LR; type of model χ^2 test
e(chi2_ct)	Wald or LR; type of model χ^2 test corresponding to e(chi2_c)
e(dispers)	mean or constant
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(opt)	type of optimization
e(which)	max or min; whether optimizer is to perform maximization or minimization
e(ml_method)	type of ml method
e(user)	name of likelihood-evaluator program
e(technique)	maximization technique
e(properties)	b V
e(predict)	program used to implement predict
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(Cns)	constraints matrix
e(ilog)	iteration log (up to 20 iterations)
e(gradient)	gradient vector
e(V)	variance–covariance matrix of the estimators
e(V_modelbased)	model-based variance

Functions

e(sample)	marks estimation sample

Methods and formulas

Methods and formulas are presented under the following headings:

Mean-dispersion model
Constant-dispersion model

Mean-dispersion model

A negative binomial distribution can be regarded as a gamma mixture of Poisson random variables. The number of times an event occurs, y_j, is distributed as Poisson$(\nu_j\mu_j)$. That is, its conditional likelihood is

$$f(y_j \mid \nu_j) = \frac{(\nu_j\mu_j)^{y_j} e^{-\nu_j\mu_j}}{\Gamma(y_j+1)}$$

where $\mu_j = \exp(\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j)$ and ν_j is an unobserved parameter with a Gamma$(1/\alpha, \alpha)$ density:

$$g(\nu) = \frac{\nu^{(1-\alpha)/\alpha} e^{-\nu/\alpha}}{\alpha^{1/\alpha}\Gamma(1/\alpha)}$$

This gamma distribution has a mean of 1 and a variance of α, where α is our ancillary parameter.

The unconditional likelihood for the jth observation is therefore

$$f(y_j) = \int_0^\infty f(y_j \mid \nu) g(\nu)\, d\nu = \frac{\Gamma(m+y_j)}{\Gamma(y_j+1)\Gamma(m)}\, p_j^m (1-p_j)^{y_j}$$

where $p_j = 1/(1+\alpha\mu_j)$ and $m = 1/\alpha$. Solutions for α are handled by searching for $\ln\alpha$ because α must be greater than zero. The conditional probability of observing y_j events given that y_j is greater than the truncation point τ_j is

$$\Pr(Y = y_j \,|\, y_j > \tau_j, \mathbf{x}_j) = \frac{f(y_j)}{\Pr(Y > \tau_j \,|\, \mathbf{x}_j)}$$

The log likelihood (with weights w_j and offsets) is given by

$$m = 1/\alpha \qquad p_j = 1/(1+\alpha\mu_j) \qquad \mu_j = \exp(\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j)$$

$$\ln L = \sum_{j=1}^{n} w_j \Big[\ln\{\Gamma(m+y_j)\} - \ln\{\Gamma(y_j+1)\} - \ln\{\Gamma(m)\} + m\ln(p_j) + y_j\ln(1-p_j) - \ln\{\Pr(Y > \tau_j \,|\, p_j, m)\} \Big]$$

Constant-dispersion model

The constant-dispersion model assumes that y_j is conditionally distributed as Poisson(μ_j^*), where $\mu_j^* \sim$ Gamma$(\mu_j/\delta, \delta)$ for some dispersion parameter δ [by contrast, the mean-dispersion model assumes that $\mu_j^* \sim$ Gamma$(1/\alpha, \alpha\mu_j)$]. The log likelihood is given by

$$m_j = \mu_j/\delta \qquad p = 1/(1+\delta)$$

$$\ln L = \sum_{j=1}^{n} w_j \Big[\ln\{\Gamma(m_j + y_j)\} - \ln\{\Gamma(y_j + 1)\} - \ln\{\Gamma(m_j)\} + m_j \ln(p) + y_j \ln(1-p) - \ln\{\Pr(Y > \tau_j \,|\, p, m_j)\} \Big]$$

with everything else defined as shown above in the calculations for the mean-dispersion model.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`tnbreg` also supports estimation with survey data. For details on variance–covariance estimates with survey data, see [SVY] **variance estimation**.

Title

tnbreg postestimation — Postestimation tools for tnbreg

Description Syntax for predict Menu for predict Options for predict
Methods and formulas Also see

Description

The following postestimation commands are available after `tnbreg`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]

predict [type] {stub* | newvar_reg newvar_disp} [if] [in], scores
```

statistic	Description
Main	
`n`	number of events; the default
`ir`	incidence rate
`cm`	conditional mean, $E(y_j \mid y_j > \tau_j)$
`pr(`*n*`)`	probability $\Pr(y_j = n)$
`pr(`*a*`,`*b*`)`	probability $\Pr(a \le y_j \le b)$
`cpr(`*n*`)`	conditional probability $\Pr(y_j = n \mid y_j > \tau_j)$
`cpr(`*a*`,`*b*`)`	conditional probability $\Pr(a \le y_j \le b \mid y_j > \tau_j)$
`xb`	linear prediction
`stdp`	standard error of the linear prediction

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`n`, the default, calculates the predicted number of events, which is $\exp(\mathbf{x}_j\boldsymbol{\beta})$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\exp(\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j)$ if `offset()` was specified; or $\exp(\mathbf{x}_j\boldsymbol{\beta}) \times \text{exposure}_j$ if `exposure()` was specified.

`ir` calculates the incidence rate $\exp(\mathbf{x}_j\boldsymbol{\beta})$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the `n` and the `nooffset` options.

`cm` calculates the conditional mean,

$$E(y_j \mid y_j > \tau_j) = \frac{E(y_j)}{\Pr(y_j > \tau_j)}$$

where τ_j is the truncation point found in `e(llopt)`.

`pr(`*n*`)` calculates the probability $\Pr(y_j = n)$, where *n* is a nonnegative integer that may be specified as a number or a variable.

`pr(`*a*`,`*b*`)` calculates the probability $\Pr(a \le y_j \le b)$, where *a* and *b* are nonnegative integers that may be specified as numbers or variables;

b missing ($b \ge .$) means $+\infty$;
`pr(20,.)` calculates $\Pr(y_j \ge 20)$;
`pr(20,`*b*`)` calculates $\Pr(y_j \ge 20)$ in observations for which $b \ge .$ and calculates $\Pr(20 \le y_j \le b)$ elsewhere.

`pr(.,b)` produces a syntax error. A missing value in an observation of the variable a causes a missing value in that observation for `pr(a,b)`.

`cpr(n)` calculates the conditional probability $\Pr(y_j = n \,|\, y_j > \tau_j)$, where τ_j is the truncation point found in `e(llopt)`. n is an integer greater than the truncation point that may be specified as a number or a variable.

`cpr(a,b)` calculates the conditional probability $\Pr(a \leq y_j \leq b \,|\, y_j > \tau_j)$, where τ_j is the truncation point found in `e(llopt)`. The syntax for this option is analogous to that used for `pr(a,b)` except that a must be greater than the truncation point.

`xb` calculates the linear prediction, which is $\mathbf{x}_j\boldsymbol{\beta}$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ if `offset()` was specified; or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$ if `exposure()` was specified; see `nooffset` below.

`stdp` calculates the standard error of the linear prediction.

`nooffset` is relevant only if you specified `offset()` or `exposure()` when you fit the model. It modifies the calculations made by `predict` so that they ignore the offset or exposure variable; the linear prediction is treated as $\mathbf{x}_j\boldsymbol{\beta}$ rather than as $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$. Specifying `predict ..., nooffset` is equivalent to specifying `predict ..., ir`.

`scores` calculates equation-level score variables.

The first new variable will contain $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

The second new variable will contain $\partial \ln L/\partial(\ln\alpha)$ for `dispersion(mean)`.

The second new variable will contain $\partial \ln L/\partial(\ln\delta)$ for `dispersion(constant)`.

Methods and formulas

In the following formulas, we use the same notation as in [R] **tnbreg**.

Methods and formulas are presented under the following headings:

Mean-dispersion model
Constant-dispersion model

Mean-dispersion model

The equation-level scores are given by

$$\text{score}(\mathbf{x}\boldsymbol{\beta})_j = p_j(y_j - \mu_j) - \frac{p_j^{(m+1)}\mu_j}{\Pr(Y > \tau_j \,|\, p_j, m)}$$

$$\text{score}(\omega)_j = -m\left\{\frac{\alpha(\mu_j - y_j)}{1+\alpha\mu_j} - \ln(1+\alpha\mu_j) + \psi(y_j+m) - \psi(m)\right\} - \frac{p_j^m}{\Pr(Y > \tau_j \,|\, p_j, m)}\{m\ln(p_j) + \mu_j p_j\}$$

where $\omega_j = \ln\alpha_j$, $\psi(z)$ is the digamma function, and τ_j is the truncation point found in `e(llopt)`.

Constant-dispersion model

The equation-level scores are given by

$$\text{score}(\mathbf{x}\boldsymbol{\beta})_j = m_j \left\{ \psi(y_j + m_j) - \psi(m_j) + \ln(p) + \frac{p^{m_j} \ln(p)}{\Pr(Y > \tau_j \,|\, p, m_j)} \right\}$$

$$\text{score}(\omega)_j = y_j - (y_j + m_j)(1 - p) - \text{score}(\mathbf{x}\boldsymbol{\beta})_j - \frac{\mu_j p}{\Pr(Y > \tau_j \,|\, p, m_j)}$$

where $\omega_j = \ln\delta_j$ and τ_j is the truncation point found in `e(llopt)`.

```

options	Description
Model	
noconstant	suppress constant term
*ll[(#)]	left-censoring limit
*ul[(#)]	right-censoring limit
offset(*varname*)	include *varname* in model with coefficient constrained to 1
SE/Robust	
vce(*vcetype*)	*vcetype* may be oim, robust, cluster *clustvar*, bootstrap, or jackknife
Reporting	
level(#)	set confidence level; default is level(95)
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
coeflegend	display legend instead of statistics

*You must specify at least one of ll[(#)] or ul[(#)].

indepvars may contain factor variables; see [U] **11.4.3 Factor variables**.

depvar and *indepvars* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

bootstrap, by, fp, jackknife, nestreg, rolling, statsby, stepwise, and svy are allowed; see [U] **11.1.10 Prefix commands**.

Weights are not allowed with the bootstrap prefix; see [R] **bootstrap**.

aweights are not allowed with the jackknife prefix; see [R] **jackknife**.

vce() and weights are not allowed with the svy prefix; see [SVY] **svy**.

aweights, fweights, iweights, and pweights are allowed; see [U] **11.1.6 weight**.

coeflegend does not appear in the dialog box.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Linear models and related > Censored regression > Tobit regression

Description

`tobit` fits a model of *depvar* on *indepvars* where the censoring values are fixed.

Options

Model

`noconstant`; see [R] **estimation options**.

`ll`[`(#)`] and `ul`[`(#)`] indicate the lower and upper limits for censoring, respectively. You may specify one or both. Observations with *depvar* $\leq$ `ll()` are left-censored; observations with *depvar* $\geq$ `ul()` are right-censored; and remaining observations are not censored. You do not have to specify the censoring values at all. It is enough to type `ll`, `ul`, or both. When you do not specify a censoring value, `tobit` assumes that the lower limit is the minimum observed in the data (if `ll` is specified) and the upper limit is the maximum (if `ul` is specified).

`offset(`*varname*`)`; see [R] **estimation options**.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

Reporting

`level(#)`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Maximization

maximize_options: `iterate(#)`, [`no`]`log`, `trace`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, and `nonrtolerance`; see [R] **maximize**. These options are seldom used.

Unlike most maximum likelihood commands, `tobit` defaults to `nolog`—it suppresses the iteration log.

The following option is available with `tobit` but is not shown in the dialog box:

`coeflegend`; see [R] **estimation options**.

Remarks and examples

Tobit estimation was originally developed by Tobin (1958). A consumer durable was purchased if a consumer's desire was high enough, where desire was measured by the dollar amount spent by the purchaser. If no purchase was made, the measure of desire was censored at zero.

▷ Example 1: Censored from below

We will demonstrate `tobit` with an artificial example, which in the process will allow us to emphasize the assumptions underlying the estimation. We have a dataset containing the mileage ratings and weights of 74 cars. There are no censored variables in this dataset, but we are going to create one. Before that, however, the relationship between mileage and weight in our complete data is

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. generate wgt = weight/1000
. regress mpg wgt
```

Source	SS	df	MS	Number of obs =	74
Model	1591.99024	1	1591.99024	F(1, 72) =	134.62
Residual	851.469221	72	11.8259614	Prob > F =	0.0000
				R-squared =	0.6515
				Adj R-squared =	0.6467
Total	2443.45946	73	33.4720474	Root MSE =	3.4389

mpg	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
wgt	-6.008687	.5178782	-11.60	0.000	-7.041058	-4.976316
_cons	39.44028	1.614003	24.44	0.000	36.22283	42.65774

(We divided `weight` by 1,000 simply to make discussing the resulting coefficients easier. We find that each additional 1,000 pounds of weight reduces mileage by 6 mpg.)

`mpg` in our data ranges from 12 to 41. Let us now pretend that our data were censored in the sense that we could not observe a mileage rating below 17 mpg. If the true mpg is 17 or less, all we know is that the mpg is less than or equal to 17:

```
. replace mpg=17 if mpg<=17
(14 real changes made)
. tobit mpg wgt, ll
```

Tobit regression		Number of obs =	74
		LR chi2(1) =	72.85
		Prob > chi2 =	0.0000
Log likelihood = -164.25438		Pseudo R2 =	0.1815

mpg	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
wgt	-6.87305	.7002559	-9.82	0.000	-8.268658	-5.477442
_cons	41.49856	2.05838	20.16	0.000	37.39621	45.6009
/sigma	3.845701	.3663309			3.115605	4.575797

```
  Obs. summary:         18  left-censored observations at mpg<=17
                        56     uncensored observations
                         0 right-censored observations
```

The `replace` before estimation was not really necessary—we remapped all the mileage ratings below 17 to 17 merely to reassure you that `tobit` was not somehow using uncensored data. We typed `ll` after `tobit` to inform `tobit` that the data were left-censored. `tobit` found the minimum of `mpg` in our data and assumed that was the censoring point. We could also have dispensed with `replace` and typed `ll(17)`, informing `tobit` that all values of the dependent variable 17 and below are really censored at 17. In either case, at the bottom of the table, we are informed that there are, as a result, 18 left-censored observations.

On these data, our estimate is now a reduction of 6.9 mpg per 1,000 extra pounds of weight as opposed to 6.0. The parameter reported as `/sigma` is the estimated standard error of the regression; the resulting 3.8 is comparable with the estimated root mean squared error reported by `regress` of 3.4.

◁

❑ Technical note

You would never want to throw away information by purposefully censoring variables. The `regress` estimates are in every way preferable to those of `tobit`. Our example is designed solely to illustrate the relationship between `tobit` and `regress`. If you have uncensored data, use `regress`. If your data are censored, you have no choice but to use `tobit`.

❑

▷ Example 2: Censored from above

`tobit` can also fit models that are censored from above. This time, let's assume that we do not observe the actual mileage rating of cars yielding 24 mpg or better—we know only that it is at least 24. (Also assume that we have undone the change to `mpg` we made in the previous example.)

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. generate wgt = weight/1000
. regress mpg wgt
  (output omitted)
. tobit mpg wgt, ul(24)
Tobit regression                                  Number of obs   =         74
                                                  LR chi2(1)      =      90.72
                                                  Prob > chi2     =     0.0000
Log likelihood =  -129.8279                       Pseudo R2       =     0.2589

------------------------------------------------------------------------------
         mpg |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
         wgt |  -5.080645     .43493   -11.68   0.000    -5.947459   -4.213831
       _cons |   36.08037   1.432056    25.19   0.000     33.22628    38.93445
-------------+----------------------------------------------------------------
      /sigma |   2.385357   .2444604                      1.898148    2.872566
------------------------------------------------------------------------------

  Obs. summary:          0  left-censored observations
                        51     uncensored observations
                        23 right-censored observations at mpg>=24
```

◁

▷ Example 3: Two-limit tobit model

tobit can also fit models that are censored from both sides (the so-called two-limit tobit):

```
. tobit mpg wgt, ll(17) ul(24)
Tobit regression                                  Number of obs   =         74
                                                  LR chi2(1)      =      77.60
                                                  Prob > chi2     =     0.0000
Log likelihood = -104.25976                       Pseudo R2       =     0.2712

------------------------------------------------------------------------------
         mpg |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
         wgt |  -5.764448   .7245417    -7.96   0.000    -7.208457   -4.320438
       _cons |   38.07469   2.255917    16.88   0.000     33.57865    42.57072
-------------+----------------------------------------------------------------
      /sigma |   2.886337   .3952143                      2.098676    3.673998
------------------------------------------------------------------------------
  Obs. summary:         18  left-censored observations at mpg<=17
                        33     uncensored observations
                        23 right-censored observations at mpg>=24
```

Stored results

tobit stores the following in e():

Scalars

e(N)	number of observations
e(N_unc)	number of uncensored observations
e(N_lc)	number of left-censored observations
e(N_rc)	number of right-censored observations
e(llopt)	contents of ll(), if specified
e(ulopt)	contents of ul(), if specified
e(k_aux)	number of auxiliary parameters
e(df_m)	model degrees of freedom
e(df_r)	residual degrees of freedom
e(r2_p)	pseudo-R-squared
e(chi2)	χ^2
e(ll)	log likelihood
e(ll_0)	log likelihood, constant-only model
e(N_clust)	number of clusters
e(F)	F statistic
e(p)	significance
e(rank)	rank of e(V)
e(converged)	1 if converged, 0 otherwise

Macros

e(cmd)	tobit
e(cmdline)	command as typed
e(depvar)	name of dependent variable
e(wtype)	weight type
e(wexp)	weight expression
e(title)	title in estimation output
e(clustvar)	name of cluster variable
e(offset)	linear offset variable
e(chi2type)	LR; type of model χ^2 test
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(properties)	b V
e(predict)	program used to implement predict
e(footnote)	program and arguments to display footnote
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(V)	variance–covariance matrix of the estimators
e(V_modelbased)	model-based variance

Functions

e(sample)	marks estimation sample

James Tobin (1918–2002) was an American economist who after education and research at Harvard moved to Yale, where he was on the faculty from 1950 to 1988. He made many outstanding contributions to economics and was awarded the Nobel Prize in 1981 "for his analysis of financial markets and their relations to expenditure decisions, employment, production and prices". He trained in the U.S. Navy with the writer in Herman Wouk, who later fashioned a character after Tobin in the novel *The Caine Mutiny* (1951): "A mandarin-like midshipman named Tobit, with a domed forehead, measured quiet speech, and a mind like a sponge, was ahead of the field by a spacious percentage."

Methods and formulas

See *Methods and formulas* in [R] **intreg**.

See Tobin (1958) for the original derivation of the tobit model. An introductory description of the tobit model can be found in, for instance, Wooldridge (2013, sec. 17.2), Davidson and MacKinnon (2004, 484–486), Long (1997, 196–210), and Maddala and Lahiri (2006, 333–336). Cameron and Trivedi (2010, chap. 16) discuss the tobit model using Stata examples.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster *clustvar*), respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

tobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **variance estimation**.

Title

tobit postestimation — Postestimation tools for tobit

Description | Syntax for predict | Menu for predict | Options for predict
Remarks and examples | References | Also see

Description

The following postestimation commands are available after `tobit`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`hausman`	Hausman's specification test
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`linktest`	link test for model specification
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]

predict [type] {stub* | newvar_reg newvar_sigma} [if] [in], scores
```

statistic	Description
Main	
`xb`	linear prediction; the default
`stdp`	standard error of the linear prediction
`stdf`	standard error of the forecast
`pr(`*a*`,`*b*`)`	$\Pr(a < y_j < b)$
`e(`*a*`,`*b*`)`	$E(y_j \mid a < y_j < b)$
`ystar(`*a*`,`*b*`)`	$E(y_j^*)$, $y_j^* = \max\{a, \min(y_j, b)\}$

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where *a* and *b* may be numbers or variables; *a* missing ($a \geq .$) means $-\infty$, and *b* missing ($b \geq .$) means $+\infty$; see [U] **12.2.1 Missing values**.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see *Methods and formulas* in [R] **regress postestimation**.

`pr(`*a*`,`*b*`)` calculates $\Pr(a < \mathbf{x}_j\mathbf{b} + u_j < b)$, the probability that $y_j|\mathbf{x}_j$ would be observed in the interval (a, b).

a and *b* may be specified as numbers or variable names; *lb* and *ub* are variable names;
`pr(20,30)` calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < 30)$;
`pr(`*lb*`,`*ub*`)` calculates $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < ub)$; and
`pr(20,`*ub*`)` calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$.

a missing ($a \geq .$) means $-\infty$; `pr(.,30)` calculates $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$;
`pr(`*lb*`,30)` calculates $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$ in observations for which $lb \geq .$
and calculates $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < 30)$ elsewhere.

b missing ($b \geq .$) means $+\infty$; `pr(20,.)` calculates $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$;
`pr(20,`*ub*`)` calculates $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$ in observations for which $ub \geq .$
and calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$ elsewhere.

`e(`*a*`,`*b*`)` calculates $E(\mathbf{x}_j\mathbf{b} + u_j \mid a < \mathbf{x}_j\mathbf{b} + u_j < b)$, the expected value of $y_j|\mathbf{x}_j$ conditional on $y_j|\mathbf{x}_j$ being in the interval (a, b), meaning that $y_j|\mathbf{x}_j$ is truncated.
a and *b* are specified as they are for `pr()`.

`ystar(`*a*`,`*b*`)` calculates $E(y_j^*)$, where $y_j^* = a$ if $\mathbf{x}_j\mathbf{b} + u_j \leq a$, $y_j^* = b$ if $\mathbf{x}_j\mathbf{b} + u_j \geq b$, and $y_j^* = \mathbf{x}_j\mathbf{b} + u_j$ otherwise, meaning that y_j^* is censored. *a* and *b* are specified as they are for `pr()`.

`nooffset` is relevant only if you specified `offset(`*varname*`)`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $\mathbf{x}_j\mathbf{b}$ rather than as $\mathbf{x}_j\mathbf{b} + \text{offset}_j$.

`scores` calculates equation-level score variables.

The first new variable will contain $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

The second new variable will contain $\partial \ln L/\partial\sigma$.

Remarks and examples

Following Cong (2000), write the tobit model as

$$y_i^* = \begin{cases} y_i, & \text{if } a < y_i < b \\ a, & \text{if } y_i \leq a \\ b, & \text{if } y_i \geq b \end{cases}$$

y_i is a latent variable; instead, we observe y_i^*, which is bounded between a and b if y_i is outside those bounds.

There are four types of marginal effects that may be of interest in the tobit model, depending on the application:

1. The β coefficients themselves measure how the unobserved variable y_i changes with respect to changes in the regressors.
2. The marginal effects of the truncated expected value $E(y_i^*|a < y_i^* < b)$ measure the changes in y_i with respect to changes in the regressors among the subpopulation for which y_i is not at a boundary.
3. The marginal effects of the censored expected value $E(y_i^*)$ describe how the observed variable y_i^* changes with respect to the regressors.
4. The marginal effects of $\Pr(\mathrm{a} < \mathrm{y_i^*} < \mathrm{b})$ describe how the probability of being uncensored changes with respect to the regressors.

In the next example, we show how to obtain each of these.

Example 1

In example 3 of [R] **tobit**, we fit a two-limit tobit model of mpg on wgt.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. generate wgt = weight/1000
. tobit mpg wgt, ll(17) ul(24)
Tobit regression                                  Number of obs   =         74
                                                  LR chi2(1)      =      77.60
                                                  Prob > chi2     =     0.0000
Log likelihood = -104.25976                       Pseudo R2       =     0.2712

------------------------------------------------------------------------------
         mpg |      Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]
-------------+----------------------------------------------------------------
         wgt |  -5.764448   .7245417    -7.96   0.000    -7.208457   -4.320438
       _cons |   38.07469   2.255917    16.88   0.000     33.57865    42.57072
-------------+----------------------------------------------------------------
       /sigma |   2.886337   .3952143                      2.098676    3.673998
------------------------------------------------------------------------------
  Obs. summary:         18  left-censored observations at mpg<=17
                        33     uncensored observations
                        23 right-censored observations at mpg>=24
```

`tobit` reports the β coefficients for the latent regression model. The marginal effect of x_k on y is simply the corresponding β_k, because $E(y|x)$ is linear in x. Thus a 1,000-pound increase in a car's weight (which is a 1-unit increase in `wgt`) would lower fuel economy by 5.8 mpg.

To estimate the means of the marginal effects on the expected value of the censored outcome, conditional on weight being each of three values (2,000; 3,000; and 4,000 pounds), we type

```
. margins, dydx(wgt) predict(ystar(17,24)) at(wgt=(2 3 4))
Conditional marginal effects                      Number of obs   =         74

          3  |  -1.412822   .3289702    -4.29   0.000    -2.057591    -.768052
------------------------------------------------------------------------------
```

The $E(y^*|x)$ is nonlinear in x, so the marginal effect for a continuous covariate is not the same as the change in y^* induced by a one-unit change in x. Recall that the marginal effect at a point is the slope of the tangent line at that point. In our example, we estimate the mean of the marginal effects for different values of `wgt`. The estimated mean of the marginal effects is -1.1 mpg for a 2,000 pound car; -4.5 mpg for a 3,000 pound car; and -1.4 mpg for a 4,000 pound car.

To estimate the means of the marginal effects on the expected value of the truncated outcome at the same levels of wgt, we type

```
. margins, dydx(wgt) predict(e(17,24)) at(wgt=(2 3 4))
Conditional marginal effects                    Number of obs   =         74
Model VCE    : OIM

Expression   : E(mpg|17<mpg<24), predict(e(17,24))
dy/dx w.r.t. : wgt
1._at        : wgt             =           2
2._at        : wgt             =           3
3._at        : wgt             =           4
```

	dy/dx	Delta-method Std. Err.	z	P>|z|	[95% Conf.	Interval]
wgt						
_at						
1	-1.166572	.0827549	-14.10	0.000	-1.328768	-1.004375
2	-2.308842	.4273727	-5.40	0.000	-3.146477	-1.471207
3	-1.288896	.0889259	-14.49	0.000	-1.463188	-1.114604

The mean of the marginal effects of a change in wgt on y_i (which is bounded between 17 and 24) is about -1.2 mpg for a 2,000 pound car; -2.3 mpg for a 3,000 pound car; and -1.3 for a 4,000 pound car.

`nolegend`	suppress table legend
display_options	control column formats and line width
`coeflegend`	display legend instead of statistics

`bootstrap`, `jackknife`, `mi estimate`, `rolling`, `statsby`, and `svy` are allowed; see **[U] 11.1.10 Prefix commands**.
`vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix.
Weights are not allowed with the `bootstrap` prefix; see **[R] bootstrap**.
`vce()` and weights are not allowed with the `svy` prefix; see **[SVY] svy**.
`fweights`, `iweights`, and `pweights` are allowed; see **[U] 11.1.6 weight**.
`coeflegend` does not appear in the dialog box.
See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Totals

Description

`total` produces estimates of totals, along with standard errors.

Options

if/in/over

over(*varlist* [, nolabel]) specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in *varlist*.

When this option is supplied with one variable name, such as over(*varname*), the value labels of *varname* are used to identify the subpopulations. If *varname* does not have labeled values (or there are unlabeled values), the values themselves are used, provided that they are nonnegative integers. Noninteger values, negative values, and labels that are not valid Stata names are substituted with a default identifier.

When over() is supplied with multiple variable names, each subpopulation is assigned a unique default identifier.

nolabel specifies that value labels attached to the variables identifying the subpopulations be ignored.

SE/Cluster

vce(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (analytic), that allow for intragroup correlation (cluster *clustvar*), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] ***vce_option***.

vce(analytic), the default, uses the analytically derived variance estimator associated with the sample total.

Reporting

level(#); see [R] **estimation options**.

noheader prevents the table header from being displayed. This option implies nolegend.

nolegend prevents the table legend identifying the subpopulations from being displayed.

display_options: cformat(%*fmt*) and nolstretch; see [R] **estimation options**.

The following option is available with total but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

▷ Example 1

Suppose that we collected data on incidence of heart attacks. The variable heartatk indicates whether a person ever had a heart attack (1 means yes; 0 means no). We can then estimate the total number of persons who have had heart attacks for each sex in the population represented by the data we collected.

```
. use http://www.stata-press.com/data/r13/total
. total heartatk [pw=swgt], over(sex)
Total estimation                    Number of obs    =      4946
         Male: sex = Male
       Female: sex = Female
```

Over	Total	Std. Err.	[95% Conf.	Interval]
heartatk				
Male	944559	104372.3	739943	1149175
Female	581590	82855.59	419156.3	744023.7

Stored results

`total` stores the following in `e()`:

Scalars

`e(N)`	number of observations
`e(N_over)`	number of subpopulations
`e(N_clust)`	number of clusters
`e(k_eq)`	number of equations in `e(b)`
`e(df_r)`	sample degrees of freedom
`e(rank)`	rank of `e(V)`

Macros

`e(cmd)`	`total`
`e(cmdline)`	command as typed
`e(varlist)`	*varlist*
`e(wtype)`	weight type
`e(wexp)`	weight expression
`e(title)`	title in estimation output
`e(cluster)`	name of cluster variable
`e(over)`	*varlist* from `over()`
`e(over_labels)`	labels from `over()` variables
`e(over_namelist)`	names from `e(over_labels)`
`e(vce)`	*vcetype* specified in `vce()`
`e(vcetype)`	title used to label Std. Err.
`e(properties)`	`b V`
`e(estat_cmd)`	program used to implement `estat`
`e(marginsnotok)`	predictions disallowed by `margins`

Matrices

`e(b)`	vector of total estimates
`e(V)`	(co)variance estimates
`e(_N)`	vector of numbers of nonmissing observations
`e(error)`	error code corresponding to `e(b)`

Functions

`e(sample)`	marks estimation sample

Methods and formulas

Methods and formulas are presented under the following headings:

The total estimator
Survey data
The survey total estimator
The poststratified total estimator
Subpopulation estimation

The total estimator

Let y denote the variable on which to calculate the total and $y_j, j = 1, \ldots, n$, denote an individual observation on y. Let w_j be the frequency weight (or `iweight`), and if no weight is specified, define $w_j = 1$ for all j. See the next section for `pweighted` data. The sum of the weights is an estimate of the population size:

$$\widehat{N} = \sum_{j=1}^{n} w_j$$

If the population values of y are denoted by $Y_j, j = 1, \ldots, N$, the associated population total is

$$Y = \sum_{j=1}^{N} Y_j = N\overline{y}$$

where $\overline{y}$ is the population mean. The total is estimated as

$$\widehat{Y} = \widehat{N}\overline{y}$$

The variance estimator for the total is

$$\widehat{V}(\widehat{Y}) = \widehat{N}^2\widehat{V}(\overline{y})$$

where $\widehat{V}(\overline{y})$ is the variance estimator for the mean; see [R] **mean**. The standard error of the total is the square root of the variance.

If x, x_j, $\overline{x}$, and $\widehat{X}$ are similarly defined for another variable (observed jointly with y), the covariance estimator between $\widehat{X}$ and $\widehat{Y}$ is

$$\widehat{\mathrm{Cov}}(\widehat{X}, \widehat{Y}) = \widehat{N}^2\widehat{\mathrm{Cov}}(\overline{x}, \overline{y})$$

where $\widehat{\mathrm{Cov}}(\overline{x}, \overline{y})$ is the covariance estimator between two means; see [R] **mean**.

Survey data

See [SVY] **variance estimation** and [SVY] **poststratification** for discussions that provide background information for the following formulas.

The survey total estimator

Let Y_j be a survey item for the jth individual in the population, where $j = 1, \ldots, M$ and M is the size of the population. The associated population total for the item of interest is

$$Y = \sum_{j=1}^{M} Y_j$$

Let y_j be the survey item for the jth sampled individual from the population, where $j = 1, \ldots, m$ and m is the number of observations in the sample.

The estimator $\widehat{Y}$ for the population total Y is

$$\widehat{Y} = \sum_{j=1}^{m} w_j y_j$$

where w_j is a sampling weight. The estimator for the number of individuals in the population is

$$\widehat{M} = \sum_{j=1}^{m} w_j$$

The score variable for the total estimator is the variable itself,

$$z_j(\widehat{Y}) = y_j$$

The poststratified total estimator

Let P_k denote the set of sampled observations that belong to poststratum k, and define $I_{P_k}(j)$ to indicate if the jth observation is a member of poststratum k, where $k = 1, \ldots, L_P$ and L_P is the number of poststrata. Also, let M_k denote the population size for poststratum k. P_k and M_k are identified by specifying the `poststrata()` and `postweight()` options on `svyset`; see [SVY] **svyset**.

The estimator for the poststratified total is

$$\widehat{Y}^P = \sum_{k=1}^{L_P} \frac{M_k}{\widehat{M}_k} \widehat{Y}_k = \sum_{k=1}^{L_P} \frac{M_k}{\widehat{M}_k} \sum_{j=1}^{m} I_{P_k}(j)\, w_j y_j$$

where

$$\widehat{M}_k = \sum_{j=1}^{m} I_{P_k}(j) w_j$$

The score variable for the poststratified total is

$$z_j(\widehat{Y}^P) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{\widehat{M}_k} \left(y_j - \frac{\widehat{Y}_k}{\widehat{M}_k} \right)$$

Subpopulation estimation

Let S denote the set of sampled observations that belong to the subpopulation of interest, and define $I_S(j)$ to indicate if the jth observation falls within the subpopulation.

The estimator for the subpopulation total is

$$\widehat{Y}^S = \sum_{j=1}^{m} I_S(j)\, w_j y_j$$

and its score variable is

$$z_j(\widehat{Y}^S) = I_S(j)\, y_j$$

The estimator for the poststratified subpopulation total is

$$\widehat{Y}^{PS} = \sum_{k=1}^{L_P} \frac{M_k}{\widehat{M}_k} \widehat{Y}_k^S = \sum_{k=1}^{L_P} \frac{M_k}{\widehat{M}_k} \sum_{j=1}^{m} I_{P_k}(j) I_S(j)\, w_j y_j$$

and its score variable is

$$z_j(\widehat{Y}^{PS}) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{\widehat{M}_k} \left\{ I_S(j)\, y_j - \frac{\widehat{Y}_k^S}{\widehat{M}_k} \right\}$$

Title

total postestimation — Postestimation tools for total

Description Remarks and examples Also see

Description

The following postestimation commands are available after `total`:

Command	Description
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

Remarks and examples

▷ Example 1

Continuing with our data on incidence of heart attacks from example 1 in [R] **total**, we want to test whether there are twice as many heart attacks among men than women in the population.

```
. use http://www.stata-press.com/data/r13/total
. total heartatk [pw=swgt], over(sex)
  (output omitted)
. test _b[Male] = 2*_b[Female]
 ( 1)  [heartatk]Male - 2*[heartatk]Female = 0
       F(  1,  4945) =    1.25
            Prob > F =    0.2643
```

Thus we do not reject our hypothesis that the total number of heart attacks for men is twice that for women in the population.

Syntax

```
tpoisson depvar [indepvars] [if] [in] [weight] [, options]
```

options	Description
Model	
`noconstant`	suppress constant term
`ll(#|`*varname*`)`	truncation point; default value is `ll(0)`, zero truncation
`exposure(`*varname*$_e$`)`	include ln(*varname*$_e$) in model with coefficient constrained to 1
`offset(`*varname*$_o$`)`	include *varname*$_o$ in model with coefficient constrained to 1
`constraints(`*constraints*`)`	apply specified linear constraints
`collinear`	keep collinear variables
SE/Robust	
`vce(`*vcetype*`)`	*vcetype* may be `oim`, `robust`, `cluster` *clustvar*, `opg`, `bootstrap`, or `jackknife`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`irr`	report incidence-rate ratios
`nocnsreport`	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
`coeflegend`	display legend instead of statistics

indepvars may contain factor variables; see [U] **11.4.3 Factor variables**.

depvar and *indepvars* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] **11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] **svy**.

`fweights`, `iweights`, and `pweights` are allowed; see [U] **11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Count outcomes > Truncated Poisson regression

Description

tpoisson estimates the parameters of a truncated Poisson model by maximum likelihood. The dependent variable *depvar* is regressed on *indepvars*, where *depvar* is a positive count variable whose values are all above the truncation point.

Options

Model

noconstant; see [R] **estimation options**.

ll(# | *varname*) specifies the truncation point, which is a nonnegative integer. The default is zero truncation, ll(0).

exposure(*varname*$_e$), offset(*varname*$_o$), constraints(*constraints*), collinear; see [R] **estimation options**.

SE/Robust

vce(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster *clustvar*), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] ***vce_option***.

Reporting

level(#); see [R] **estimation options**.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, e^{β_i} rather than β_i. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. irr may be specified at estimation or when replaying previously estimated results.

nocnsreport; see [R] **estimation options**.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(*style*), cformat(%*fmt*), pformat(%*fmt*), sformat(%*fmt*), and nolstretch; see [R] **estimation options**.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] **maximize**. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

The following option is available with tpoisson but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

Truncated Poisson regression is used to model the number of occurrences of an event when that number is restricted to be above the truncation point. If the dependent variable is not truncated, standard Poisson regression may be more appropriate; see [R] **poisson**. Truncated Poisson regression was first proposed by Grogger and Carson (1991). For an introduction to Poisson regression, see Cameron and Trivedi (2005, 2010) and Long and Freese (2014). For an introduction to truncated Poisson models, see Cameron and Trivedi (2013) and Long (1997, chap. 8).

Suppose that the patients admitted to a hospital for a given condition form a random sample from a population of interest and that each admitted patient stays at least one day. You are interested in modeling the length of stay of patients in days. The sample is truncated at zero because you only have data on individuals who stayed at least one day. `tpoisson` accounts for the truncated sample, whereas `poisson` does not.

Truncation is not the same as censoring. Right-censored Poisson regression was implemented in Stata by Raciborski (2011).

▷ Example 1

Consider the Simonoff (2003) dataset of running shoes for a sample of runners who registered an online running log. A running-shoe marketing executive is interested in knowing how the number of running shoes purchased relates to other factors such as gender, marital status, age, education, income, typical number of runs per week, average miles run per week, and the preferred type of running. These data are naturally truncated at zero. A truncated Poisson model is fit to the number of shoes owned on runs per week, miles run per week, gender, age, and marital status.

No options are needed because zero truncation is the default for `tpoisson`.

```
. use http://www.stata-press.com/data/r13/runshoes
. tpoisson shoes rpweek mpweek male age married
Iteration 0:   log likelihood = -88.328151
Iteration 1:   log likelihood = -86.272639
Iteration 2:   log likelihood = -86.257999
Iteration 3:   log likelihood = -86.257994
Truncated Poisson regression                    Number of obs   =         60
Truncation point: 0                             LR chi2(5)      =      22.75
                                                Prob > chi2     =     0.0004
Log likelihood = -86.257994                     Pseudo R2       =     0.1165
```

shoes	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
rpweek	.1575811	.1097893	1.44	0.151	-.057602	.3727641
mpweek	.0210673	.0091113	2.31	0.021	.0032094	.0389252
male	.0446134	.2444626	0.18	0.855	-.4345246	.5237513
age	.0185565	.0137786	1.35	0.178	-.008449	.045562
married	-.1283912	.2785044	-0.46	0.645	-.6742498	.4174674
_cons	-1.205844	.6619774	-1.82	0.069	-2.503296	.0916078

Using the zero-truncated Poisson regression with these data, only the coefficient on average miles per week is statistically significant at the 5% level.

◁

▷ Example 2

Semiconductor manufacturing requires that silicon wafers be coated with a layer of metal oxide. The depth of this layer is strictly controlled. In this example, a critical oxide layer is designed for 300 ± 20 angstroms (Å).

After the oxide layer is coated onto a wafer, the wafer enters a photolithography step in which the lines representing the electrical connections are printed on the oxide and later etched and filled with metal. The widths of these lines are measured. In this example, they are controlled to 90 ± 5 micrometers (μm).

After these and other steps, each wafer is electrically tested at probe. If too many failures are discovered, the wafer is rejected and sent for engineering analysis. In this example, the maximum number of probe failures tolerated for this product is 10.

A major failure at probe has been encountered—88 wafers had more than 10 failures each. The 88 wafers that failed were tested using 4 probe machines. The engineer suspects that the failures were a result of faulty probe machines, poor depth control, or poor line widths. The line widths and depths in these data are the actual measurement minus its specification target, 300 Å for the oxide depths and 90 μm for the line widths.

The following table tabulates the average failure rate for each probe using Stata's `mean` command; see [R] **mean**.

```
. use http://www.stata-press.com/data/r13/probe
. mean failures, over(probe) nolegend
Mean estimation                     Number of obs    =        88
```

Over	Mean	Std. Err.	[95% Conf.	Interval]
failures				
1	15.875	1.186293	13.51711	18.23289
2	14.95833	.5912379	13.78318	16.13348
3	16.47059	.9279866	14.62611	18.31506
4	23.09677	.9451117	21.21826	24.97529

The 95% confidence intervals in this table suggest that there are about 5–11 additional failures per wafer on probe 4. These are unadjusted for varying line widths and oxide depths. Possibly, probe 4 received the wafers with larger line widths or extreme oxide depths.

Truncated Poisson regression more clearly identifies the root causes for the increased failures by estimating the differences between probes adjusted for the line widths and oxide depths. It also allows us to determine whether the deviations from specifications in line widths or oxide depths might be contributing to the problem.

```

depth	-.0005034	.0033375	-0.15	0.880	-.0070447	.006038
width	.0330225	.015573	2.12	0.034	.0025001	.063545
_cons	2.714025	.0752617	36.06	0.000	2.566515	2.861536

The coefficients listed for the probes are testing the null hypothesis: H_0: probe$_i$ = probe$_1$, where i equals 2, 3, and 4. Because the only coefficient that is statistically significant is the one for testing for H_0: probe$_4$ = probe$_1$, $p < 0.001$, and because the p-values for the other probes are not statistically significant, that is, $p \geq 0.275$, the implication is that there is a difference between probe 4 and the other machines. Because the coefficient for this test is positive, 0.425, the conclusion is that the average failure rate for probe 4, after adjusting for line widths and oxide depths, is higher than the other probes. Possibly, probe 4 needs calibration or the head used with this machine is defective.

Line-width control is statistically significant, $p = 0.034$, but variation in oxide depths is not causing the increased failure rate. The engineer concluded that the sudden increase in failures is the result of two problems. First, probe 4 is malfunctioning, and second, there is a possible lithography or etching problem.

◁

Stored results

tpoisson stores the following in e():

Scalars

e(N)	number of observations
e(k)	number of parameters
e(k_eq)	number of equations in e(b)
e(k_eq_model)	number of equations in overall model test
e(k_dv)	number of dependent variables
e(df_m)	model degrees of freedom
e(r2_p)	pseudo-R-squared
e(ll)	log likelihood
e(ll_0)	log likelihood, constant-only model
e(N_clust)	number of clusters
e(chi2)	χ^2
e(p)	significance
e(rank)	rank of e(V)
e(ic)	number of iterations
e(rc)	return code
e(converged)	1 if converged, 0 otherwise

Macros

e(cmd)	tpoisson
e(cmdline)	command as typed
e(depvar)	name of dependent variable
e(llopt)	contents of ll(), or 0 if not specified
e(wtype)	weight type
e(wexp)	weight expression
e(title)	title in estimation output
e(clustvar)	name of cluster variable
e(offset)	linear offset variable
e(chi2type)	Wald or LR; type of model χ^2 test
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(opt)	type of optimization
e(which)	max or min; whether optimizer is to perform maximization or minimization
e(ml_method)	type of ml method
e(user)	name of likelihood-evaluator program
e(technique)	maximization technique
e(properties)	b V
e(predict)	program used to implement predict
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(Cns)	constraints matrix
e(ilog)	iteration log (up to 20 iterations)
e(gradient)	gradient vector
e(V)	variance–covariance matrix of the estimators
e(V_modelbased)	model-based variance

Functions

e(sample)	marks estimation sample

Methods and formulas

The conditional probability of observing y_j events given that $y_j > \tau_j$, where τ_j is the truncation point, is given by

$$\Pr(Y = y_j \mid y_j > \tau_j, \mathbf{x}_j) = \frac{\exp(-\lambda)\lambda^{y_j}}{y_j!\Pr(Y > \tau_j \mid \mathbf{x}_j)}$$

The log likelihood (with weights w_j and offsets) is given by

$$\xi_j = \mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$$

$$f(y_j) = \frac{\exp\{-\exp(\xi_j)\}\exp(\xi_j y_j)}{y_j!\Pr(Y > \tau_j \mid \xi_j)}$$

$$\ln L = \sum_{j=1}^{n} w_j \left[-\exp(\xi_j) + \xi_j y_j - \ln(y_j!) - \ln\{\Pr(Y > \tau_j \mid \xi_j)\}\right]$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`tpoisson` also supports estimation with survey data. For details on variance–covariance estimates with survey data, see [SVY] **variance estimation**.

Title

tpoisson postestimation — Postestimation tools for tpoisson

Description Syntax for predict Menu for predict Options for predict
Methods and formulas Also see

Description

The following postestimation commands are available after `tpoisson`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

statistic	Description
Main	
`n`	number of events; the default
`ir`	incidence rate
`cm`	conditional mean, $E(y_j \mid y_j > \tau_j)$
`pr(`*n*`)`	probability $\Pr(y_j = n)$
`pr(`*a*`,`*b*`)`	probability $\Pr(a \leq y_j \leq b)$
`cpr(`*n*`)`	conditional probability $\Pr(y_j = n \mid y_j > \tau_j)$
`cpr(`*a*`,`*b*`)`	conditional probability $\Pr(a \leq y_j \leq b \mid y_j > \tau_j)$
`xb`	linear prediction
`stdp`	standard error of the linear prediction
`score`	first derivative of the log likelihood with respect to $\mathbf{x}_j\boldsymbol{\beta}$

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`n`, the default, calculates the predicted number of events, which is $\exp(\mathbf{x}_j\boldsymbol{\beta})$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\exp(\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j)$ if `offset()` was specified; or $\exp(\mathbf{x}_j\boldsymbol{\beta}) \times \text{exposure}_j$ if `exposure()` was specified.

`ir` calculates the incidence rate $\exp(\mathbf{x}_j\boldsymbol{\beta})$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the `n` and the `nooffset` options.

`cm` calculates the conditional mean,

$$E(y_j \mid y_j > \tau_j) = \frac{E(y_j)}{\Pr(y_j > \tau_j)}$$

where τ_j is the truncation point found in `e(llopt)`.

`pr(`*n*`)` calculates the probability $\Pr(y_j = n)$, where *n* is a nonnegative integer that may be specified as a number or a variable.

`pr(`*a*`,`*b*`)` calculates the probability $\Pr(a \leq y_j \leq b)$, where *a* and *b* are nonnegative integers that may be specified as numbers or variables;

b missing ($b \geq .$) means $+\infty$;
`pr(20,.)` calculates $\Pr(y_j \geq 20)$;
`pr(20,`*b*`)` calculates $\Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $\Pr(20 \leq y_j \leq b)$ elsewhere.

`pr(.,b)` produces a syntax error. A missing value in an observation of the variable a causes a missing value in that observation for `pr(a,b)`.

`cpr(n)` calculates the conditional probability $\Pr(y_j = n \,|\, y_j > \tau_j)$, where τ_j is the truncation point found in `e(llopt)`. n is an integer greater than the truncation point that may be specified as a number or a variable.

`cpr(a,b)` calculates the conditional probability $\Pr(a \leq y_j \leq b \,|\, y_j > \tau_j)$, where τ_j is the truncation point found in `e(llopt)`. The syntax for this option is analogous to that used for `pr(a,b)` except that a must be greater than the truncation point.

`xb` calculates the linear prediction, which is $\mathbf{x}_j\boldsymbol{\beta}$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ if `offset()` was specified; or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$ if `exposure()` was specified; see `nooffset` below.

`stdp` calculates the standard error of the linear prediction.

`score` calculates the equation-level score, $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

`nooffset` is relevant only if you specified `offset()` or `exposure()` when you fit the model. It modifies the calculations made by `predict` so that they ignore the offset or exposure variable; the linear prediction is treated as $\mathbf{x}_j\boldsymbol{\beta}$ rather than as $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$. Specifying `predict ..., nooffset` is equivalent to specifying `predict ..., ir`.

Methods and formulas

In the following formula, we use the same notation as in [R] **tpoisson**.

The equation-level scores are given by

$$\text{score}(\mathbf{x}\boldsymbol{\beta})_j = y_j - e^{\xi_j} - \frac{e^{-e^{\xi_j}} e^{\xi_j}}{\Pr(Y > \tau_j \,|\, \xi_j)}$$

where τ_j is the truncation point found in `e(llopt)`.

Title

translate — Print and translate logs

Syntax | Description | Options for print | Options for translate
Remarks and examples | Stored results | Also see

Syntax

Print log and SMCL files

```
print filename [ , like(ext) name(windowname) override_options ]
```

Translate log files to SMCL files and vice versa

```
translate filename_in filename_out [ , translator(tname) name(windowname)
    override_options replace ]
```

View translator parameter settings

```
translator query [tname]
```

Change translator parameter settings

```
translator set [tname setopt setval]
```

Return translator parameter settings to default values

```
translator reset tname
```

List current mappings from one extension to another

```
transmap query [ .ext ]
```

Specify that files with one extension be treated the same as files with another extension

```
transmap define .ext_new .ext_old
```

filename in `print`, in addition to being a filename to be printed, may be specified as `@Results` to mean the Results window and `@Viewer` to mean the Viewer window.

filename$_{\text{in}}$ in `translate` may be specified just as *filename* in `print`.

tname in `translator` specifies the name of a translator; see the `translator()` option under *Options for translate*.

Description

`print` prints log, SMCL, and text files. Although there is considerable flexibility in how `print` (and `translate`, which `print` uses) can be set to work, they have already been set up and should just work:

```
. print mylog.smcl
. print mylog.log
```

Unix users may discover that they need to do a bit of setup before print works; see *Printing files, Unix* below. International Unix users may also wish to modify the default paper size. All users can tailor print and translate to their needs.

print may also be used to print the current contents of the Results window or the Viewer. For instance, the current contents of the Results window could be printed by typing

```
. print @Results
```

translate translates log and SMCL files from one format to another, the other typically being suitable for printing. translate can also translate SMCL logs (logs created by typing, say, log using mylog) to plain text:

```
. translate mylog.smcl mylog.log
```

You can use translate to recover a log when you have forgotten to start one. You may type

```
. translate @Results mylog.txt
```

to capture as plain text what is currently shown in the Results window.

This entry provides a general overview of print and translate and covers in detail the printing and translation of text (nongraphic) files.

translator query, translator set, and translator reset show, change, and restore the default values of the settings for each translator.

transmap define and transmap query create and show mappings from one file extension to another for use with print and translate.

For example, print myfile.txt knows to use a translator appropriate for printing text files because of the .txt extension. However, it does not know what to do with .xyz files. If you have .xyz files and always wish to treat them as .txt files, you can type transmap define .xyz .txt.

Options for print

like(*ext*) specifies how the file should be translated to a form suitable for printing. The default is to determine the translation method from the extension of *filename*. Thus mylog.smcl is translated according to the rule for translating smcl files, myfile.txt is translated according to the rule for translating txt files, and so on. (These rules are, in fact, translate's smcl2prn and txt2prn translators, but put that aside for the moment.)

Rules for the following extensions are predefined:

.txt	assume input file contains plain text
.log	assume input file contains Stata log text
.smcl	assume input file contains SMCL

To print a file that has an extension different from those listed above, you can define a new extension, but you do not have to do that. Assume that you wish to print the file read.me, which you know to contain plain text. If you were just to type print read.me, you would be told that Stata cannot translate .me files. (You would actually be told that the translator for me2prn was not found.) You could type print read.me, like(txt) to tell print to print read.me like a .txt file.

On the other hand, you could type

```
. transmap define .me .txt
```

to tell Stata that .me files are always to be treated like .txt files. If you did that, Stata would remember the new rule, even in future sessions.

When you specify the like() option, you override the recorded rules. So, if you were to type print mylog.smcl, like(txt), the file would be printed as plain text (meaning that all the SMCL commands would show).

name(*windowname*) specifies which window to print when printing a Viewer. The default is for Stata to print the topmost Viewer [Unix(GUI) users: See the second technical note in *Printing files, Unix*]. The name() option is ignored when printing the Results window.

The window name is located inside parentheses in the window title. For example, if the title for a Viewer window is *Viewer (#1) [help print]*, the name for the window is #1.

override_options refers to translate's options for overriding default values. print uses translate to translate the file into a format suitable for sending to the printer, and thus translate's *override_options* may also be used with print. The settings available vary between each translator (for example, smcl2ps will have different settings than smcl2txt) and may also differ across operating systems (for example, Windows may have different printing options than Mac OS X). To find out what you can override when printing .smcl files, type

```
. translator query smcl2prn
(output omitted)
```

In the omitted output, you might learn that there is an rmargin # tunable value, which specifies the right margin in inches. You could specify the *override_option* rmargin(#) to temporarily override the default value, or you could type translator set smcl2prn rmargin # beforehand to permanently reset the value.

Alternatively, on some computers with some translators, you might discover that nothing can be set.

Options for translate

translator(*tname*) specifies the name of the translator to be used to translate the file. The available translators are

tname	Input	Output
smcl2ps	SMCL	PostScript
log2ps	Stata text log	PostScript
txt2ps	generic text file	PostScript
Viewer2ps	Viewer window	PostScript
Results2ps	Results window	PostScript
smcl2prn	SMCL	default printer format
log2prn	Stata text log	default printer format
txt2prn	generic text log	default printer format
Results2prn	Results window	default printer format
Viewer2prn	Viewer window	default printer format
smcl2txt	SMCL	generic text file
smcl2log	SMCL	Stata text log
Results2txt	Results window	generic text file
Viewer2txt	Viewer window	generic text file
smcl2pdf	SMCL	PDF
log2pdf	Stata text log	PDF
txt2pdf	generic text log	PDF
Results2pdf	Results window	PDF
Viewer2pdf	Viewer window	PDF

If `translator()` is not specified, `translate` determines which translator to use from extensions of the filenames specified. Typing `translate myfile.smcl myfile.ps` would use the `smcl2ps` translator. Typing `translate myfile.smcl myfile.ps, translate(smcl2prn)` would override the default and use the `smcl2prn` translator.

Actually, when you type `translate` *a*`.`*b* *c*`.`*d*, `translate` looks up `.`*b* in the `transmap` extension-synonym table. If `.`*b* is not found, the translator *b*2*d* is used. If `.`*b* is found in the table, the mapped extension is used (call it *b*′), and then the translator *b*′2*d* is used. For example,

Command	Translator used
`. translate myfile.smcl myfile.ps`	`smcl2ps`
`. translate myfile.odd myfile.ps`	`odd2ps`, which does not exist, so error
`. transmap define .odd .txt`	
`. translate myfile.odd myfile.ps`	`txt2ps`

You can list the mappings that `translate` uses by typing `transmap query`.

`name(`*windowname*`)` specifies which window to translate when translating a Viewer. The default is for Stata to translate the topmost Viewer. The `name()` option is ignored when translating the Results window.

The window name is located inside parentheses in the window title. For example, if the title for a Viewer window is *Viewer (#1) [help print]*, the name for the window is `#1`.

override_options override any of the default options of the specified or implied translator. To find out what you can override for, say, `log2ps`, type

```
. translator query log2ps
(output omitted)
```

In the omitted output, you might learn that there is an `rmargin` # tunable value, which, for `log2ps`, specifies the right margin in inches. You could specify the *override_option* `rmargin(#)` to temporarily override the default value or type `translator set log2ps rmargin` # beforehand to permanently reset the value.

`replace` specifies that *filename*$_{\text{out}}$ be replaced if it already exists.

Remarks and examples

Remarks are presented under the following headings:

Printing files
Printing files, Mac and Windows
Printing files, Unix
Translating files from one format to another

Printing files

Printing should be easy; just type

```
. print mylog.smcl
. print mylog.log
```

You can use `print` to print SMCL files, plain text files, and even the contents of the Results and Viewer windows:

```
. print @Results
. print @Viewer
. print @Viewer, name(#2)
```

For information about printing and translating graph files, see [G-2] **graph print** and see [G-2] **graph export**.

Printing files, Mac and Windows

When you type `print`, you are using the same facility that you would be using if you had selected **Print** from the **File** menu. If you try to print a file that Stata does not know about, Stata will complain:

```
. print read.me
translator me2prn not found
(perhaps you need to specify the like() option)
r(111);
```

Then you could type

```
. print read.me, like(txt)
```

to indicate that you wanted `read.me` sent to the printer in the same fashion as if the file were named `readme.txt`, or you could type

```
. transmap define .me .txt
. print read.me
```

Here you are telling Stata once and for all that you want files ending in `.me` to be treated in the same way as files ending in `.txt`. Stata will remember this mapping, even across sessions. To clear the `.me` mapping, type

```
. transmap define .me
```

To see all the mappings, type

```
. transmap query
```

To print to a file, use the `translate` command, not `print`:

```
. translate mylog.smcl mylog.prn
```

`translate` prints to a file by using the Windows print driver when the new filename ends in `.prn`. Under Mac, the `prn` translators are the same as the `pdf` translators. We suggest that you simply use the `.pdf` file extension when printing to a file.

Printing files, Unix

Stata assumes that you have a PostScript printer attached to your Unix computer and that the Unix command `lpr(1)` can be used to send PostScript files to it, but you can change this. On your Unix system, typing

```
mycomputer$ lpr < filename
```

may not be sufficient to print PostScript files. For instance, perhaps on your system you would need to type

```
mycomputer$ lpr -Plexmark < filename
```

or

```
mycomputer$ lpr -Plexmark filename
```

or something else. To set the print command to be `lpr -Plexmark` *filename* and to state that the printer expects to receive PostScript files, type

```
. printer define prn ps "lpr -Plexmark @"
```

To set the print command to `lpr -Plexmark <` *filename* and to state that the printer expects to receive plain text files, type

```
. printer define prn txt "lpr -Plexmark < @"
```

That is, just type the command necessary to send files to your printer and include an `@` sign where the filename should be substituted. Two file formats are available: `ps` and `txt`. The default setting, as shipped from the factory, is

```
. printer define prn ps "lpr < @"
```

We will return to the `printer` command in the technical note that follows because it has some other capabilities you should know about.

In any case, after you redefine the default printer, the following should just work:

```
. print mylog.smcl
. print mylog.log
```

If you try to print a file that Stata does not know about, it will complain:

```
. print read.me
translator me2prn not found
r(111);
```

Here you could type

```
. print read.me, like(txt)
```

to indicate that you wanted `read.me` sent to the printer in the same fashion as if the file were named `readme.txt`, or you could type

```
. transmap define .me .txt
. print read.me
```

Here you are telling Stata once and for all that you want files ending in `.me` to be treated in the same way as files ending in `.txt`. Stata will remember this setting for `.me`, even across sessions.

If you want to clear the `.me` setting, type

```
. transmap define .me
```

If you want to see all your settings, type

```
. transmap query
```

❑ Technical note

The syntax of the `printer` command is

`printer define` *printername* [{ `ps` | `txt` } "*Unix command with* `@`"]

`printer query` [*printername*]

You may define multiple printers. By default, `print` uses the printer named `prn`, but `print` has the syntax

`print` *filename* [`, like(`*ext*`) printer(`*printername*`)` *override_options*]

so, if you define multiple printers, you may route your output to them.

For instance, if you have a second printer on your system, you might type

```
. printer define lexmark ps "lpr -Plexmark < @"
```

After doing that, you could type

```
. print myfile.smcl, printer(lexmark)
```

Any printers that you set will be remembered even across sessions. You can delete printers:

```
. printer define lexmark
```

You can list all the defined printers by typing `printer query`, and you can list the definition of a particular printer, say, `prn`, by typing `printer query prn`.

The default printer `prn` we have predefined for you is

```
. printer define prn ps "lpr < @"
```

meaning that we assume that it is a PostScript printer and that the Unix command `lpr(1)`, without options, is sufficient to cause files to print. Feel free to change the default definition. If you change it, the change will be remembered across sessions. ❑

❑ Technical note

Unix(GUI) users should note that X-Windows does not have the concept of a window z-order, which prevents Stata from determining which window is the topmost window. Instead, Stata determines which window is topmost based on which window has the focus. However, some window managers will set the focus to a window without bringing the window to the top. What Stata considers the topmost window may not appear topmost visually. For this reason, you should always use the `name()` option to ensure that the correct window is printed. ❑

❑ Technical note

When you select the Results window to print from the **Print** menu or toolbar button, the result is the same as if you were to issue the `print` command. When you select a Viewer window to print from the **Print** menu or toolbar button, the result is the same as if you were to issue the `print` command with a `name()` option. ❑

The translation to PostScript format is done by `translate` and, in particular, is performed by the translators `smcl2ps`, `log2ps`, and `txt2ps`. There are many tunable parameters in each of these translators. You can display the current values of these tunable parameters for, say, `smcl2ps` by typing

```
. translator query smcl2ps
(output omitted)
```

and you can set any of the tunable parameters (for instance, setting `smcl2ps`'s `rmargin` value to 1) by typing

```
. translator set smcl2ps rmargin 1
(output omitted)
```

Any settings you make will be remembered across sessions. You can reset `smcl2ps` to be as it was when Stata was shipped by typing

```
. translator reset smcl2ps
```

Translating files from one format to another

If you have a SMCL log, which you might have created by previously typing `log using mylog`, you can translate it to an text log by typing

```
. translate myfile.smcl myfile.log
```

and you can translate it to a PostScript file by typing

```
. translate myfile.smcl myfile.ps
```

`translate` translates files from one format to another, and, in fact, `print` uses `translate` to produce a file suitable for sending to the printer.

When you type

```
. translate a.b c.d
```

`translate` looks for the predefined translator *b*2*d* and uses that to perform the translation. If there is a `transmap` synonym for *b*, however, the mapped value *b*′ is used: *b*′2*d*.

Only certain translators exist, and they are listed under the description of the `translate()` option in *Options for translate* above, or you can type

```
. translator query
```

for a complete (and perhaps more up-to-date) list.

Anyway, `translate` forms the name *b*2*d* or *b*′2*d*, and if the translator does not exist, `translate` issues an error message. With the `translator()` option, you can specify exactly which translator to use, and then it does not matter how your files are named.

The only other thing to know is that some translators have tunable parameters that affect how they perform their translation. You can type

```
. translator query translator_name
```

to find out what those parameters are. Some translators have no tunable parameters, and some have many:

```
. translator query smcl2ps
```

You can temporarily override any setting by specifying the *setopt*(*setval*) option on the `translate` (or `print`) command. For instance, you can type

```
. translate ..., ... cmdnumber(off)
```

or you can reset the value permanently by typing

```
. translator set smcl2ps setopt setval
```

For instance,

```
. translator set smcl2ps cmdnumber off
```

If you reset a value, Stata will remember the change, even in future sessions.

Mac and Windows users: The `smcl2ps` (and the other `*2ps` translators) are not used by `print`, even when you have a PostScript printer attached to your computer. Instead, the Mac or Windows print driver is used. Resetting `smcl2ps` values will not affect printing; instead, you change the defaults in the Printers Control Panel in Windows and by selecting **Page Setup...** from the **File** menu in Mac. You can, however, `translate` files yourself using the `smcl2ps` translator and the other `*2ps` translators.

Stored results

`transmap query` *.ext* stores in macro `r(suffix)` the mapped extension (without the leading period) or stores *ext* if the *ext* is not mapped.

`translator query` *translatorname* stores *setval* in macro `r(`*setopt*`)` for every *setopt*, *setval* pair.

`printer query` *printername* (Unix only) stores in macro `r(suffix)` the "filetype" of the input that the printer expects (currently "`ps`" or "`txt`") and, in macro `r(command)`, the command to send output to the printer.

Syntax

```
truncreg depvar [indepvars] [if] [in] [weight] [, options]
```

options	Description
Model	
noconstant	suppress constant term
ll(*varname*|#)	lower limit for left-truncation
ul(*varname*|#)	upper limit for right-truncation
offset(*varname*)	include *varname* in model with coefficient constrained to 1
constraints(*constraints*)	apply specified linear constraints
collinear	keep collinear variables
SE/Robust	
vce(*vcetype*)	*vcetype* may be oim, robust, cluster *clustvar*, opg, bootstrap, or jackknife
Reporting	
level(#)	set confidence level; default is level(95)
noskip	perform likelihood-ratio test
nocnsreport	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
coeflegend	display legend instead of statistics

indepvars may contain factor variables; see [U] **11.4.3 Factor variables**.

depvar and *indepvars* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

bootstrap, by, fp, jackknife, mi estimate, rolling, statsby, and svy are allowed; see [U] **11.1.10 Prefix commands**.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] **mi estimate**.

Weights are not allowed with the bootstrap prefix; see [R] **bootstrap**.

aweights are not allowed with the jackknife prefix; see [R] **jackknife**.

vce(), noskip, and weights are not allowed with the svy prefix; see [SVY] **svy**.

aweights, fweights, iweights, and pweights are allowed; see [U] **11.1.6 weight**.

coeflegend does not appear in the dialog box.

See [U] **20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Linear models and related > Truncated regression

Description

`truncreg` fits a regression model of *depvar* on *indepvars* from a sample drawn from a restricted part of the population. Under the normality assumption for the whole population, the error terms in the truncated regression model have a truncated normal distribution, which is a normal distribution that has been scaled upward so that the distribution integrates to one over the restricted range.

Options

Model

`noconstant`; see [R] **estimation options**.

`ll(`*varname*`|#)` and `ul(`*varname*`|#)` indicate the lower and upper limits for truncation, respectively. You may specify one or both. Observations with *depvar* $\leq$ `ll()` are left-truncated, observations with *depvar* $\geq$ `ul()` are right-truncated, and the remaining observations are not truncated. See [R] **tobit** for a more detailed description.

`offset(`*varname*`)`, `constraints(`*constraints*`)`, `collinear`; see [R] **estimation options**.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

Reporting

`level(#)`; see [R] **estimation options**.

`noskip` specifies that a full maximum-likelihood model with only a constant for the regression equation be fit. This model is not displayed but is used as the base model to compute a likelihood-ratio test for the model test statistic displayed in the estimation header. By default, the overall model test statistic is an asymptotically equivalent Wald test of all the parameters in the regression equation being zero (except the constant). For many models, this option can substantially increase estimation time.

`nocnsreport`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Maximization

maximize_options: `difficult`, `technique(`*algorithm_spec*`)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(`*init_specs*`)`; see [R] **maximize**. These options are seldom used, but you may use the `ltol(#)` option to relax the convergence criterion; the default is `1e-6` during specification searches.

Setting the optimization type to `technique(bhhh)` resets the default *vcetype* to `vce(opg)`.

The following option is available with `truncreg` but is not shown in the dialog box:

`coeflegend`; see [R] **estimation options**.

Remarks and examples

Truncated regression fits a model of a dependent variable on independent variables from a restricted part of a population. Truncation is essentially a characteristic of the distribution from which the sample data are drawn. If x has a normal distribution with mean μ and standard deviation σ, the density of the truncated normal distribution is

$$f(x \mid a < x < b) = \frac{f(x)}{\Phi\left(\frac{b-\mu}{\sigma}\right) - \Phi\left(\frac{a-\mu}{\sigma}\right)} = \frac{\frac{1}{\sigma}\phi\left(\frac{x-\mu}{\sigma}\right)}{\Phi\left(\frac{b-\mu}{\sigma}\right) - \Phi\left(\frac{a-\mu}{\sigma}\right)}$$

where ϕ and Φ are the density and distribution functions of the standard normal distribution.

Compared with the mean of the untruncated variable, the mean of the truncated variable is greater if the truncation is from below, and the mean of the truncated variable is smaller if the truncation is from above. Moreover, truncation reduces the variance compared with the variance in the untruncated distribution.

▷ Example 1

We will demonstrate `truncreg` with part of the Mroz dataset distributed with Berndt (1996). This dataset contains 753 observations on women's labor supply. Our subsample is of 250 observations, with 150 market laborers and 100 nonmarket laborers.

◁

❑ Technical note

Whether truncated regression is more appropriate than the ordinary least-squares estimation depends on the purpose of that estimation. If we are interested in the mean of wife's working hours conditional on the subsample of market laborers, least-squares estimation is appropriate. However if we are interested in the mean of wife's working hours regardless of market or nonmarket labor status, least-squares estimates could be seriously misleading.

Truncation and censoring are different concepts. A sample has been censored if no observations have been systematically excluded but some of the information contained in them has been suppressed. In a truncated distribution, only the part of the distribution above (or below, or between) the truncation points is relevant to our computations. We need to scale it up by the probability that an observation falls in the range that interests us to make the distribution integrate to one. The censored distribution used by tobit, however, is a mixture of discrete and continuous distributions. Instead of rescaling over the observable range, we simply assign the full probability from the censored regions to the censoring points. The truncated regression model is sometimes less well behaved than the tobit model. Davidson and MacKinnon (1993) provide an example where truncation results in more inconsistency than censoring.

❑

Stored results

truncreg stores the following in e():

Scalars

e(N)	number of observations
e(N_bf)	number of obs. before truncation
e(chi2)	model χ^2
e(k_eq)	number of equations in e(b)
e(k_eq_model)	number of equations in overall model test
e(k_aux)	number of auxiliary parameters
e(df_m)	model degrees of freedom
e(ll)	log likelihood
e(ll_0)	log likelihood, constant-only model
e(N_clust)	number of clusters
e(sigma)	estimate of sigma
e(p)	significance
e(rank)	rank of e(V)
e(ic)	number of iterations

e(V_modelbased)	model-based variance
e(means)	means of independent variables
e(dummy)	indicator for dummy variables

Functions

e(sample)	marks estimation sample

Methods and formulas

Greene (2012, 833–839) and Davidson and MacKinnon (1993, 534–537) provide introductions to the truncated regression model.

Let $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$ be the model. $\mathbf{y}$ represents continuous outcomes either observed or not observed. Our model assumes that $\boldsymbol{\epsilon} \sim N(\mathbf{0}, \sigma^2\mathbf{I})$.

Let a be the lower limit and b be the upper limit. The log likelihood is

$$\ln L = -\frac{n}{2}\log(2\pi\sigma^2) - \frac{1}{2\sigma^2}\sum_{j=1}^{n}(y_j - \mathbf{x}_j\boldsymbol{\beta})^2 - \sum_{j=1}^{n}\log\left\{\Phi\left(\frac{b - \mathbf{x}_j\boldsymbol{\beta}}{\sigma}\right) - \Phi\left(\frac{a - \mathbf{x}_j\boldsymbol{\beta}}{\sigma}\right)\right\}$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`truncreg` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **variance estimation**.

Title

truncreg postestimation — Postestimation tools for truncreg

Description Syntax for predict Menu for predict Options for predict Also see

Description

The following postestimation commands are available after `truncreg`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `mi` or `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]

predict [type] {stub* | newvar_reg newvar_lnsigma} [if] [in], scores
```

statistic	Description
Main	
`xb`	linear prediction; the default
`stdp`	standard error of the prediction
`stdf`	standard error of the forecast
`pr(`*a*`,`*b*`)`	$\Pr(a < y_j < b)$
`e(`*a*`,`*b*`)`	$E(y_j \mid a < y_j < b)$
`ystar(`*a*`,`*b*`)`	$E(y_j^*)$, $y_j^* = \max\{a, \min(y_j, b)\}$

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where *a* and *b* may be numbers or variables; *a* missing ($a \geq .$) means $-\infty$, and *b* missing ($b \geq .$) means $+\infty$; see **[U] 12.2.1 Missing values**.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see *Methods and formulas* in **[R] regress postestimation**.

`pr(`*a*`,`*b*`)` calculates $\Pr(a < \mathbf{x}_j\mathbf{b} + u_j < b)$, the probability that $y_j|\mathbf{x}_j$ would be observed in the interval (a, b).

a and *b* may be specified as numbers or variable names; *lb* and *ub* are variable names;
`pr(20,30)` calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < 30)$;
`pr(`*lb*`,`*ub*`)` calculates $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < ub)$; and
`pr(20,`*ub*`)` calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$.

a missing ($a \geq .$) means $-\infty$; `pr(.,30)` calculates $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$;
`pr(`*lb*`,30)` calculates $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$ in observations for which $lb \geq .$
and calculates $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < 30)$ elsewhere.

b missing ($b \geq .$) means $+\infty$; `pr(20,.)` calculates $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$;
`pr(20,`*ub*`)` calculates $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$ in observations for which $ub \geq .$
and calculates $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$ elsewhere.

`e(`*a*`,`*b*`)` calculates $E(\mathbf{x}_j\mathbf{b} + u_j \mid a < \mathbf{x}_j\mathbf{b} + u_j < b)$, the expected value of $y_j|\mathbf{x}_j$ conditional on $y_j|\mathbf{x}_j$ being in the interval (a, b), meaning that $y_j|\mathbf{x}_j$ is truncated.
a and *b* are specified as they are for `pr()`.

`ystar(`*a*`,`*b*`)` calculates $E(y_j^*)$, where $y_j^* = a$ if $\mathbf{x}_j\mathbf{b} + u_j \leq a$, $y_j^* = b$ if $\mathbf{x}_j\mathbf{b} + u_j \geq b$, and $y_j^* = \mathbf{x}_j\mathbf{b} + u_j$ otherwise, meaning that y_j^* is censored. *a* and *b* are specified as they are for `pr()`.

`nooffset` is relevant only if you specified `offset(`*varname*`)`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $\mathbf{x}_j\mathbf{b}$ rather than as $\mathbf{x}_j\mathbf{b} + \text{offset}_j$.

`scores` calculates equation-level score variables.

The first new variable will contain $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

The second new variable will contain $\partial \ln L/\partial\sigma$.

Syntax

One-sample t test

```
ttest varname == # [if] [in] [, level(#)]
```

Two-sample t test using groups

```
ttest varname [if] [in], by(groupvar) [options1]
```

Two-sample t test using variables

```
ttest varname1 == varname2 [if] [in], unpaired [unequal welch level(#)]
```

Paired t test

```
ttest varname1 == varname2 [if] [in] [, level(#)]
```

Immediate form of one-sample t test

```
ttesti #obs #mean #sd #val [, level(#)]
```

Immediate form of two-sample t test

```
ttesti #obs1 #mean1 #sd1 #obs2 #mean2 #sd2 [, options2]
```

$options_1$	Description
Main	
* `by(`*groupvar*`)`	variable defining the groups
`unequal`	unpaired data have unequal variances
`welch`	use Welch's approximation
`level(#)`	set confidence level; default is `level(95)`

*`by(`*groupvar*`)` is required.

$options_2$	Description
Main	
`unequal`	unpaired data have unequal variances
`welch`	use Welch's approximation
`level(#)`	set confidence level; default is `level(95)`

`by` is allowed with `ttest`; see [D] **by**.

Menu

ttest

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > t test (mean-comparison test)

ttesti

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > t test calculator

Description

`ttest` performs t tests on the equality of means. In the first form, `ttest` tests that *varname* has a mean of #. In the second form, `ttest` tests that *varname* has the same mean within the two groups defined by *groupvar*. In the third form, `ttest` tests that *varname*$_1$ and *varname*$_2$ have the same mean, assuming *unpaired* data. In the fourth form, `ttest` tests that *varname*$_1$ and *varname*$_2$ have the same mean, assuming *paired* data.

`ttesti` is the immediate form of `ttest`; see **[U] 19 Immediate commands**.

For the equivalent of a two-sample t test with sampling weights (`pweights`), use the `svy: mean` command with the `over()` option, and then use `lincom`; see [R] **mean** and [SVY] **svy postestimation**.

Options

Main

`by(`*groupvar*`)` specifies the *groupvar* that defines the two groups that `ttest` will use to test the hypothesis that their means are equal. Specifying `by(`*groupvar*`)` implies an unpaired (two sample) t test. Do not confuse the `by()` option with the `by` prefix; you can specify both.

`unpaired` specifies that the data be treated as unpaired. The `unpaired` option is used when the two sets of values to be compared are in different variables.

`unequal` specifies that the unpaired data not be assumed to have equal variances.

`welch` specifies that the approximate degrees of freedom for the test be obtained from Welch's formula (1947) rather than from Satterthwaite's approximation formula (1946), which is the default when `unequal` is specified. Specifying `welch` implies `unequal`.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see **[U] 20.7 Specifying the width of confidence intervals**.

Remarks and examples

Remarks are presented under the following headings:

One-sample t test
Two-sample t test
Paired t test
Two-sample t test compared with one-way ANOVA
Immediate form
Video examples

One-sample t test

▷ Example 1

In the first form, `ttest` tests whether the mean of the sample is equal to a known constant under the assumption of unknown variance. Assume that we have a sample of 74 automobiles. We know each automobile's average mileage rating and wish to test whether the overall average for the sample is 20 miles per gallon.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. ttest mpg==20
One-sample t test
```

Variable	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
mpg	74	21.2973	.6725511	5.785503	19.9569	22.63769

```
    mean = mean(mpg)                                          t =   1.9289
Ho: mean = 20                                 degrees of freedom =       73

    Ha: mean < 20               Ha: mean != 20                 Ha: mean > 20
 Pr(T < t) = 0.9712         Pr(|T| > |t|) = 0.0576          Pr(T > t) = 0.0288
```

The test indicates that the underlying mean is not 20 with a significance level of 5.8%.

◁

Two-sample t test

▷ Example 2: Two-sample t test using groups

We are testing the effectiveness of a new fuel additive. We run an experiment in which 12 cars are given the fuel treatment and 12 cars are not. The results of the experiment are as follows:

treated	mpg
0	20
0	23
0	21
0	25
0	18
0	17
0	18
0	24
0	20
0	24
0	23
0	19
1	24
1	25
1	21
1	22
1	23
1	18
1	17
1	28
1	24
1	27
1	21
1	23

The treated variable is coded as 1 if the car received the fuel treatment and 0 otherwise.

We can test the equality of means of the treated and untreated group by typing

```
. use http://www.stata-press.com/data/r13/fuel3
. ttest mpg, by(treated)
Two-sample t test with equal variances
```

Group	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
0	12	21	.7881701	2.730301	19.26525	22.73475
1	12	22.75	.9384465	3.250874	20.68449	24.81551
combined	24	21.875	.6264476	3.068954	20.57909	23.17091
diff		-1.75	1.225518		-4.291568	.7915684

```
    diff = mean(0) - mean(1)                                      t =  -1.4280
Ho: diff = 0                                     degrees of freedom =       22
    Ha: diff < 0                 Ha: diff != 0                 Ha: diff > 0
 Pr(T < t) = 0.0837         Pr(|T| > |t|) = 0.1673          Pr(T > t) = 0.9163
```

We do not find a statistically significant difference in the means.

If we were not willing to assume that the variances were equal and wanted to use Welch's formula, we could type

```
. ttest mpg, by(treated) welch
Two-sample t test with unequal variances
```

Group	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
0	12	21	.7881701	2.730301	19.26525	22.73475
1	12	22.75	.9384465	3.250874	20.68449	24.81551
combined	24	21.875	.6264476	3.068954	20.57909	23.17091
diff		-1.75	1.225518		-4.28369	.7836902

```
    diff = mean(0) - mean(1)                                      t =  -1.4280
Ho: diff = 0                     Welch's degrees of freedom =  23.2465
    Ha: diff < 0                 Ha: diff != 0                 Ha: diff > 0
 Pr(T < t) = 0.0833         Pr(|T| > |t|) = 0.1666          Pr(T > t) = 0.9167
```

◁

❑ Technical note

In two-sample using groups randomized designs, subjects will sometimes refuse the assigned treatment but still be measured for an outcome. In this case, take care to specify the group properly. You might be tempted to let *varname* contain missing where the subject refused and thus let `ttest` drop such observations from the analysis. Zelen (1979) argues that it would be better to specify that the subject belongs to the group in which he or she was randomized, even though such inclusion will dilute the measured effect.

❑

▷ Example 3: Two-sample t test using variables

There is a second, inferior way to organize the data in the preceding example. We ran a test on 24 cars, 12 without the additive and 12 with. We now create two new variables, `mpg1` and `mpg2`.

mpg1	mpg2
20	24
23	25
21	21
25	22
18	23
17	18
18	17
24	28
20	24
24	27
23	21
19	23

This method is inferior because it suggests a connection that is not there. There is no link between the car with 20 mpg and the car with 24 mpg in the first row of the data. Each column of data could be arranged in any order. Nevertheless, if our data are organized like this, `ttest` can accommodate us.

```
. use http://www.stata-press.com/data/r13/fuel
. ttest mpg1==mpg2, unpaired
Two-sample t test with equal variances
```

Variable	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
mpg1	12	21	.7881701	2.730301	19.26525	22.73475
mpg2	12	22.75	.9384465	3.250874	20.68449	24.81551
combined	24	21.875	.6264476	3.068954	20.57909	23.17091
diff		-1.75	1.225518		-4.291568	.7915684

```
    diff = mean(mpg1) - mean(mpg2)                                t =  -1.4280
Ho: diff = 0                                     degrees of freedom =       22

    Ha: diff < 0                 Ha: diff != 0                 Ha: diff > 0
 Pr(T < t) = 0.0837         Pr(|T| > |t|) = 0.1673          Pr(T > t) = 0.9163
```

◁

Paired t test

▷ Example 4

Suppose that the preceding data were actually collected by running a test on 12 cars. Each car was run once with the fuel additive and once without. Our data are stored in the same manner as in example 3, but this time, there is most certainly a connection between the mpg values that appear in the same row. These come from the same car. The variables `mpg1` and `mpg2` represent mileage without and with the treatment, respectively.

```
. use http://www.stata-press.com/data/r13/fuel
. ttest mpg1==mpg2
Paired t test
```

Variable	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
mpg1	12	21	.7881701	2.730301	19.26525	22.73475
mpg2	12	22.75	.9384465	3.250874	20.68449	24.81551
diff	12	-1.75	.7797144	2.70101	-3.46614	-.0338602

```
     mean(diff) = mean(mpg1 - mpg2)                                t =  -2.2444
 Ho: mean(diff) = 0                             degrees of freedom =       11

 Ha: mean(diff) < 0           Ha: mean(diff) != 0           Ha: mean(diff) > 0
 Pr(T < t) = 0.0232         Pr(|T| > |t|) = 0.0463          Pr(T > t) = 0.9768
```

We find that the means are statistically different from each other at any level greater than 4.6%. ◁

Two-sample t test compared with one-way ANOVA

▷ Example 5

In example 2, we saw that `ttest` can be used to test the equality of a pair of means; see [R] **oneway** for an extension that allows testing the equality of more than two means.

Suppose that we have data on the 50 states. The dataset contains the median age of the population (`medage`) and the region of the country (`region`) for each state. Region 1 refers to the Northeast, region 2 to the North Central, region 3 to the South, and region 4 to the West. Using `oneway`, we can test the equality of all four means.

```
. use http://www.stata-press.com/data/r13/census
(1980 Census data by state)
. oneway medage region
                        Analysis of Variance
    Source              SS         df      MS            F     Prob > F
------------------------------------------------------------------------
Between groups      46.3961903      3   15.4653968      7.56     0.0003
 Within groups      94.1237947     46   2.04616945
------------------------------------------------------------------------
    Total           140.519985     49    2.8677548
Bartlett's test for equal variances:  chi2(3) =  10.5757  Prob>chi2 = 0.014
```

We find that the means are different, but we are interested only in testing whether the means for the Northeast (`region==1`) and West (`region==4`) are different. We could use `oneway`:

```
. oneway medage region if region==1 | region==4
                        Analysis of Variance
    Source              SS         df      MS            F     Prob > F
------------------------------------------------------------------------
Between groups       46.241247      1    46.241247     20.02     0.0002
 Within groups      46.1969169     20   2.30984584
------------------------------------------------------------------------
    Total           92.4381638     21   4.40181733
Bartlett's test for equal variances:  chi2(1) =   2.4679  Prob>chi2 = 0.116
```

We could also use ttest:

```
. ttest medage if region==1 | region==4, by(region)
Two-sample t test with equal variances
```

Group	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
NE	9	31.23333	.3411581	1.023474	30.44662	32.02005
West	13	28.28462	.4923577	1.775221	27.21186	29.35737
combined	22	29.49091	.4473059	2.098051	28.56069	30.42113
diff		2.948718	.6590372		1.57399	4.323445

```
    diff = mean(NE) - mean(West)                                  t =   4.4743
Ho: diff = 0                                     degrees of freedom =       20

    Ha: diff < 0                 Ha: diff != 0                 Ha: diff > 0
 Pr(T < t) = 0.9999         Pr(|T| > |t|) = 0.0002          Pr(T > t) = 0.0001
```

The significance levels of both tests are the same.

◁

Immediate form

▷ Example 6

ttesti is like ttest, except that we specify summary statistics rather than variables as arguments. For instance, we are reading an article that reports the mean number of sunspots per month as 62.6 with a standard deviation of 15.8. There are 24 months of data. We wish to test whether the mean is 75:

```
. ttesti 24 62.6 15.8 75
One-sample t test
```

	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
x	24	62.6	3.225161	15.8	55.92825	69.27175

```
    mean = mean(x)                                                t =  -3.8448
Ho: mean = 75                                    degrees of freedom =       23

    Ha: mean < 75                Ha: mean != 75                 Ha: mean > 75
 Pr(T < t) = 0.0004         Pr(|T| > |t|) = 0.0008          Pr(T > t) = 0.9996
```

◁

▷ Example 7

There is no immediate form of ttest with paired data because the test is also a function of the covariance, a number unlikely to be reported in any published source. For nonpaired data, however, we might type

```
. ttesti 20 20 5  32 15 4
Two-sample t test with equal variances
```

	Obs	Mean	Std. Err.	Std. Dev.	[95% Conf.	Interval]
x	20	20	1.118034	5	17.65993	22.34007
y	32	15	.7071068	4	13.55785	16.44215
combined	52	16.92308	.6943785	5.007235	15.52905	18.3171
diff		5	1.256135		2.476979	7.523021

```
    diff = mean(x) - mean(y)                                      t =   3.9805
Ho: diff = 0                     degrees of freedom =       50
    Ha: diff < 0                 Ha: diff != 0                 Ha: diff > 0
 Pr(T < t) = 0.9999         Pr(|T| > |t|) = 0.0002          Pr(T > t) = 0.0001
```

If we had typed `ttesti 20 20 5  32 15 4, unequal`, the test would have assumed unequal variances.

Video examples

t test for two paired samples in Stata

Immediate commands in Stata: One-sample t test from summary data

Immediate commands in Stata: Two-sample t test from summary data

Stored results

`ttest` and `ttesti` store the following in `r()`:

Scalars

`r(N_1)`	sample size n_1	`r(sd_1)`	standard deviation for first variable
`r(N_2)`	sample size n_2	`r(sd_2)`	standard deviation for second variable
`r(p_l)`	lower one-sided p-value	`r(sd)`	combined standard deviation
`r(p_u)`	upper one-sided p-value	`r(mu_1)`	$\bar{x}_1$ mean for population 1
`r(p)`	two-sided p-value	`r(mu_2)`	$\bar{x}_2$ mean for population 2
`r(se)`	estimate of standard error	`r(df_t)`	degrees of freedom
`r(t)`	t statistic	`r(level)`	confidence level

Methods and formulas

See, for instance, Hoel (1984, 140–161) or Dixon and Massey (1983, 121–130) for an introduction and explanation of the calculation of these tests. Acock (2014, 162–173) and Hamilton (2013, 145–150) describe t tests using applications in Stata.

The test for $\mu = \mu_0$ for unknown σ is given by

$$t = \frac{(\overline{x} - \mu_0)\sqrt{n}}{s}$$

The statistic is distributed as Student's t with $n-1$ degrees of freedom (Gosset [Student, pseud.] 1908).

The test for $\mu_x = \mu_y$ when σ_x and σ_y are unknown but $\sigma_x = \sigma_y$ is given by

$$t = \frac{\overline{x} - \overline{y}}{\left\{\frac{(n_x-1)s_x^2+(n_y-1)s_y^2}{n_x+n_y-2}\right\}^{1/2}\left(\frac{1}{n_x}+\frac{1}{n_y}\right)^{1/2}}$$

The result is distributed as Student's t with $n_x + n_y - 2$ degrees of freedom.

You could perform `ttest` (without the `unequal` option) in a regression setting given that regression assumes a homoskedastic error model. To compare with the `ttest` command, denote the underlying observations on x and y by x_j, $j = 1, \ldots, n_x$, and y_j, $j = 1, \ldots, n_y$. In a regression framework, typing `ttest` without the `unequal` option is equivalent to

1. creating a new variable z_j that represents the stacked observations on x and y (so that $z_j = x_j$ for $j = 1, \ldots, n_x$ and $z_{n_x+j} = y_j$ for $j = 1, \ldots, n_y$)
2. and then estimating the equation $z_j = \beta_0 + \beta_1 d_j + \epsilon_j$, where $d_j = 0$ for $j = 1, \ldots, n_x$ and $d_j = 1$ for $j = n_x + 1, \ldots, n_x + n_y$ (that is, $d_j = 0$ when the z observations represent x, and $d_j = 1$ when the z observations represent y).

The estimated value of β_1, b_1, will equal $\overline{y} - \overline{x}$, and the reported t statistic will be the same t statistic as given by the formula above.

The test for $\mu_x = \mu_y$ when σ_x and σ_y are unknown and $\sigma_x \neq \sigma_y$ is given by

$$t = \frac{\overline{x} - \overline{y}}{\left(s_x^2/n_x + s_y^2/n_y\right)^{1/2}}$$

The result is distributed as Student's t with ν degrees of freedom, where ν is given by (with Satterthwaite's [1946] formula)

$$\frac{\left(s_x^2/n_x + s_y^2/n_y\right)^2}{\frac{\left(s_x^2/n_x\right)^2}{n_x-1} + \frac{\left(s_y^2/n_y\right)^2}{n_y-1}}$$

With Welch's formula (1947), the number of degrees of freedom is given by

$$-2 + \frac{\left(s_x^2/n_x + s_y^2/n_y\right)^2}{\frac{\left(s_x^2/n_x\right)^2}{n_x+1} + \frac{\left(s_y^2/n_y\right)^2}{n_y+1}}$$

The test for $\mu_x = \mu_y$ for matched observations (also known as paired observations, correlated pairs, or permanent components) is given by

$$t = \frac{\overline{d}\sqrt{n}}{s_d}$$

where $\overline{d}$ represents the mean of $x_i - y_i$ and s_d represents the standard deviation. The test statistic t is distributed as Student's t with $n - 1$ degrees of freedom.

You can also use `ttest` without the `unpaired` option in a regression setting because a paired comparison includes the assumption of constant variance. The `ttest` with an unequal variance assumption does not lend itself to an easy representation in regression settings and is not discussed here. $(x_j - y_j) = \beta_0 + \epsilon_j$.

William Sealy Gosset (1876–1937) was born in Canterbury, England. He studied chemistry and mathematics at Oxford and worked as a chemist with the brewers Guinness in Dublin. Gosset became interested in statistical problems, which he discussed with Karl Pearson and later with Fisher and Neyman. He published several important papers under the pseudonym "Student", and he lent that name to the t test he invented.

Menu

Help > Check for Updates

Description

The `update` command reports on the current update level and installs official updates to Stata. Official updates are updates to Stata as it was originally shipped from StataCorp, not the additions to Stata published in, for instance, the *Stata Journal* (SJ). Those additions are installed using the `net` command and updated using the `adoupdate` command; see [R] **net** and [R] **adoupdate**.

`update` without arguments reports on the update level of the currently installed Stata.

`update from` sets an update source, where *location* is a directory name or URL. If you are on the Internet, type `update from http://www.stata.com`.

`update query` compares the update level of the currently installed Stata with that available from the update source and displays a report.

`update all` updates all necessary files. This is what you should type to check for and install updates.

`set update_query` determines if `update query` is to be automatically performed when Stata is launched. Only Mac and Windows platforms can be set for automatic updating.

`set update_interval #` sets the number of days to elapse before performing the next automatic `update query`. The default # is 7. The interval starts from the last time an `update query` was performed (automatically or manually). Only Mac and Windows platforms can be set for automatic updating.

`set update_prompt` determines whether a dialog is to be displayed before performing an automatic `update query`. The dialog allows you to perform an `update query` now, perform one the next time Stata is launched, perform one after the next interval has passed, or disable automatic `update query`. Only Mac and Windows platforms can be set for automatic updating.

Options

`from(`*location*`)` specifies the location of the update source. You can specify the `from()` option on the individual `update` commands or use the `update from` command. Which you do makes no difference. You typically do not need to use this option.

`detail` specifies to display verbose output during the update process.

`force` specifies to force downloading of all files even if, based on the date comparison, Stata does not think it is necessary. There is seldom a reason to specify this option.

`exit` instructs Stata to exit when the update has successfully completed. There is seldom a reason to specify this option.

Remarks and examples

`update` updates the official components of Stata from the official source: http://www.stata.com. If you are connected to the Internet, the easy thing to do is to type

```
. update all
```

and follow the instructions. If Stata is up to date, `update all` will do nothing. Otherwise, it will download whatever is necessary and install the files. If you just want to know what updates are available, type

```
. update query
```

`update query` will check if any updates are available and report that information. If updates are available, it will recommend that you type `update all`.

If you want to report the current update level, type

```
. update
```

`update` will report the update level of the Stata installation. `update` will also show you the date that updates were last checked and if any updates were available at that time.

Stored results

`update` without a subcommand, `update from`, and `update query` store the following in `r()`:

Scalars

`r(inst_exe)`	date of executable installed (*)
`r(avbl_exe)`	date of executable available over web (*) (**)
`r(inst_ado)`	date of ado-files installed (*)
`r(avbl_ado)`	date of ado-files available over web (*) (**)
`r(inst_utilities)`	date of utilities installed (*)
`r(avbl_utilities)`	date of utilities available over web (*) (**)
`r(inst_docs)`	date of documentation installed (*)
`r(avbl_docs)`	date of documentation available over web (*) (**)

Macros

`r(name_exe)`	name of the Stata executable
`r(dir_exe)`	directory in which executable is stored
`r(dir_ado)`	directory in which ado-files are stored
`r(dir_utilities)`	directory in which utilities are stored
`r(dir_docs)`	directory in which PDF documentation is stored

Notes:

* Dates are stored as integers counting the number of days since January 1, 1960; see [D] **datetime**.

** These dates are not stored by `update` without a subcommand because `update` by itself reports information solely about the local computer and does not check what is available on the web.

Title

vce_option **—** Variance estimators

Syntax Description Options Remarks and examples
Methods and formulas Also see

Syntax

estimation_cmd ... [, `vce(`*vcetype*`)` ...]

vcetype	Description
Likelihood based	
`oim`	observed information matrix (OIM)
`opg`	outer product of the gradient (OPG) vectors
Sandwich estimators	
`robust`	Huber/White/sandwich estimator
`cluster` *clustvar*	clustered sandwich estimator
Replication based	
`bootstrap` [, *bootstrap_options*]	bootstrap estimation
`jackknife` [, *jackknife_options*]	jackknife estimation

Description

This entry describes the `vce()` option, which is common to most estimation commands. `vce()` specifies how to estimate the variance–covariance matrix (VCE) corresponding to the parameter estimates. The standard errors reported in the table of parameter estimates are the square root of the variances (diagonal elements) of the VCE.

Options

SE/Robust

`vce(oim)` is usually the default for models fit using maximum likelihood. `vce(oim)` uses the observed information matrix (OIM); see [R] **ml**.

`vce(opg)` uses the sum of the outer product of the gradient (OPG) vectors; see [R] **ml**. This is the default VCE when the `technique(bhhh)` option is specified; see [R] **maximize**.

`vce(robust)` uses the robust or sandwich estimator of variance. This estimator is robust to some types of misspecification so long as the observations are independent; see **[U] 20.21 Obtaining robust variance estimates**.

If the command allows `pweights` and you specify them, `vce(robust)` is implied; see [U] **20.23.3 Sampling weights**.

`vce(cluster` *clustvar*`)` specifies that the standard errors allow for intragroup correlation, relaxing the usual requirement that the observations be independent. That is, the observations are independent across groups (clusters) but not necessarily within groups. *clustvar* specifies to which group each observation belongs, for example, `vce(cluster personid)` in data with repeated observations on individuals. `vce(cluster` *clustvar*`)` affects the standard errors and variance–covariance matrix of the estimators but not the estimated coefficients; see [U] **20.21 Obtaining robust variance estimates**.

`vce(bootstrap` [`,` *bootstrap_options*]`)` uses a bootstrap; see [R] **bootstrap**. After estimation with `vce(bootstrap)`, see [R] **bootstrap postestimation** to obtain percentile-based or bias-corrected confidence intervals.

`vce(jackknife` [`,` *jackknife_options*]`)` uses the delete-one jackknife; see [R] **jackknife**.

Remarks and examples

Remarks are presented under the following headings:

Prefix commands
Passing options in vce()

Prefix commands

Specifying `vce(bootstrap)` or `vce(jackknife)` is often equivalent to using the corresponding prefix command. Here is an example using `jackknife` with `regress`.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)

. regress mpg turn trunk, vce(jackknife)
(running regress on estimation sample)

       _cons |   55.82001   5.031107    11.09   0.000     45.79303    65.84699
------------------------------------------------------------------------------
```

Here it does not matter whether we specify the `vce(jackknife)` option or instead use the `jackknife` prefix.

However, `vce(jackknife)` should be used in place of the `jackknife` prefix whenever available because they are not always equivalent. For example, to use the `jackknife` prefix with `clogit` properly, you must tell `jackknife` to omit whole groups rather than individual observations. Specifying `vce(jackknife)` does this automatically.

```
. use http://www.stata-press.com/data/r13/clogitid
. jackknife, cluster(id): clogit y x1 x2, group(id)
  (output omitted)
```

This extra information is automatically communicated to `jackknife` by `clogit` when the `vce()` option is specified.

```
. clogit y x1 x2, group(id) vce(jackknife)
(running clogit on estimation sample)

Passing options in vce()

If you wish to specify more options to the bootstrap or jackknife estimation, you can include them within the `vce()` option. Below we request 300 bootstrap replications and save the replications in `bsreg.dta`:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress mpg turn trunk, vce(bootstrap, nodots seed(123) rep(300) saving(bsreg))
Linear regression                               Number of obs      =        74
                                                Replications       =       300
                                                Wald chi2(2)       =    127.28
                                                Prob > chi2        =    0.0000
                                                R-squared          =    0.5521
                                                Adj R-squared      =    0.5395
                                                Root MSE           =    3.9260

Methods and formulas

By default, Stata's maximum likelihood estimators display standard errors based on variance estimates given by the inverse of the negative Hessian (second derivative) matrix. If `vce(robust)`, `vce(cluster` *clustvar*`)`, or `pweights` is specified, standard errors are based on the robust variance estimator (see [U] **20.21 Obtaining robust variance estimates**); likelihood-ratio tests are not appropriate here (see [SVY] **survey**), and the model χ^2 is from a Wald test. If `vce(opg)` is specified, the standard errors are based on the outer product of the gradients; this option has no effect on likelihood-ratio tests, though it does affect Wald tests.

If `vce(bootstrap)` or `vce(jackknife)` is specified, the standard errors are based on the chosen replication method; here the model χ^2 or F statistic is from a Wald test using the respective replication-based covariance matrix. The t distribution is used in the coefficient table when the `vce(jackknife)` option is specified. `vce(bootstrap)` and `vce(jackknife)` are also available with some commands that are not maximum likelihood estimators.

File > View...

Description

`view` displays file contents in the Viewer.

`view file` displays the specified file. `file` is optional, so if you had a SMCL session log created by typing `log using mylog`, you could view it by typing `view mylog.smcl`. `view file` can properly display `.smcl` files (logs and the like), `.sthlp` files, and text files. `view file`'s `asis` option specifies that the file be displayed as plain text, regardless of the *filename*'s extension.

`view browse` opens your browser pointed to *url*. Typing `view browse http://www.stata.com` would bring up your browser pointed to the http://www.stata.com website.

[`view`] `help` displays the specified topic in the Viewer. For example, to review the help for Stata's `print` command, you could type `help print`. See [R] **help** for more details.

[`view`] `search` displays the results of the `search` command in the Viewer. For instance, to search the system help for information on robust regression, you could type `search robust regression`. See [R] **search** for more details.

`view news` does the same as the `news` command—see [R] **news**—but displays the results in the Viewer. (`news` displays the latest news from http://www.stata.com.)

`view net` does the same as the `net` command—see [R] **net**—but displays the result in the Viewer. For instance, typing `view net search hausman test` would search the Internet for additions to Stata related to the Hausman test. Typing `view net from http://www.stata.com` would go to the Stata additions download site at http://www.stata.com.

`view ado` does the same as the `ado` command—see [R] **net**—but displays the result in the Viewer. For instance, typing `view ado dir` would show a list of files you have installed.

`view update` does the same as the `update` command—see [R] **update**—but displays the result in the Viewer. Typing `view update` would show the dates of what you have installed, and from there you could click to compare those dates with the latest updates available. Typing `view update query` would skip the first step and show the comparison.

Options

`asis`, allowed with `view file`, specifies that the file be displayed as text, regardless of the *filename*'s extension. `view file`'s default action is to display files ending in `.smcl` and `.sthlp` as SMCL; see [P] **smcl**.

`adopath`, allowed with `view file`, specifies that Stata search the `S_ADO` path for *filename* and display it, if found.

Remarks and examples

Most users access the Viewer by selecting **File > View...** and proceeding from there. Some commands allow you to skip that step. Some common interactive uses of commands that display their results in the Viewer are the following:

```
. view mysession.smcl
. view mysession.log

. help print
. help regress

. view news
. view browse http://www.stata.com

. search hausman test

. view net
. view ado

. view update query
```

vwls — Variance-weighted least squares

Syntax | Menu | Description | Options
Remarks and examples | Stored results | Methods and formulas | References
Also see

Syntax

`vwls` *depvar indepvars* [*if*] [*in*] [*weight*] [, *options*]

options	Description
Model	
`noconstant`	suppress constant term
`sd(`*varname*`)`	variable containing estimate of conditional standard deviation
Reporting	
`level(#)`	set confidence level; default is `level(95)`
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
`coeflegend`	display legend instead of statistics

indepvars may contain factor variables; see **[U] 11.4.3 Factor variables**.

`bootstrap`, `by`, `jackknife`, `rolling`, and `statsby` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`fweights` are allowed; see **[U] 11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Linear models and related > Other > Variance-weighted least squares

Description

`vwls` estimates a linear regression using variance-weighted least squares. It differs from ordinary least-squares (OLS) regression in that it does not assume homogeneity of variance, but requires that the conditional variance of *depvar* be estimated prior to the regression. The estimated variance need not be constant across observations. `vwls` treats the estimated variance as if it were the true variance when it computes the standard errors of the coefficients.

You must supply an estimate of the conditional standard deviation of *depvar* to `vwls` by using the `sd(`*varname*`)` option, or you must have grouped data with the groups defined by the *indepvars* variables. In the latter case, `vwls` treats all *indepvars* as categorical variables, computes the mean and standard deviation of *depvar* separately for each subgroup, and computes the regression of the subgroup means on *indepvars*.

`regress` with analytic weights can be used to produce another kind of "variance-weighted least squares"; see *Remarks and examples* for an explanation of the difference.

Options

Model

`noconstant`; see [R] **estimation options**.

`sd(`*varname*`)` is an estimate of the conditional standard deviation of *depvar* (that is, it can vary observation by observation). All values of *varname* must be > 0. If you specify `sd()`, you cannot use `fweights`.

If `sd()` is not given, the data will be grouped by *indepvars*. Here *indepvars* are treated as categorical variables, and the means and standard deviations of *depvar* for each subgroup are calculated and used for the regression. Any subgroup for which the standard deviation is zero is dropped.

Reporting

`level(#)`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

The following option is available with `vwls` but is not shown in the dialog box:

`coeflegend`; see [R] **estimation options**.

Remarks and examples

The `vwls` command is intended for use with two special—and different—types of data. The first contains data that consist of measurements from physical science experiments in which all error is due solely to measurement errors and the sizes of the measurement errors are known.

You can also use variance-weighted least-squares linear regression for certain problems in categorical data analysis, such as when all the independent variables are categorical and the outcome variable is either continuous or a quantity that can sensibly be averaged. If each of the subgroups defined by the categorical variables contains a reasonable number of subjects, then the variance of the outcome variable can be estimated independently within each subgroup. For the purposes of estimation, `vwls` treats each subgroup as one observation, with the dependent variable being the subgroup mean of the outcome variable.

The `vwls` command fits the model

$$y_i = \mathbf{x}_i\boldsymbol{\beta} + \varepsilon_i$$

where the errors ε_i are independent normal random variables with the distribution $\varepsilon_i \sim N(0, \nu_i)$. The independent variables $\mathbf{x}_i$ are assumed to be known without error.

As described above, `vwls` assumes that you already have estimates s_i^2 for the variances ν_i. The error variance is not estimated in the regression. The estimates s_i^2 are used to compute the standard errors of the coefficients; see *Methods and formulas* below.

In contrast, weighted OLS regression assumes that the errors have the distribution $\varepsilon_i \sim N(0, \sigma^2/w_i)$, where the w_i are known weights and σ^2 is an unknown parameter that is estimated in the regression. This is the difference from variance-weighted least squares: in weighted OLS, the magnitude of the error variance is estimated in the regression using all the data.

Example 1

An artificial, but informative, example illustrates the difference between variance-weighted least squares and weighted OLS.

We measure the quantities x_i and y_i and estimate that the standard deviation of y_i is s_i. We enter the data into Stata:

```
. use http://www.stata-press.com/data/r13/vwlsxmpl
. list
```

	x	y	s
1.	1	1.2	.5
2.	2	1.9	.5
3.	3	3.2	1
4.	4	4.3	1
5.	5	4.9	1
6.	6	6.0	2
7.	7	7.2	2
8.	8	7.9	2

Because we want observations with smaller variance to carry larger weight in the regression, we compute an OLS regression with analytic weights proportional to the inverse of the squared standard deviations:

```
. regress y x [aweight=s^(-2)]
(sum of wgt is   1.1750e+01)
```

Source	SS	df	MS		
Model	22.6310183	1	22.6310183	Number of obs	= 8
Residual	.193355117	6	.032225853	F(1, 6)	= 702.26
				Prob > F	= 0.0000
				R-squared	= 0.9915
				Adj R-squared	= 0.9901
Total	22.8243734	7	3.26062477	Root MSE	= .17952

y	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
x	.9824683	.0370739	26.50	0.000	.8917517	1.073185
_cons	.1138554	.1120078	1.02	0.349	-.1602179	.3879288

If we compute a variance-weighted least-squares regression by using `vwls`, we get the same results for the coefficient estimates but very different standard errors:

```
. vwls y x, sd(s)
```

Variance-weighted least-squares regression		Number of obs	= 8
Goodness-of-fit chi2(6)	= 0.28	Model chi2(1)	= 33.24
Prob > chi2	= 0.9996	Prob > chi2	= 0.0000

y	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
x	.9824683	.170409	5.77	0.000	.6484728	1.316464
_cons	.1138554	.51484	0.22	0.825	-.8952124	1.122923

Although the values of y_i were nicely linear with x_i, the `vwls` regression used the large estimates for the standard deviations to compute large standard errors for the coefficients. For weighted OLS regression, however, the scale of the analytic weights has no effect on the standard errors of the coefficients—only the relative proportions of the analytic weights affect the regression.

If we are sure of the sizes of our error estimates for y_i, using `vwls` is valid. However, if we can estimate only the relative proportions of error among the y_i, then `vwls` is not appropriate.

◁

▷ Example 2

Let's now consider an example of the use of `vwls` with categorical data. Suppose that we have blood pressure data for $n = 400$ subjects, categorized by gender and race (black or white). Here is a description of the data:

```
. use http://www.stata-press.com/data/r13/bp
. table gender race, c(mean bp sd bp freq) row col format(%8.1f)
```

	Race		
Gender	White	Black	Total
Female	117.1	118.5	117.8
	10.3	11.6	10.9
	100.0	100.0	200.0
Male	122.1	125.8	124.0
	10.6	15.5	13.3
	100.0	100.0	200.0
Total	119.6	122.2	120.9
	10.7	14.1	12.6
	200.0	200.0	400.0

Performing a variance-weighted regression using `vwls` gives

```
. vwls bp gender race
Variance-weighted least-squares regression          Number of obs   =      400
Goodness-of-fit chi2(1)     =    0.88               Model chi2(2)   =    27.11
Prob > chi2                 =  0.3486               Prob > chi2     =   0.0000
```

bp	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
gender	5.876522	1.170241	5.02	0.000	3.582892	8.170151
race	2.372818	1.191683	1.99	0.046	.0371631	4.708473
_cons	116.6486	.9296297	125.48	0.000	114.8266	118.4707

By comparison, an OLS regression gives the following result:

```
. regress bp gender race
```

Source	SS	df	MS		
Model	4485.66639	2	2242.83319	Number of obs	= 400
Residual	58442.7305	397	147.210908	F(2, 397)	= 15.24
				Prob > F	= 0.0000
				R-squared	= 0.0713
				Adj R-squared	= 0.0666
Total	62928.3969	399	157.71528	Root MSE	= 12.133

bp	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
gender	6.1775	1.213305	5.09	0.000	3.792194	8.562806
race	2.5875	1.213305	2.13	0.034	.2021938	4.972806
_cons	116.4862	1.050753	110.86	0.000	114.4205	118.552

Note the larger value for the `race` coefficient (and smaller p-value) in the OLS regression. The assumption of homogeneity of variance in OLS means that the mean for black men pulls the regression line higher than in the `vwls` regression, which takes into account the larger variance for black men and reduces its effect on the regression.

◁

Stored results

`vwls` stores the following in `e()`:

Scalars

`e(N)`	number of observations
`e(df_m)`	model degrees of freedom
`e(chi2)`	model χ^2
`e(df_gf)`	goodness-of-fit degrees of freedom
`e(chi2_gf)`	goodness-of-fit χ^2
`e(rank)`	rank of `e(V)`

Macros

`e(cmd)`	`vwls`
`e(cmdline)`	command as typed
`e(depvar)`	name of dependent variable
`e(properties)`	`b V`
`e(predict)`	program used to implement `predict`
`e(asbalanced)`	factor variables `fvset` as `asbalanced`
`e(asobserved)`	factor variables `fvset` as `asobserved`

Matrices

`e(b)`	coefficient vector
`e(V)`	variance–covariance matrix of the estimators

Functions

`e(sample)`	marks estimation sample

Methods and formulas

Let $\mathbf{y} = (y_1, y_2, \ldots, y_n)'$ be the vector of observations of the dependent variable, where n is the number of observations. When `sd()` is specified, let s_1, s_2, …, s_n be the standard deviations supplied by `sd()`. For categorical data, when `sd()` is not given, the means and standard deviations of y for each subgroup are computed, and n becomes the number of subgroups, $\mathbf{y}$ is the vector of subgroup means, and s_i are the standard deviations for the subgroups.

Let $\mathbf{V} = \text{diag}(s_1^2, s_2^2, \ldots, s_n^2)$ denote the estimate of the variance of $\mathbf{y}$. Then the estimated regression coefficients are

$$\mathbf{b} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}$$

and their estimated covariance matrix is

$$\widehat{\text{Cov}}(\mathbf{b}) = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}$$

A statistic for the goodness of fit of the model is

$$Q = (\mathbf{y} - \mathbf{X}\mathbf{b})'\,\mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\mathbf{b})$$

where Q has a χ^2 distribution with $n - k$ degrees of freedom (k is the number of independent variables plus the constant, if any).

Title

vwls postestimation — Postestimation tools for vwls

Description Syntax for predict Menu for predict Options for predict Also see

Description

The following postestimation commands are available after `vwls`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estimates`	cataloging estimation results
`forecast`	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`linktest`	link test for model specification
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

Syntax for predict

`predict` [*type*] *newvar* [*if*] [*in*] [`, xb stdp`]

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

[R] **vwls** — Variance-weighted least squares

[U] 20 Estimation and postestimation commands

Title

which — Display location and version for an ado-file

Syntax Description Option Remarks and examples Also see

Syntax

`which` *fname*[`.`*ftype*] [`, all`]

Description

`which` looks for *fname*`.`*ftype* along the `S_ADO` path. If Stata finds the file, `which` displays the full path and filename, along with, if the file is text, all lines in the file that begin with "`*!`" in the first column. If Stata cannot find the file, `which` issues the message "file not found along ado-path" and sets the return code to 111. *ftype* must be a file type for which Stata usually looks along the ado-path to find. Allowable *ftype*s are

`.ado`, `.class`, `.dlg`, `.idlg`, `.sthlp`, `.ihlp`, `.hlp`, `.key`, `.maint`, `.mata`, `.mlib`, `.mo`, `.mnu`, `.plugin`, `.scheme`, `.stbcal`, and `.style`

If *ftype* is omitted, `which` assumes `.ado`. When searching for `.ado` files, if Stata cannot find the file, Stata then checks to see if *fname* is a built-in Stata command, allowing for valid abbreviations. If it is, the message "built-in command" is displayed; if not, the message "command not found as either built-in or ado-file" is displayed and the return code is set to 111.

For information about internal version control, see [P] **version**.

Option

`all` forces `which` to report the location of all files matching the *fname*`.`*ftype* found along the search path. The default is to report just the first one found.

Remarks and examples

If you write programs, you know that you make changes to the programs over time. If you are like us, you also end up with multiple versions of the program stored on your disk, perhaps in different directories. You may even have given copies of your programs to other Stata users, and you may not remember which version of a program you or your friends are using. The `which` command helps you solve this problem.

▷ Example 1

The `which` command displays the path for *filename*`.ado` and any lines in the code that begin with "`*!`". For example, we might want information about the `test` command, described in [R] **test**, which is an ado-file written by StataCorp. Here is what happens when we type `which test`:

```
. which test
C:\Program Files\Stata13\ado\base\t\test.ado
*! version 2.2.2  07feb2012
```

`which` displays the path for the `test.ado` file and also a line beginning with "`*!`" that indicates the version of the file. This is how we, at StataCorp, do version control—see [U] **18.11.1 Version** for an explanation of our version control numbers.

We do not need to be so formal. `which` will display anything typed after lines that begin with '`*!`'. For instance, we might write `myprog.ado`:

```
. which myprog
.\myprog.ado
*! first written 1/03/2013
*! bug fix on 1/05/2013 (no variance case)
*! updated 1/24/2013 to include noconstant option
*! still suspicious if variable takes on only two values
```

It does not matter where in the program the lines beginning with `*!` are—`which` will list them (in particular, our "still suspicious" comment was buried about 50 lines down in the code). All that is important is that the `*!` marker appear in the first two columns of a line.

◁

▷ Example 2

If we type `which` *command*, where *command* is a built-in command rather than an ado-file, Stata responds with

```
. which summarize
built-in command:  summarize
```

If *command* was neither a built-in command nor an ado-file, Stata would respond with

```
. which junk
command junk not found as either built-in or ado-file
r(111);
```

◁

[U] **17 Ado-files**

[U] **18.11.1 Version**

Title

xi — Interaction expansion

Syntax | Menu | Description | Options
Remarks and examples | Stored results | References | Also see

Syntax

```
xi [ , prefix(string) noomit ] term(s)

xi [ , prefix(string) noomit ] : any_stata_command varlist_with_terms ...
```

where a *term* has the form

`i.`*varname*	or	`I.`*varname*
`i.`*varname*$_1$`*i.`*varname*$_2$		`I.`*varname*$_1$`*I.`*varname*$_2$
`i.`*varname*$_1$`*`*varname*$_3$		`I.`*varname*$_1$`*`*varname*$_3$
`i.`*varname*$_1$`|`*varname*$_3$		`I.`*varname*$_1$`|`*varname*$_3$

varname, *varname*$_1$, and *varname*$_2$ denote numeric or string categorical variables. *varname*$_3$ denotes a continuous, numeric variable.

Menu

Data > Create or change data > Other variable-creation commands > Interaction expansion

> Most commands in Stata now allow factor variables; see **[U] 11.4.3 Factor variables**. To determine if a command allows factor variables, see the information printed below the options table for the command. If the command allows factor variables, it will say something like "*indepvars* may contain factor variables".
>
> We recommend that you use factor variables instead of `xi` if a command allows factor variables.
>
> We include **[R] xi** in our documentation so that readers can consult it when using a Stata command that does not allow factor variables.

Description

`xi` expands terms containing categorical variables into indicator (also called dummy) variable sets by creating new variables and, in the second syntax (`xi:` *any_stata_command*), executes the specified command with the expanded terms. The dummy variables created are

`i.`*varname*	creates dummies for categorical variable *varname*
`i.`*varname*$_1$`*i.`*varname*$_2$	creates dummies for categorical variables *varname*$_1$ and *varname*$_2$: all interactions and main effects
`i.`*varname*$_1$`*`*varname*$_3$	creates dummies for categorical variable *varname*$_1$ and continuous variable *varname*$_3$: all interactions and main effects
`i.`*varname*$_1$`|`*varname*$_3$	creates dummies for categorical variable *varname*$_1$ and continuous variable *varname*$_3$: all interactions and main effect of *varname*$_3$, but no main effect of *varname*$_1$

Options

`prefix(`*string*`)` allows you to choose a prefix other than `_I` for the newly created interaction variables. The prefix cannot be longer than four characters. By default, `xi` will create interaction variables starting with `_I`. When you use `xi`, it drops all previously created interaction variables starting with the prefix specified in the `prefix(`*string*`)` option or with `_I` by default. Therefore, if you want to keep the variables with a certain prefix, specify a different prefix in the `prefix(`*string*`)` option.

`noomit` prevents `xi` from omitting groups. This option provides a way to generate an indicator variable for every category having one or more variables, which is useful when combined with the `noconstant` option of an estimation command.

Remarks and examples

Remarks are presented under the following headings:

Background
Indicator variables for simple effects
Controlling the omitted dummy
Categorical variable interactions
Interactions with continuous variables
Using xi: Interpreting output
How xi names variables
xi as a command rather than a command prefix
Warnings

`xi` provides a convenient way to include dummy or indicator variables when fitting a model (say, with `regress` or `logistic`). For instance, assume that the categorical variable `agegrp` contains 1 for ages 20–24, 2 for ages 25–39, 3 for ages 40–44, etc. Typing

```
. xi: logistic outcome weight i.agegrp bp
```

estimates a logistic regression of `outcome` on `weight`, dummies for each `agegrp` category, and `bp`. That is, `xi` searches out and expands terms starting with "`i.`" or "`I.`" but ignores the other variables. `xi` will expand both numeric and string categorical variables, so if you had a string variable `race` containing "white", "black", and "other", typing

```
. xi: logistic outcome weight bp i.agegrp i.race
```

would include indicator variables for the race group as well.

The `i.` indicator variables `xi` expands may appear anywhere in the *varlist*, so

```
. xi: logistic outcome i.agegrp weight i.race bp
```

would fit the same model.

You can also create interactions of categorical variables; typing

```
xi: logistic outcome weight bp i.agegrp*i.race
```

fits a model with indicator variables for all `agegrp` and `race` combinations, including the `agegrp` and `race` main-effect terms (that is, the terms that are created when you just type `i.agegrp i.race`).

You can interact dummy variables with continuous variables; typing

```
xi: logistic outcome bp i.agegrp*weight i.race
```

fits a model with indicator variables for all agegrp categories interacted with weight, plus the main-effect terms weight and i.agegrp.

You can get the interaction terms without the agegrp main effect (but with the weight main effect) by typing

```
xi: logistic outcome bp i.agegrp|weight i.race
```

You can also include multiple interactions:

```
xi: logistic outcome bp i.agegrp*weight i.agegrp*i.race
```

We will now back up and describe the construction of dummy variables in more detail.

Background

The terms *continuous*, *categorical*, and *indicator* or *dummy* variables are used below. Continuous variables measure something—such as height or weight—and at least conceptually can take on any real number over some range. Categorical variables, on the other hand, take on a finite number of values, each denoting membership in a subclass—for example, excellent, good, and poor, which might be coded 0, 1, 2, or 1, 2, 3, or even "Excellent", "Good", and "Poor". An indicator or dummy variable—the terms are used interchangeably—is a special type of two-valued categorical variable that contains values 0, denoting false, and 1, denoting true. The information contained in any k-valued categorical variable can be equally well represented by k indicator variables. Instead of one variable recording values representing excellent, good, and poor, you can have three indicator variables, indicating the truth or falseness of "result is excellent", "result is good", and "result is poor".

xi provides a convenient way to convert categorical variables to dummy or indicator variables when you fit a model (say, with regress or logistic).

▷ Example 1

For instance, assume that the categorical variable agegrp contains 1 for ages 20–24, 2 for ages 25–39, and 3 for ages 40–44. (There is no one over 44 in our data.) As it stands, agegrp would be a poor candidate for inclusion in a model even if we thought age affected the outcome. The reason is that the coding would restrict the effect of being in the second age group to be twice the effect of being in the first, and, similarly, the effect of being in the third to be three times the first. That is, if we fit the model,

$$y = \beta_0 + \beta_1 \texttt{agegrp} + X\beta_2$$

the effect of being in the first age group is β_1, the second $2\beta_1$, and the third $3\beta_1$. If the coding 1, 2, and 3 is arbitrary, we could just as well have coded the age groups 1, 4, and 9, making the effects β_1, $4\beta_1$, and $9\beta_1$.

The solution is to convert the categorical variable agegrp to a set of indicator variables, a_1, a_2, and a_3, where a_i is 1 if the individual is a member of the ith age group and 0 otherwise. We can then fit the model

$$y = \beta_0 + \beta_{11}a_1 + \beta_{12}a_2 + \beta_{13}a_3 + X\beta_2$$

The effect of being in age group 1 is now β_{11}; 2, β_{12}; and 3, β_{13}; and these results are independent of our (arbitrary) coding. The only difficulty at this point is that the model is unidentified in the sense that there are an infinite number of $(\beta_0, \beta_{11}, \beta_{12}, \beta_{13})$ that fit the data equally well.

To see this, pretend that $(\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) = (1, 1, 3, 4)$. The predicted values of y for the various age groups are

$$y = \begin{cases} 1 + 1 + X\beta_2 = 2 + X\beta_2 & \text{(age group 1)} \\ 1 + 3 + X\beta_2 = 4 + X\beta_2 & \text{(age group 2)} \\ 1 + 4 + X\beta_2 = 5 + X\beta_2 & \text{(age group 3)} \end{cases}$$

Now pretend that $(\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) = (2, 0, 2, 3)$. The predicted values of y are

$$y = \begin{cases} 2 + 0 + X\beta_2 = 2 + X\beta_2 & \text{(age group 1)} \\ 2 + 2 + X\beta_2 = 4 + X\beta_2 & \text{(age group 2)} \\ 2 + 3 + X\beta_2 = 5 + X\beta_2 & \text{(age group 3)} \end{cases}$$

These two sets of predictions are indistinguishable: for age group 1, $y = 2 + X\beta_2$ regardless of the coefficient vector used, and similarly for age groups 2 and 3. This arises because we have three equations and four unknowns. Any solution is as good as any other, and, for our purposes, we merely need to choose one of them. The popular selection method is to set the coefficient on the first indicator variable to 0 (as we have done in our second coefficient vector). This is equivalent to fitting the model

$$y = \beta_0 + \beta_{12}a_2 + \beta_{13}a_3 + X\beta_2$$

How we select a particular coefficient vector (identifies the model) does not matter. It does, however, affect the *interpretation* of the coefficients.

For instance, we could just as well choose to omit the second group. In our artificial example, this would yield $(\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) = (4, -2, 0, 1)$ instead of $(2, 0, 2, 3)$. These coefficient vectors are the same in the sense that

$$y = \begin{cases} 2 + 0 + X\beta_2 = 2 + X\beta_2 = 4 - 2 + X\beta_2 & \text{(age group 1)} \\ 2 + 2 + X\beta_2 = 4 + X\beta_2 = 4 + 0 + X\beta_2 & \text{(age group 2)} \\ 2 + 3 + X\beta_2 = 5 + X\beta_2 = 4 + 1 + X\beta_2 & \text{(age group 3)} \end{cases}$$

But what does it mean that β_{13} can just as well be 3 or 1? We obtain $\beta_{13} = 3$ when we set $\beta_{11} = 0$, so $\beta_{13} = \beta_{13} - \beta_{11}$ and β_{13} measures the difference between age groups 3 and 1.

In the second case, we obtain $\beta_{13} = 1$ when we set $\beta_{12} = 0$, so $\beta_{13} - \beta_{12} = 1$ and β_{13} measures the difference between age groups 3 and 2. There is no inconsistency. According to our $\beta_{12} = 0$ model, the difference between age groups 3 and 1 is $\beta_{13} - \beta_{11} = 1 - (-2) = 3$, the same result we got in the $\beta_{11} = 0$ model.

◁

▷ Example 2

The issue of interpretation is important because it can affect the way we discuss results. Imagine that we are studying recovery after a coronary bypass operation. Assume that the age groups are children under 13 (we have two of them), young adults under 25 (we have a handful of them), adults under 46 (of which we have even more), mature adults under 56, older adults under 65, and elderly adults. We follow the prescription of omitting the first group, so all our results are reported relative to children under 13. While there is nothing statistically wrong with this, readers will be suspicious when we make statements like "compared with young children, older and elder adults . . . ". Moreover, we will probably have to end each statement with "although results are not statistically significant" because we have only two children in our comparison group. Of course, even with results reported in this way, we can do reasonable comparisons (say, with mature adults), but we will have to do extra work to perform the appropriate linear hypothesis test using Stata's `test` command.

Here it would be better to force the omitted group to be more reasonable, such as mature adults. There is, however, a generic rule for automatic comparison group selection that, although less popular, tends to work better than the omit-the-first-group rule. That rule is to omit the most prevalent group. The most prevalent is usually a reasonable baseline.

◁

In any case, the prescription for categorical variables is

1. Convert each k-valued categorical variable to k indicator variables.
2. Drop one of the k indicator variables; any one will do, but dropping the first is popular, dropping the most prevalent is probably better in terms of having the computer guess at a reasonable interpretation, and dropping a specified one often eases interpretation the most.
3. Fit the model on the remaining $k - 1$ indicator variables.

`xi` automates this procedure.

We will now consider each of `xi`'s features in detail.

Indicator variables for simple effects

When you type `i.`*varname*, `xi` internally tabulates *varname* (which may be a string or a numeric variable) and creates indicator (dummy) variables for each observed value, omitting the indicator for the smallest value. For instance, say that `agegrp` takes on the values 1, 2, 3, and 4. Typing

```
xi: logistic outcome i.agegrp
```

creates indicator variables named `_Iagegrp_2`, `_Iagegrp_3`, and `_Iagegrp_4`. (`xi` chooses the names and tries to make them readable; `xi` guarantees that the names are unique.) The expanded logistic model is

```
. logistic outcome _Iagegrp_2 _Iagegrp_3 _Iagegrp_4
```

Afterward, you can drop the new variables `xi` leaves behind by typing '`drop _I*`' (note the capitalization).

`xi` provides the following features when you type `i.`*varname*:

- *varname* may be string or numeric.
- Dummy variables are created automatically.
- By default, the dummy-variable set is identified by dropping the dummy corresponding to the smallest value of the variable (how to specify otherwise is discussed below).
- The new dummy variables are left in your dataset. By default, the names of the new dummy variables start with `_I`; therefore, you can drop them by typing '`drop _I*`'. You do not have to do this; each time you use `xi`, any automatically generated dummies with the same prefix as the one specified in the `prefix(`*string*`)` option, or `_I` by default, are dropped and new ones are created.
- The new dummy variables have variable labels so that you can determine what they correspond to by typing '`describe`'.
- `xi` may be used with any Stata command (not just `logistic`).

Controlling the omitted dummy

By default, `i.`*varname* omits the dummy corresponding to the smallest value of *varname*; for a string variable, this is interpreted as dropping the first in an alphabetical, case-sensitive sort. `xi` provides two alternatives to dropping the first: `xi` will drop the dummy corresponding to the most prevalent value of *varname*, or `xi` will let you choose the particular dummy to be dropped.

To change `xi`'s behavior to dropping the most prevalent dummy, type

```
. char _dta[omit] prevalent
```

although whether you type "prevalent" or "yes" or anything else does not matter. Setting this characteristic affects the expansion of all categorical variables in the dataset. If you resave your dataset, the prevalent preference will be remembered. If you want to change the behavior back to the default drop-the-first rule, type

```
. char _dta[omit]
```

to clear the characteristic.

Once you set `_dta[omit]`, `i.`*varname* omits the dummy corresponding to the most prevalent value of *varname*. Thus the coefficients on the dummies have the interpretation of change from the most prevalent group. For example,

```
. char _dta[omit] prevalent
. xi: regress y i.agegrp
```

might create `_Iagegrp_1` through `_Iagegrp_4`, resulting in `_Iagegrp_2` being omitted if `agegrp` $=$ 2 is most common (as opposed to the default dropping of `_Iagegrp_1`). The model is then

$$\texttt{y} = b_0 + b_1\ \texttt{_Iagegrp_1} + b_3\ \texttt{_Iagegrp_3} + b_4\ \texttt{_Iagegrp_4} + u$$

Then

Predicted `y` for `agegrp` 1 $= b_0 + b_1$	Predicted `y` for `agegrp` 3 $= b_0 + b_3$
Predicted `y` for `agegrp` 2 $= b_0$	Predicted `y` for `agegrp` 4 $= b_0 + b_4$

Thus the model's reported t or Z statistics are for a test of whether each group is different from the most prevalent group.

Perhaps you wish to omit the dummy for `agegrp` 3 instead. You do this by setting the variable's `omit` characteristic:

```
. char agegrp[omit] 3
```

This overrides `_dta[omit]` if you have set it. Now when you type

```
. xi: regress y i.agegrp
```

`_Iagegrp_3` will be omitted, and you will fit the model

$$\texttt{y} = b'_0 + b'_1\ \texttt{_Iagegrp_1} + b'_2\ \texttt{_Iagegrp_2} + b'_4\ \texttt{_Iagegrp_4} + u$$

Later if you want to return to the default omission, type

```
. char agegrp[omit]
```

to clear the characteristic.

In summary, `i.`*varname* omits the first group by default, but if you define

```
. char _dta[omit] prevalent
```

the default behavior changes to dropping the most prevalent group. Either way, if you define a characteristic of the form

```
. char varname[omit] #
```

or, if *varname* is a string,

```
. char varname[omit] string-literal
```

the specified value will be omitted.

Examples:
```
. char agegrp[omit] 1
. char race[omit] White      (for race, a string variable)
. char agegrp[omit]          (to restore default for agegrp)
```

Categorical variable interactions

`i.`*varname*$_1$`*i.`*varname*$_2$ creates the dummy variables associated with the interaction of the categorical variables *varname*$_1$ and *varname*$_2$. The identification rules — which categories are omitted — are the same as those for `i.`*varname*. For instance, assume that `agegrp` takes on four values and `race` takes on three values. Typing

```
. xi: regress y i.agegrp*i.race
```

results in

model:	dummies for:
$y = a + b_2$ `_Iagegrp_2` $+ b_3$ `_Iagegrp_3` $+ b_4$ `_Iagegrp_4`	(`agegrp`)
$+ c_2$ `_Irace_2` $+ c_3$ `_Irace_3`	(`race`)
$+ d_{22}$ `_IageXrac_2_2` $+ d_{23}$ `_IageXrac_2_3`	
$+ d_{32}$ `_IageXrac_3_2` $+ d_{33}$ `_IageXrac_3_3`	(`agegrp*race`)
$+ d_{42}$ `_IageXrac_4_2` $+ d_{43}$ `_IageXrac_4_3`	
$+ u$	

That is, typing

```
. xi: regress y i.agegrp*i.race
```

is the same as typing

```
. xi: regress y i.agegrp i.race i.agegrp*i.race
```

Although there are many other ways the interaction could have been parameterized, this method has the advantage that you can test the joint significance of the interactions by typing

```
. testparm _IageXrac*
```

When you perform the estimation step, whether you specify `i.agegrp*i.race` or `i.race*i.agegrp` makes no difference (other than in the names given to the interaction terms; in the first case, the names will begin with `_IageXrac`; in the second, `_IracXage`). Thus

```
. xi: regress y i.race*i.agegrp
```

fits the same model.

You may also include multiple interactions simultaneously:

```
. xi: regress y i.agegrp*i.race i.agegrp*i.sex
```

The model fit is

model:	dummies for:
$y = a + b_2$ _Iagegrp_2 $+ b_3$ _Iagegrp_3 $+ b_4$ _Iagegrp_4	(agegrp)
$+ c_2$ _Irace_2 $+ c_3$ _Irace_3	(race)
$+ d_{22}$ _IageXrac_2_2 $+ d_{23}$ _IageXrac_2_3	
$+ d_{32}$ _IageXrac_3_2 $+ d_{33}$ _IageXrac_3_3	(agegrp*race)
$+ d_{42}$ _IageXrac_4_2 $+ d_{43}$ _IageXrac_4_3	
$+ e_2$ _Isex_2	(sex)
$+ f_{22}$ _IageXsex_2_2 $+ f_{23}$ _IageXsex_2_3 $+ f_{24}$ _IageXsex_2_4	(agegrp*sex)
$+ u$	

The agegrp dummies are (correctly) included only once.

Interactions with continuous variables

i.*varname*$_1$*i.*varname*$_2$ (as distinguished from i.*varname*$_1$*i.*varname*$_2$—note the second i.) specifies an interaction of a categorical variable with a continuous variable. For instance,

```
. xi: regress y i.agegr*wgt
```

results in the model

$y = a + b_2$ _Iagegrp_2 $+ b_3$ _Iagegrp_3 $+ b_4$ _Iagegrp_4	(agegrp dummies)
$+ c$ wgt	(continuous wgt effect)
$+ d_2$ _IageXwgt_2 $+ d_3$ _IageXwgt_3 $+ d_4$ _IageXwgt_4	(agegrp*wgt interactions)
$+ u$	

A variation on this notation, using | rather than *, omits the agegrp dummies. Typing

```
. xi: regress y i.agegrp|wgt
```

fits the model

$y = a' + c'$ wgt	(continuous wgt effect)
$+ d'_2$ _IageXwgt_2 $+ d'_3$ _IageXwgt_3 $+ d'_4$ _IageXwgt_4	(agegrp*wgt interactions)
$+ u'$	

The predicted values of y are

agegrp*wgt model	agegrp|wgt model	
$y = a + c$ wgt	$a' + c'$ wgt	if agegrp $= 1$
$a + c$ wgt $+ b_2 + d_2$ wgt	$a' + c'$wgt $+ d'_2$ wgt	if agegrp $= 2$
$a + c$ wgt $+ b_3 + d_3$ wgt	$a' + c'$wgt $+ d'_3$ wgt	if agegrp $= 3$
$a + c$ wgt $+ b_4 + d_4$ wgt	$a' + c'$wgt $+ d'_4$ wgt	if agegrp $= 4$

That is, typing

```
. xi: regress y i.agegrp*wgt
```

is equivalent to typing

```
. xi: regress y i.agegrp i.agegrp|wgt
```

In either case, you do not need to specify separately the continuous variable `wgt`; it is included automatically.

Using xi: Interpreting output

```
. xi: regress mpg i.rep78
i.rep78                _Irep78_1-5   (naturally coded; _Irep78_1 omitted)
  (output from regress appears)
```

Interpretation: `i.rep78` expanded to the dummies `_Irep78_1`, `_Irep78_2`, ..., `_Irep78_5`. The numbers on the end are "natural" in the sense that `_Irep78_1` corresponds to `rep78` = 1, `_Irep78_2` to `rep78` = 2, and so on. Finally, the dummy for `rep78` = 1 was omitted.

```
. xi: regress mpg i.make
i.make                 _Imake_1-74   (_Imake_1 for make==AMC Concord omitted)
  (output from regress appears)
```

Interpretation: `i.make` expanded to `_Imake_1`, `_Imake_2`, ..., `_Imake_74`. The coding is not natural because `make` is a string variable. `_Imake_1` corresponds to one make, `_Imake_2` to another, and so on. You can find out the coding by typing `describe`. `_Imake_1` for the AMC Concord was omitted.

How xi names variables

By default, `xi` assigns to the dummy variables it creates names having the form

_I*stub*_*groupid*

You may subsequently refer to the entire set of variables by typing '`I`*stub*`*`'. For example,

name	=	_I	+	*stub*	+	_	+	*groupid*	Entire set
_Iagegrp_1		_I		agegrp		_		1	_Iagegrp*
_Iagegrp_2		_I		agegrp		_		2	_Iagegrp*
_IageXwgt_1		_I		ageXwgt		_		1	_IageXwgt*
_IageXrac_1_2		_I		ageXrac		_		1_2	_IageXrac*
_IageXrac_2_1		_I		ageXrac		_		2_1	_IageXrac*

If you specify a prefix in the `prefix(`*string*`)` option, say, `_S`, then `xi` will name the variables starting with the prefix

_S*stub*_*groupid*

xi as a command rather than a command prefix

`xi` can be used as a command prefix or as a command by itself. In the latter form, `xi` merely creates the indicator and interaction variables. Typing

```
. xi: regress y i.agegrp*wgt
i.agegrp              _Iagegrp_1-4   (naturally coded; _Iagegrp_1 omitted)
i.agegrp*wgt          _IageXwgt_1-4   (coded as above)
 (output from regress appears)
```

is equivalent to typing

```
. xi i.agegrp*wgt
i.agegrp              _Iagegrp_1-4   (naturally coded; _Iagegrp_1 omitted)
i.agegrp*wgt          _IageXwgt_1-4   (coded as above)
. regress y _Iagegrp* _IageXwgt*
 (output from regress appears)
```

Warnings

1. `xi` creates new variables in your dataset; most are `byte`s, but interactions with continuous variables will have the storage type of the underlying continuous variable. You may get the message "insufficient memory". If so, you will need to increase the amount of memory allocated to Stata's data areas; see **[U] 6 Managing memory**.
2. When using `xi` with an estimation command, you may get the message "matsize too small". If so, see [R] **matsize**.

Stored results

`xi` stores the following characteristics:

`_dta[__xi__Vars__Prefix__]`	prefix names
`_dta[__xi__Vars__To__Drop__]`	variables created

Syntax

```
zinb depvar [indepvars] [if] [in] [weight] ,
    inflate(varlist[ , offset(varname) ] | _cons) [options ]
```

options	Description
Model	
* `inflate( )`	equation that determines whether the count is zero
`noconstant`	suppress constant term
`exposure(`*varname*$_e$`)`	include ln(*varname*$_e$) in model with coefficient constrained to 1
`offset(`*varname*$_o$`)`	include *varname*$_o$ in model with coefficient constrained to 1
`constraints(`*constraints*`)`	apply specified linear constraints
`collinear`	keep collinear variables
`probit`	use probit model to characterize excess zeros; default is logit
SE/Robust	
`vce(`*vcetype*`)`	*vcetype* may be `oim`, `robust`, `cluster` *clustvar*, `opg`, `bootstrap`, or `jackknife`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`irr`	report incidence-rate ratios
`vuong`	perform Vuong test
`zip`	perform ZIP likelihood-ratio test
`nocnsreport`	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
`coeflegend`	display legend instead of statistics

* `inflate(`*varlist*`[ , offset(`*varname*`) ] | _cons)` is required.

indepvars and *varlist* may contain factor variables; see **[U] 11.4.3 Factor variables**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see **[R] bootstrap**.

`vce()`, `vuong`, `zip`, and weights are not allowed with the `svy` prefix; see **[SVY] svy**.

`fweights`, `iweights`, and `pweights` are allowed; see **[U] 11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Count outcomes > Zero-inflated negative binomial regression

Description

`zinb` estimates a zero-inflated negative binomial (ZINB) regression of *depvar* on *indepvars*, where *depvar* is a nonnegative count variable.

Options

Model

`inflate(`*varlist*`[ , offset(`*varname*`)] | _cons)` specifies the equation that determines whether the observed count is zero. Conceptually, omitting `inflate()` would be equivalent to fitting the model with `nbreg`.

`inflate(`*varlist*`[, offset(`*varname*`)])` specifies the variables in the equation. You may optionally include an offset for this *varlist*.

`inflate(_cons)` specifies that the equation determining whether the count is zero contains only an intercept. To run a zero-inflated model of *depvar* with only an intercept in both equations, type `zinb` *depvar*`, inflate(_cons)`.

`noconstant`, `exposure(`*varname*$_e$`)`, `offset(`*varname*$_o$`)`, `constraints(`*constraints*`)`, `collinear`; see [R] **estimation options**.

`probit` requests that a probit, instead of logit, model be used to characterize the excess zeros in the data.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

Reporting

`level(#)`; see [R] **estimation options**.

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is, e^{β_i} rather than β_i. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

`vuong` specifies that the Vuong (1989) test of ZINB versus negative binomial be reported. This test statistic has a standard normal distribution with large positive values favoring the ZINB model and large negative values favoring the negative binomial model.

`zip` requests that a likelihood-ratio test comparing the ZINB model with the zero-inflated Poisson model be included in the output.

`nocnsreport`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] **maximize**. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

The following option is available with zinb but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

See Long (1997, 242–247) and Greene (2012, 821–826) for a discussion of zero-modified count models. For information about the test developed by Vuong (1989), see Greene (2012, 823–824) and Long (1997). Greene (1994) applied the test to zero-inflated Poisson and negative binomial models, and there is a description of that work in Greene (2012).

Negative binomial regression fits models of the number of occurrences (counts) of an event. You could use nbreg for this (see [R] **nbreg**), but in some count-data models, you might want to account for the prevalence of zero counts in the data.

For instance, you could count how many fish each visitor to a park catches. Many visitors may catch zero, because they do not fish (as opposed to being unsuccessful). You may be able to model whether a person fishes depending on several covariates related to fishing activity and model how many fish a person catches depending on several covariates having to do with the success of catching fish (type of lure/bait, time of day, temperature, season, etc.). This is the type of data for which the zinb command is useful.

The zero-inflated (or zero-altered) negative binomial model allows overdispersion through the splitting process that models the outcomes as zero or nonzero.

▷ Example 1

We have data on the number of fish caught by visitors to a national park. Some of the visitors do not fish, but we do not have the data on whether a person fished; we have data merely on how many fish were caught, together with several covariates. Because our data have a preponderance of zeros (142 of 250), we use the zinb command to model the outcome.

```
. use http://www.stata-press.com/data/r13/fish
. zinb count persons livebait, inf(child camper) vuong
Fitting constant-only model:
Iteration 0:   log likelihood = -519.33992
  (output omitted)
Iteration 8:   log likelihood = -442.66299
Fitting full model:
Iteration 0:   log likelihood = -442.66299  (not concave)
  (output omitted)
Iteration 8:   log likelihood = -401.54776
Zero-inflated negative binomial regression        Number of obs   =        250
                                                  Nonzero obs     =        108
                                                  Zero obs        =        142
Inflation model = logit                           LR chi2(2)      =      82.23
Log likelihood  = -401.5478                       Prob > chi2     =     0.0000
```

count	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
count						
persons	.9742984	.1034938	9.41	0.000	.7714543	1.177142
livebait	1.557523	.4124424	3.78	0.000	.7491503	2.365895

Functions

e(sample)	marks estimation sample

Methods and formulas

Several models in the literature are (correctly) described as zero inflated. The `zinb` command maximizes the log likelihood $\ln L$, defined by

$$
\begin{aligned}
m &= 1/\alpha \\
p_j &= 1/(1+\alpha\mu_j) \\
\xi_j^{\beta} &= \mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j^{\beta} \\
\xi_j^{\gamma} &= \mathbf{z}_j\boldsymbol{\gamma} + \text{offset}_j^{\gamma} \\
\mu_j &= \exp(\xi_j^{\beta}) \\
\ln L &= \sum_{j\in S} w_j \ln\left[F(\xi_j^{\gamma}) + \left\{1 - F(\xi_j^{\gamma})\right\}p_j^m\right] \\
&\qquad + \sum_{j\notin S} w_j\Big[\ln\left\{1 - F(\xi_j^{\gamma})\right\} + \ln\Gamma(m+y_j) - \ln\Gamma(y_j+1) \\
&\qquad\qquad - \ln\Gamma(m) + m\ln p_j + y_j\ln(1-p_j)\Big]
\end{aligned}
$$

where w_j are the weights, F is the inverse of the logit link (or the inverse of the probit link if `probit` was specified), and S is the set of observations for which the outcome $y_j = 0$.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`zinb` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **variance estimation**.

Title

zinb postestimation — Postestimation tools for zinb

Description | Syntax for predict | Menu for predict | Options for predict
Methods and formulas | Reference | Also see

Description

The following postestimation commands are available after `zinb`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]

predict [type] {stub* | newvar_reg newvar_inflate newvar_lnalpha} [if] [in], scores
```

statistic	Description
Main	
`n`	number of events; the default
`ir`	incidence rate
`pr`	probability of a degenerate zero
`pr(`*n*`)`	probability $\Pr(y_j = n)$
`pr(`*a*`,`*b*`)`	probability $\Pr(a \leq y_j \leq b)$
`xb`	linear prediction
`stdp`	standard error of the linear prediction

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`n`, the default, calculates the predicted number of events, which is $(1 - p_j)\exp(\mathbf{x}_j\boldsymbol{\beta})$ if neither `offset()` nor `exposure()` was specified when the model was fit, where p_j is the predicted probability of a zero outcome; $(1 - p_j)\exp\{(\mathbf{x}_j\boldsymbol{\beta}) + \text{offset}_j\}$ if `offset()` was specified; or $(1 - p_j)\{\exp(\mathbf{x}_j\boldsymbol{\beta}) \times \text{exposure}_j\}$ if `exposure()` was specified.

`ir` calculates the incidence rate $\exp(\mathbf{x}_j\boldsymbol{\beta})$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the `n` and the `nooffset` options.

`pr` calculates the probability $\Pr(y_j = 0)$, where this zero was obtained from the degenerate distribution $F(\mathbf{z}_j\boldsymbol{\gamma})$. If `offset()` was specified within the `inflate()` option, then $F(\mathbf{z}_j\boldsymbol{\gamma} + \text{offset}_j^{\gamma})$ is calculated.

`pr(`*n*`)` calculates the probability $\Pr(y_j = n)$, where *n* is a nonnegative integer that may be specified as a number or a variable. Note that `pr` is not equivalent to `pr(0)`.

`pr(`*a*`,`*b*`)` calculates the probability $\Pr(a \leq y_j \leq b)$, where *a* and *b* are nonnegative integers that may be specified as numbers or variables;

b missing ($b \geq .$) means $+\infty$;
`pr(20,.)` calculates $\Pr(y_j \geq 20)$;
`pr(20,`*b*`)` calculates $\Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $\Pr(20 \leq y_j \leq b)$ elsewhere.

`pr(.,`*b*`)` produces a syntax error. A missing value in an observation of the variable *a* causes a missing value in that observation for `pr(`*a*`,`*b*`)`.

`xb` calculates the linear prediction, which is $\mathbf{x}_j\boldsymbol{\beta}$ if neither `offset()` nor `exposure()` was specified; $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ if `offset()` was specified; or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$ if `exposure()` was specified; see `nooffset` below.

`stdp` calculates the standard error of the linear prediction.

`nooffset` is relevant only if you specified `offset()` or `exposure()` when you fit the model. It modifies the calculations made by `predict` so that they ignore the offset or exposure variable; the linear prediction is treated as $\mathbf{x}_j\boldsymbol{\beta}$ rather than as $\mathbf{x}_j\boldsymbol{\beta}+\text{offset}_j$ or $\mathbf{x}_j\boldsymbol{\beta}+\ln(\text{exposure}_j)$. Specifying `predict ..., nooffset` is equivalent to specifying `predict ..., ir`.

`scores` calculates equation-level score variables.

The first new variable will contain $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

The second new variable will contain $\partial \ln L/\partial(\mathbf{z}_j\boldsymbol{\gamma})$.

The third new variable will contain $\partial \ln L/\partial \ln\alpha$.

Methods and formulas

The probabilities calculated using the `pr(`n`)` option are the probability $\Pr(y_i = n)$. These are calculated using

$$\Pr(0|\mathbf{x}_i) = \omega_i + (1-\omega_i)\, p_2(0|\mathbf{x}_i)$$

$$\Pr(n|\mathbf{x}_i) = (1-\omega_i)\, p_2(n|\mathbf{x}_i) \qquad \text{for } n = 1, 2, \ldots$$

where ω_i is the probability of obtaining an observation from the degenerate distribution whose mass is concentrated at zero, and $p_2(n|\mathbf{x}_i)$ is the probability of $y_i = n$ from the nondegenerate, negative binomial distribution. ω_i can be obtained from the `pr` option.

See Cameron and Trivedi (2013, sec. 4.6) for further details.

Title

zip — Zero-inflated Poisson regression

Syntax | Menu | Description | Options
Remarks and examples | Stored results | Methods and formulas | References
Also see

Syntax

```
zip depvar [indepvars] [if] [in] [weight] ,
    inflate(varlist[ , offset(varname) ] | _cons) [options]
```

options	Description
Model	
* `inflate( )`	equation that determines whether the count is zero
`noconstant`	suppress constant term
`exposure(`*varname*$_e$`)`	include ln(*varname*$_e$) in model with coefficient constrained to 1
`offset(`*varname*$_o$`)`	include *varname*$_o$ in model with coefficient constrained to 1
`constraints(`*constraints*`)`	apply specified linear constraints
`collinear`	keep collinear variables
`probit`	use probit model to characterize excess zeros; default is logit
SE/Robust	
`vce(`*vcetype*`)`	*vcetype* may be `oim`, `robust`, `cluster` *clustvar*, `opg`, `bootstrap`, or `jackknife`
Reporting	
`level(#)`	set confidence level; default is `level(95)`
`irr`	report incidence-rate ratios
`vuong`	perform Vuong test
`nocnsreport`	do not display constraints
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization	
maximize_options	control the maximization process; seldom used
`coeflegend`	display legend instead of statistics

* `inflate(`*varlist*`[ , offset(`*varname*`) ] | _cons)` is required.

indepvars and *varlist* may contain factor variables; see **[U] 11.4.3 Factor variables**.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see **[U] 11.1.10 Prefix commands**.

Weights are not allowed with the `bootstrap` prefix; see **[R] bootstrap**.

`vce()`, `vuong`, and weights are not allowed with the `svy` prefix; see **[SVY] svy**.

`fweights`, `iweights`, and `pweights` are allowed; see **[U] 11.1.6 weight**.

`coeflegend` does not appear in the dialog box.

See **[U] 20 Estimation and postestimation commands** for more capabilities of estimation commands.

Menu

Statistics > Count outcomes > Zero-inflated Poisson regression

Description

`zip` estimates a zero-inflated Poisson (ZIP) regression of *depvar* on *indepvars*, where *depvar* is a nonnegative count variable.

Options

Model

`inflate(`*varlist*`[ , offset(`*varname*`)] | _cons)` specifies the equation that determines whether the observed count is zero. Conceptually, omitting `inflate()` would be equivalent to fitting the model with `poisson`; see [R] **poisson**.

`inflate(`*varlist*`[, offset(`*varname*`)])` specifies the variables in the equation. You may optionally include an offset for this *varlist*.

`inflate(_cons)` specifies that the equation determining whether the count is zero contains only an intercept. To run a zero-inflated model of *depvar* with only an intercept in both equations, type `zip` *depvar*`, inflate(_cons)`.

`noconstant`, `exposure(`*varname*$_e$`)`, `offset(`*varname*$_o$`)`, `constraints(`*constraints*`)`, `collinear`; see [R] **estimation options**.

`probit` requests that a probit, instead of logit, model be used to characterize the excess zeros in the data.

SE/Robust

`vce(`*vcetype*`)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] ***vce_option***.

Reporting

`level(#)`; see [R] **estimation options**.

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is, e^b rather than b. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

`vuong` specifies that the Vuong (1989) test of ZIP versus Poisson be reported. This test statistic has a standard normal distribution with large positive values favoring the ZIP model and large negative values favoring the Poisson model.

`nocnsreport`; see [R] **estimation options**.

display_options: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(`*style*`)`, `cformat(%`*fmt*`)`, `pformat(%`*fmt*`)`, `sformat(%`*fmt*`)`, and `nolstretch`; see [R] **estimation options**.

Maximization

maximize_options: difficult, technique(*algorithm_spec*), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(*init_specs*); see [R] **maximize**. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

The following option is available with zip but is not shown in the dialog box:

coeflegend; see [R] **estimation options**.

Remarks and examples

See Long (1997, 242–247) and Greene (2012, 821–826) for a discussion of zero-modified count models. For information about the test developed by Vuong (1989), see Greene (2012, 823–824) and Long (1997). Greene (1994) applied the test to ZIP and ZINB models, as described in Greene (2012, 824).

Poisson regression fits models of the number of occurrences (counts) of an event. You could use poisson for this (see [R] **poisson**), but in some count-data models, you might want to account for the prevalence of zero counts in the data.

For instance, you might count how many fish each visitor to a park catches. Many visitors may catch zero, because they do not fish (as opposed to being unsuccessful). You may be able to model whether a person fishes depending on several covariates related to fishing activity and model how many fish a person catches depending on several covariates having to do with the success of catching fish (type of lure/bait, time of day, temperature, season, etc.). This is the type of data for which the zip command is useful.

The zero-inflated (or zero-altered) Poisson model allows overdispersion through the splitting process that models the outcomes as zero or nonzero.

▷ Example 1

We have data on the number of fish caught by visitors to a national park. Some of the visitors do not fish, but we do not have the data on whether a person fished; we merely have data on how many fish were caught together with several covariates. Because our data have a preponderance of zeros (142 of 250), we use the zip command to model the outcome.

```
. use http://www.stata-press.com/data/r13/fish
. zip count persons livebait, inf(child camper) vuong
Fitting constant-only model:
Iteration 0:   log likelihood =  -1347.807
  (output omitted)

e(offset2)	offset for inflate()
e(chi2type)	Wald or LR; type of model χ^2 test
e(vce)	*vcetype* specified in vce()
e(vcetype)	title used to label Std. Err.
e(opt)	type of optimization
e(which)	max or min; whether optimizer is to perform maximization or minimization
e(ml_method)	type of ml method
e(user)	name of likelihood-evaluator program
e(technique)	maximization technique
e(properties)	b V
e(predict)	program used to implement predict
e(asbalanced)	factor variables fvset as asbalanced
e(asobserved)	factor variables fvset as asobserved

Matrices

e(b)	coefficient vector
e(Cns)	constraints matrix
e(ilog)	iteration log (up to 20 iterations)
e(gradient)	gradient vector
e(V)	variance–covariance matrix of the estimators
e(V_modelbased)	model-based variance

Functions

e(sample)	marks estimation sample

Methods and formulas

Several models in the literature are (correctly) described as zero inflated. The `zip` command maximizes the log-likelihood $\ln L$, defined by

$$\begin{aligned}
\xi_j^{\beta} &= \mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j^{\beta} \\
\xi_j^{\gamma} &= \mathbf{z}_j\boldsymbol{\gamma} + \text{offset}_j^{\gamma} \\
\ln L &= \sum_{j\in S} w_j \ln\left[F(\xi_j^{\gamma}) + \left\{1 - F(\xi_j^{\gamma})\right\}\exp(-\lambda_j)\right] + \\
&\qquad \sum_{j\notin S} w_j\left[\ln\left\{1 - F(\xi_j^{\gamma})\right\} - \lambda_j + \xi_j^{\beta} y_j - \ln(y_j!)\right]
\end{aligned}$$

where w_j are the weights, F is the inverse of the logit link (or the inverse of the probit link if `probit` was specified), and S is the set of observations for which the outcome $y_j = 0$.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster` *clustvar*`)`, respectively. See [P] **_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`zip` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **variance estimation**.

Title

zip postestimation — Postestimation tools for zip

Description | Syntax for predict | Menu for predict | Options for predict
Remarks and examples | Methods and formulas | Reference | Also see

Description

The following postestimation commands are available after `zip`:

Command	Description
`contrast`	contrasts and ANOVA-style joint tests of estimates
`estat ic`	Akaike's and Schwarz's Bayesian information criteria (AIC and BIC)
`estat summarize`	summary statistics for the estimation sample
`estat vce`	variance–covariance matrix of the estimators (VCE)
`estat (svy)`	postestimation statistics for survey data
`estimates`	cataloging estimation results
`forecast`[1]	dynamic forecasts and simulations
`lincom`	point estimates, standard errors, testing, and inference for linear combinations of coefficients
`lrtest`[2]	likelihood-ratio test
`margins`	marginal means, predictive margins, marginal effects, and average marginal effects
`marginsplot`	graph the results from margins (profile plots, interaction plots, etc.)
`nlcom`	point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients
`predict`	predictions, residuals, influence statistics, and other diagnostic measures
`predictnl`	point estimates, standard errors, testing, and inference for generalized predictions
`pwcompare`	pairwise comparisons of estimates
`suest`	seemingly unrelated estimation
`test`	Wald tests of simple and composite linear hypotheses
`testnl`	Wald tests of nonlinear hypotheses

[1] `forecast` is not appropriate with `svy` estimation results.

[2] `lrtest` is not appropriate with `svy` estimation results.

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]

predict [type] {stub* | newvar_reg newvar_inflate} [if] [in], scores
```

statistic	Description
Main	
`n`	number of events; the default
`ir`	incidence rate
`pr`	probability of a degenerate zero
`pr(`*n*`)`	probability $\Pr(y_j = n)$
`pr(`*a*`,`*b*`)`	probability $\Pr(a \leq y_j \leq b)$
`xb`	linear prediction
`stdp`	standard error of the linear prediction

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

`n`, the default, calculates the predicted number of events, which is $(1 - p_j)\exp(\mathbf{x}_j\boldsymbol{\beta})$ if neither `offset()` nor `exposure()` was specified when the model was fit, where p_j is the predicted probability of a zero outcome; $(1 - p_j)\exp\{(\mathbf{x}_j\boldsymbol{\beta}) + \text{offset}_j\}$ if `offset()` was specified; or $(1 - p_j)\{\exp(\mathbf{x}_j\boldsymbol{\beta}) \times \text{exposure}_j\}$ if `exposure()` was specified.

`ir` calculates the incidence rate $\exp(\mathbf{x}_j\boldsymbol{\beta})$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the `n` and the `nooffset` options.

`pr` calculates the probability $\Pr(y_j = 0)$, where this zero was obtained from the degenerate distribution $F(\mathbf{z}_j\boldsymbol{\gamma})$. If `offset()` was specified within the `inflate()` option, then $F(\mathbf{z}_j\boldsymbol{\gamma} + \text{offset}_j^{\gamma})$ is calculated.

`pr(`*n*`)` calculates the probability $\Pr(y_j = n)$, where *n* is a nonnegative integer that may be specified as a number or a variable. Note that `pr` is not equivalent to `pr(0)`.

`pr(`*a*`,`*b*`)` calculates the probability $\Pr(a \leq y_j \leq b)$, where *a* and *b* are nonnegative integers that may be specified as numbers or variables;

b missing ($b \geq .$) means $+\infty$;
`pr(20,.)` calculates $\Pr(y_j \geq 20)$;
`pr(20,`*b*`)` calculates $\Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $\Pr(20 \leq y_j \leq b)$ elsewhere.

`pr(.,`*b*`)` produces a syntax error. A missing value in an observation of the variable *a* causes a missing value in that observation for `pr(`*a*`,`*b*`)`.

`xb` calculates the linear prediction, which is $\mathbf{x}_j\boldsymbol{\beta}$ if neither `offset()` nor `exposure()` was specified; $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ if `offset()` was specified; or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$ if `exposure()` was specified; see `nooffset` below.

`stdp` calculates the standard error of the linear prediction.

`nooffset` is relevant only if you specified `offset()` or `exposure()` when you fit the model. It modifies the calculations made by `predict` so that they ignore the offset or exposure variable; the linear prediction is treated as $\mathbf{x}_j\boldsymbol{\beta}$ rather than as $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ or $\mathbf{x}_j\boldsymbol{\beta} + \ln(\text{exposure}_j)$. Specifying `predict ..., nooffset` is equivalent to specifying `predict ..., ir`.

`scores` calculates equation-level score variables.

The first new variable will contain $\partial \ln L/\partial(\mathbf{x}_j\boldsymbol{\beta})$.

The second new variable will contain $\partial \ln L/\partial(\mathbf{z}_j\boldsymbol{\gamma})$.

Remarks and examples

▷ Example 1

Continuing with example 1 from [R] **zip**, we will use `predict` to compute the predicted number of fish captured by each individual.

```
. use http://www.stata-press.com/data/r13/fish
. zip count persons livebait, inf(child camper) vuong
  (output omitted)
. predict numfished
(option n assumed; predicted number of events)
```

`predict` with the `pr` option computes the probability that an individual does not fish.

```
. predict pr, pr
```

On the other hand, `predict` with the `pr(`*n*`)` option computes the probability of catching *n* fish; particularly, the probability of catching zero fish will be

```
. predict pr0, pr(0)
. list pr pr0 in 1
```

	pr	pr0
1.	.3793549	.8609267

Notice that `pr0` is always equal to or greater than `pr`. For example, for the first individual, the probability of not fishing is 0.38; on the other hand, the probability of catching zero fish (0.86) is equal to the sum of the probability of not fishing and the probability of fishing but not catching any fish. `pr0` can be also computed as one minus the probability of catching at least one fish, that is:

```
. predict pr_catch, pr(1,.)
. gen pr0b = 1-pr_catch
```

◁

Methods and formulas

The probabilities calculated using the `pr(`*n*`)` option are the probability $\Pr(y_i = n)$. These are calculated using

$$\Pr(0|\mathbf{x}_i) = \omega_i + (1 - \omega_i)\,\exp(-\lambda_i)$$

$$\Pr(n|\mathbf{x}_i) = (1 - \omega_i)\frac{\lambda_i^n \exp(-\lambda_i)}{n!} \qquad \text{for } n = 1, 2, \ldots$$

where ω_i is the probability of obtaining an observation from the degenerate distribution whose mass is concentrated at zero. ω_i can be obtained from the `pr` option.

See Cameron and Trivedi (2013, sec. 4.6) for further details.

Subject index

This is the subject index for the *Base Reference Manual*. Readers may also want to consult the combined subject index (and the combined author index) in the *Glossary and Index*.

A

`about` command, [R] **about**
absorption in regression, [R] **areg**
`acprplot` command, [R] **regress postestimation diagnostic plots**
added-variable plots, [R] **regress postestimation diagnostic plots**
adjusted
  margins, [R] **margins**, [R] **marginsplot**
  means, [R] **contrast**, [R] **margins**, [R] **marginsplot**
  partial residual plot, [R] **regress postestimation diagnostic plots**
`ado` command, [R] **net**
`ado describe` command, [R] **net**
`ado dir` command, [R] **net**
`ado uninstall` command, [R] **net**
`ado`, `view` subcommand, [R] **view**
`ado_d`, `view` subcommand, [R] **view**
ado-files,
  editing, [R] **doedit**
  installing, [R] **net**, [R] **sj**, [R] **ssc**
  location of, [R] **which**
  official, [R] **update**
  searching for, [R] **search**, [R] **ssc**
  updating user-written, [R] **adoupdate**
`adosize`, `set` subcommand, [R] **set**
`adoupdate` command, [R] **adoupdate**
agreement, interrater, [R] **kappa**
AIC, *see* Akaike information criterion
Akaike information criterion, [R] **BIC note**, [R] **estat**, [R] **estat ic**, [R] **estimates stats**, [R] **glm**, [R] **lrtest**
`all`, `update` subcommand, [R] **update**
alternative-specific
  conditional logit (McFadden's choice) model, [R] **asclogit**
  multinomial probit regression, [R] **asmprobit**
  rank-ordered probit regression, [R] **asroprobit**
`alternatives`, `estat` subcommand, [R] **asclogit postestimation**, [R] **asmprobit postestimation**, [R] **asroprobit postestimation**, [R] **nlogit postestimation**
`ameans` command, [R] **ameans**
analysis of covariance, [R] **anova**
analysis of variance, [R] **anova**, [R] **contrast**, [R] **icc**, [R] **loneway**, [R] **oneway**
  Kruskal–Wallis, [R] **kwallis**
  plots, [R] **marginsplot**
  repeated measures, [R] **anova**
analysis-of-variance test of normality, [R] **swilk**
ANCOVA, *see* analysis of covariance
ANOVA, *see* analysis of variance
`anova` command, [R] **anova**, [R] **anova postestimation**
ARCH effects, testing for, [R] **regress postestimation time series**
`archlm`, `estat` subcommand, [R] **regress postestimation time series**
area under the curve, [R] **lroc**, *also see* pharmacokinetic data, *also see* receiver operating characteristic analysis
`areg` command, [R] **areg**, [R] **areg postestimation**
`asclogit` command, [R] **asclogit**, [R] **asclogit postestimation**
`asmprobit` command, [R] **asmprobit**, [R] **asmprobit postestimation**
`asroprobit` command, [R] **asroprobit**, [R] **asroprobit postestimation**
association test, [R] **correlate**, [R] **spearman**, [R] **tabulate twoway**, [R] **tetrachoric**
association, measures of, [R] **tabulate twoway**
asymmetry, *see* skewness
AUC, *also see* area under the curve
augmented
  component-plus-residual plot, [R] **regress postestimation diagnostic plots**
  partial residual plot, [R] **regress postestimation diagnostic plots**
autocorrelation, [R] **regress postestimation time series**, *also see* HAC variance estimate
autoregressive conditional heteroskedasticity test, [R] **regress postestimation time series**
`autotabgraphs`, `set` subcommand, [R] **set**
average
  marginal effects, [R] **margins**, [R] **marginsplot**
  partial effects (APEs), [R] **margins**, [R] **marginsplot**
  predictions, [R] **margins**, [R] **marginsplot**
averages, *see* means
`avplot` and `avplots` commands, [R] **regress postestimation diagnostic plots**

B

backed up message, [R] **maximize**
Bartlett's test for equal variances, [R] **oneway**
`base`, `fvset` subcommand, [R] **fvset**
Bayesian information criterion, [R] **BIC note**, [R] **estat**, [R] **estat ic**, [R] **estimates stats**, [R] **glm**, [R] **lrtest**
`bcskew0` command, [R] **lnskew0**
Berndt–Hall–Hall–Hausman algorithm, [R] **ml**
beta coefficients, [R] **regress**
BFGS algorithm, *see* Broyden–Fletcher–Goldfarb–Shanno algorithm
`bgodfrey`, `estat` subcommand, [R] **regress postestimation time series**
BHHH algorithm, *see* Berndt–Hall–Hall–Hausman algorithm
bias corrected and accelerated, [R] **bootstrap postestimation**, [R] **bstat**

BIC, *see* Bayesian information criterion
Bickenböller test statistic, [R] **symmetry**
binary outcome model, *see* outcomes, binary
binomial
  distribution, confidence intervals, [R] **ci**
  family regression, [R] **binreg**
  probability test, [R] **bitest**
`binreg` command, [R] **binreg**, [R] **binreg postestimation**
bioequivalence test, [R] **pk**, [R] **pkequiv**
biopharmaceutical data, *see* pharmacokinetic data
`biprobit` command, [R] **biprobit**, [R] **biprobit postestimation**
`bitest` and `bitesti` commands, [R] **bitest**
bivariate probit regression, [R] **biprobit**
biweight kernel function, [R] **kdensity**, [R] **lpoly**, [R] **qreg**
biweight regression estimates, [R] **rreg**
`blogit` command, [R] **glogit**, [R] **glogit postestimation**
Bonferroni's multiple-comparison adjustment, *see* multiple comparisons, Bonferroni's method
bootstrap
  sampling and estimation, [R] **bootstrap**, [R] **bsample**, [R] **bstat**, [R] **qreg**, [R] **rocreg**, [R] **simulate**
  standard errors, [R] ***vce_option***
`bootstrap` prefix command, [R] **bootstrap**, [R] **bootstrap postestimation**
`bootstrap`, `estat` subcommand, [R] **bootstrap postestimation**
Boston College archive, *see* Statistical Software Components archive
Box–Cox
  power transformations, [R] **lnskew0**
  regression, [R] **boxcox**
`boxcox` command, [R] **boxcox**, [R] **boxcox postestimation**
Box's conservative epsilon, [R] **anova**
`bprobit` command, [R] **glogit**, [R] **glogit postestimation**
Breusch–Godfrey test, [R] **regress postestimation time series**
Breusch–Pagan test, [R] **sureg**
Breusch–Pagan/Cook–Weisberg test for heteroskedasticity, [R] **regress postestimation**
`brier` command, [R] **brier**
Brier score decomposition, [R] **brier**
`browse`, `view` subcommand, [R] **view**
Broyden–Fletcher–Goldfarb–Shanno algorithm, [R] **ml**
`bsample` command, [R] **bsample**
`bsqreg` command, [R] **qreg**, [R] **qreg postestimation**
`bstat` command, [R] **bstat**

C

`c(cformat)` c-class value, [R] **set cformat**
`c(pformat)` c-class value, [R] **set cformat**
`c(seed)` c-class value, [R] **set emptycells**, [R] **set seed**
`c(sformat)` c-class value, [R] **set cformat**
`c(showbaselevels)` c-class value, [R] **set showbaselevels**
`c(showemptycells)` c-class value, [R] **set showbaselevels**
`c(showomitted)` c-class value, [R] **set showbaselevels**
calculator, [R] **display**
carryover effects, [R] **pk**, [R] **pkcross**, [R] **pkshape**
case–control data, [R] **clogit**, [R] **logistic**, [R] **rocreg**, [R] **symmetry**
categorical, *also see* factor variables
  contrasts after anova, [R] **contrast**
  covariates, [R] **anova**
  data, agreement, measures for, [R] **kappa**
  graphs, [R] **grmeanby**, [R] **spikeplot**
  outcomes, *see* outcomes, categorical, *also see* outcomes, binary, *also see* outcomes, ordinal
  regression, *also see* outcomes subentry
    absorbing one categorical variable, [R] **areg**
  tabulations, [R] **table**, [R] **tabstat**, [R] **tabulate oneway**, [R] **tabulate twoway**, [R] **tabulate, summarize()**
  variable creation, [R] **tabulate oneway**, [R] **xi**
`cchart` command, [R] **qc**
`cd`, `net` subcommand, [R] **net**
censored observations, [R] **heckman**, [R] **heckoprobit**, [R] **heckprobit**, [R] **intreg**, [R] **ivtobit**, [R] **tobit**, *also see* truncated observations
censored-normal regression, *see* interval regression
`centile` command, [R] **centile**
centiles, *see* percentiles, displaying
central tendency, measures of, *see* means, *see* medians
`cformat`, `set` subcommand, [R] **set**, [R] **set cformat**
`charset`, `set` subcommand, [R] **set**
`check`, `ml` subcommand, [R] **ml**
`checksum`, `set` subcommand, [R] **set**
chi-squared
  hypothesis test, [R] **hausman**, [R] **lrtest**, [R] **sdtest**, [R] **tabulate twoway**, [R] **test**, [R] **testnl**
  probability plot, [R] **diagnostic plots**
  quantile plot, [R] **diagnostic plots**
  test for marginal homogeneity, [R] **symmetry**
  test of independence, [R] **tabulate twoway**

vif, estat subcommand, [R] regress postestimation
Vuong test, [R] zinb, [R] zip
vwls command, [R] vwls, [R] vwls postestimation

W

Wald test, [R] **contrast**, [R] **predictnl**, [R] **test**, [R] **testnl**
weak instrument test, [R] **ivregress postestimation**
weighted least squares, [R] **regress**
  for grouped data, [R] **glogit**
  generalized linear models, [R] **glm**
  generalized method of moments estimation, [R] **gmm**, [R] **ivpoisson**
  instrumental-variables regression, [R] **gmm**, [R] **ivregress**
  nonlinear least-squares estimation, [R] **nl**
  nonlinear systems of equations, [R] **nlsur**
  variance, [R] **vwls**
Welsch distance, [R] **regress postestimation**
`which` command, [R] **which**
White/Huber/sandwich estimator of variance, *see* robust, Huber/White/sandwich estimator of variance
White's test for heteroskedasticity, [R] **regress postestimation**
Wilcoxon
  rank-sum test, [R] **ranksum**
  signed-ranks test, [R] **signrank**

X

`xchart` command, [R] **qc**
`xi` prefix command, [R] **xi**

Z

Zellner's seemingly unrelated regression, [R] **sureg**, [R] **reg3**, [R] **suest**
zero-altered, *see* zero-inflated
zero-inflated
  negative binomial regression, [R] **zinb**
  Poisson regression, [R] **zip**
zero-skewness transform, [R] **lnskew0**
`zinb` command, [R] **zinb**, [R] **zinb postestimation**
`zip` command, [R] **zip**, [R] **zip postestimation**
