Matthew MacDonald

Answers found here!

HTML5 is more than a markup language—it's a dozen independent web standards all rolled into one. Until now, all it's been missing is a manual. With this thorough, jargon-free guide, you'll learn how to build web apps that include video tools, dynamic drawings, geolocation, offline web apps, drag-and-drop, and many other features. HTML5 is the future of the Web, and this book will get you there.

the missing manual®

The book that should have been in the box®

The important stuff you need to know

- **Structure web pages in a new way.** Learn how HTML5 makes web design tools and search engines work smarter.
- **Add audio and video without plugins.** Build playback pages that work in every browser.
- **Draw with Canvas.** Create shapes, pictures, text, and animation—and make them interactive.
- **Go a long way with style.** Use CSS3 and HTML5 to jazz up your pages and adapt them for mobile devices.
- **Build web apps with rich desktop features.** Let users work with your app offline, and process user-selected files in the browser.
- **Create location-aware apps.** Write geolocation applications directly in the browser.

Matthew MacDonald, an author and educator with a passion for emerging technologies, writes for developer journals such as *Inside Visual Basic* and *ASPToday*. He's also written several Missing Manuals, including *Creating a Website: The Missing Manual*, *Your Brain: The Missing Manual*, and *Excel 2010: The Missing Manual*.

Table of Contents

The Missing Credits	xi
--------------------------------------	-----------

Introduction	1
-------------------------------	----------

Part One: Meet the New Language

Chapter 1: Introducing HTML5.	11
--	-----------

The Story of HTML5	11
XHTML 1.0: Getting Strict.	12
XHTML 2: The Unexpected Failure.	12
HTML5: Back From the Dead.	13
HTML: The Living Language	14
Three Key Principles of HTML5.	15
1. Don't Break the Web.	15
2. Pave the Cowpaths.	17
3. Be Practical.	17
Your First Look at HTML5 Markup	18
The HTML5 Doctype	20
Character Encoding.	21
The Language.	21
Adding a Style Sheet	22
Adding JavaScript.	22
The Final Product.	23
A Closer Look at HTML5 Syntax	24
The Loosened Rules	24
HTML5 Validation.	25
The Return of XHTML.	27

HTML5's Element Family	29
Added Elements	29
Removed Elements	30
Adapted Elements	30
Tweaked Elements	32
Standardized Elements	33
Using HTML5 Today.	34
Evaluating Browser Support	34
Browser Adoption Statistics	36
Feature Detection with Modernizr	38
Feature "Filling" with Polyfills	40
Chapter 2: A New Way to Structure Pages	43
Introducing the Semantic Elements	44
Retrofitting a Traditional HTML Page	45
Page Structure the Old Way	47
Page Structure with HTML5	49
Subtitles with <hgroup>	52
Adding a Figure with <figure>	53
Adding a Sidebar with <aside>	56
Browser Compatibility for the Semantic Elements	57
Designing a Site with the Semantic Elements	60
Deeper into Headers	61
Navigation Links with <nav>	62
Deeper into Footers	67
Deeper into Sections	69
The HTML5 Outlining System	70
How to View an Outline	70
Basic Outlines	71
Sectioning Elements	73
Solving an Outline Problem	76
Chapter 3: Meaningful Markup	81
The Semantic Elements Revisited	82
Dates and Times with <time>	83
JavaScript Calculations with <output>	84
Highlighted Text with <mark>	86
Other Standards that Boost Semantics	87
ARIA (Accessible Rich Internet Applications)	88
RDFa (Resource Description Framework)	89
Microformats	89
Microdata	95
Google Rich Snippets	97
Enhanced Search Results	98
The Recipe Search Engine	101

Part Two: Creating Modern Web Pages

Chapter 4: Web Forms, Refined 107

Understanding Forms	108
Revamping a Traditional HTML Form	109
Adding Hints with Placeholders	113
Focus: Starting in the Right Spot	115
Validation: Stopping Errors	116
How HTML5 Validation Works	116
Turning Validation Off	118
Validation Styling Hooks	119
Validating with Regular Expressions	120
Custom Validation	121
Browser Support for Validation	123
New Types of Input	125
Email Addresses	128
URLs	128
Search Boxes	128
Telephone Numbers	129
Numbers	129
Sliders	130
Dates and Times	131
Colors	132
New Elements	132
Input Suggestions with <datalist>	133
Progress Bars and Meters	135
Toolbars and Menus with <command> and <menu>	138
An HTML Editor in a Web Page	138
Using contentEditable to Edit an Element	138
Using designMode to Edit a Page	141

Chapter 5: Audio and Video 143

Understanding Video Today	144
Introducing HTML5 Audio and Video	145
Making Some Noise with <audio>	145
Getting the Big Picture with <video>	148
Format Wars and Fallbacks	149
Meet the Formats	150
Browser Support for Media Formats	152
Multiple Formats: How to Please Every Browser	154
The <source> Element	154
The Flash Fallback	155
Controlling Your Player with JavaScript	160
Adding Sound Effects	160
Creating a Custom Video Player	163
JavaScript Media Players	166
Captions and Accessibility	168

Chapter 6: Basic Drawing with the Canvas	171
Getting Started with the Canvas	172
Straight Lines	174
Paths and Shapes	177
Curved Lines	179
Transforms	182
Transparency	185
Building a Basic Paint Program	188
Preparing to Draw	189
Drawing on the Canvas	190
Saving the Picture in the Canvas	192
Browser Compatibility for the Canvas	195
Polyfilling the Canvas	196
The Canvas Fallback and Feature Detection	197
 Chapter 7: Deeper into the Canvas	 199
Other Things You Can Draw on the Canvas	200
Drawing Images	200
Slicing, Dicing, and Resizing an Image	202
Drawing Text	203
Shadows and Fancy Fills	205
Adding Shadows	205
Filling Shapes with Patterns	207
Filling Shapes with Gradients	208
Putting It Together: Drawing a Graph	211
Making Your Shapes Interactive	216
Keeping Track of What You've Drawn	217
Hit Testing with Coordinates	220
Animating the Canvas	222
A Basic Animation	223
Animating Multiple Objects	224
A Practical Example: the Maze Game	229
Setting Up the Maze	229
Animating the Face	232
Hit Testing with Pixel Colors	234
 Chapter 8: Boosting Styles with CSS3	 237
Using CSS3 Today	238
Strategy 1: Use What You Can	238
Strategy 2: Treat CSS3 Features as Enhancements	238
Strategy 3: Add Fallbacks with Modernizr	240
Browser-Specific Styles	243

Web Typography	244
Web Font Formats	245
Using a Font Kit.	247
Using Google Web Fonts	250
Using Your Own Fonts	252
Putting Text in Multiple Columns.	253
Adapting to Different Devices.	255
Media Queries	256
More Advanced Media Queries	259
Replacing an Entire Style Sheet	261
Recognizing Mobile Devices	261
Building Better Boxes	263
Transparency	263
Rounded Corners.	265
Backgrounds	266
Shadows	268
Gradients	269
Creating Effects with Transitions	271
A Basic Color Transition	272
More Transition Ideas	274
Transforms	274

Part Three: Building Web Apps with Desktop Smarts

Chapter 9: Data Storage. 281

Web Storage Basics	282
Storing Data	283
A Practical Example: Storing the Last Position in a Game	285
Browser Support for Web Storage.	287
Deeper into Web Storage.	288
Removing Items	288
Finding All the Stored Items	288
Storing Numbers and Dates	289
Storing Objects	290
Reacting to Storage Changes.	292
Reading Files	294
Getting Hold of a File.	295
Browser Support for the File API.	295
Reading a Text File	296
Replacing the Standard Upload Control	298
Reading Multiple Files at Once.	298
Reading an Image File	299

Chapter 10: Offline Applications	303
Caching Files with a Manifest	304
Creating a Manifest	305
Using Your Manifest	307
Putting Your Manifest on a Web Server	308
Updating the Manifest File	310
Browser Support for Offline Applications	312
Practical Caching Techniques	314
Accessing Uncached Files	314
Adding Fallbacks	315
Checking the Connection	317
Pointing Out Updates with JavaScript	318
Chapter 11: Communicating with the Web Server	323
Sending Messages to the Web Server	324
The XMLHttpRequest Object	325
Asking the Web Server a Question	325
Getting New Content	330
Server-Sent Events	333
The Message Format	334
Sending Messages with a Server Script	335
Processing Messages in a Web Page	337
Polling with Server-Side Events	339
Web Sockets	340
Assessing Web Sockets	341
A Simple Web Socket Client	343
Web Socket Examples on the Web	344
Chapter 12: More Cool JavaScript Tricks	347
Geolocation	348
How Geolocation Works	349
Finding a Visitor's Coordinates	351
Dealing with Errors	353
Setting Geolocation Options	355
Showing a Map	356
Monitoring a Visitor's Moves	360
Web Workers	360
A Time-Consuming Task	362
Doing Work in the Background	364
Handling Worker Errors	367
Canceling a Background Task	367
Passing More Complex Messages	368

History Management	371
The URL Problem.	372
The Traditional Solution: Hashbang URLs	373
The HTML5 Solution: Session History	374
Browser Compatibility for Session History.	377
 <i>Part Four: Appendixes</i>	
Appendix A: A Very Short Introduction to CSS	381
Appendix B: A Very Short Introduction to JavaScript	397
 Index	 419

The Missing Credits

About the Author

Matthew MacDonald is a science and technology writer with well over a dozen books to his name. Web novices can tiptoe out onto the Internet with him in *Creating a Website: The Missing Manual*. Office geeks can crunch the numbers in *Excel 2010: The Missing Manual*. And human beings of all description can discover just how strange they really are in the quirky handbooks *Your Brain: The Missing Manual* and *Your Body: The Missing Manual*.

About the Creative Team

Nan Barber (editor) has been working on the Missing Manual series since its inception. She lives in Massachusetts with her husband and various Apple products. Email: nanbarber@oreilly.com.

Adam Zaremba (production editor) has a master's degree from the Editorial Institute at Boston University. He lives in Chestnut Hill, Mass., and his favorite color is yellow...no, blue!

Shelley Powers (technical reviewer) is a former HTML5 working group member and author of several O'Reilly books. She is also an animal welfare advocate, working to close down puppy mills in Missouri. Website: <http://burningbird.net>.

Steve Suehring (Tech Reviewer) is a technical architect with an extensive background finding simple solutions to complex problems. Steve plays several musical instruments (not at the same time) and can be reached through his web site <http://www.braingia.org>.

Julie Van Keuren (proofreader) is a freelance editor and desktop publisher who runs her “little media empire” from her home in Billings, Montana. In her spare time, she enjoys swimming, biking, running, and (hey, why not?) triathlon. Email: little_media@yahoo.com.

Denise Getz (indexer) is a full-time freelance indexer, specializing in IT, health, and religious studies. Her current extracurricular passions include photography, Qigong, and raw foods cuisine. Website: www.access-indexing.com.

Acknowledgments

No author could complete a book without a small army of helpful individuals. I’m deeply indebted to the whole Missing Manual team, especially my editor, Nan Barber, who never seemed fazed by the shifting sands of HTML5; and expert tech reviewers Shelley Powers and Steve Suehring, who helped spot rogue errors and offered consistently good advice. And, as always, I’m also deeply indebted to numerous others who’ve toiled behind the scenes indexing pages, drawing figures, and proofreading the final copy.

Finally, for the parts of my life that exist outside this book, I’d like to thank all my family members. They include my parents, Nora and Paul; my extended parents, Razia and Hamid; my wife Faria; and my daughters, Maya and Brenna. Thanks, everyone!

—Matthew MacDonald

The Missing Manual Series

Missing Manuals are witty, superbly written guides to computer products that don’t come with printed manuals (which is just about all of them). Each book features a handcrafted index; cross-references to specific pages (not just chapters); and Rep-Kover, a detached-spine binding that lets the book lie perfectly flat without the assistance of weights or cinder blocks.

Recent and upcoming titles include:

Your Money: The Missing Manual by J.D. Roth

Introduction

At first glance, you might assume that HTML5 is the fifth version of the HTML web-page-writing language. But the real story is a whole lot messier.

HTML5 is a rebel. It was dreamt up by a loose group of freethinkers who weren't in charge of the official HTML standard. It allows page-writing practices that were banned a decade ago. It spends thousands of words painstakingly telling browser makers how to deal with markup mistakes, rather than rejecting them outright. It finally makes video playback possible without a browser plug-in like Flash. And it introduces an avalanche of JavaScript-fueled features that can give web pages some of the rich, interactive capabilities of desktop software.

Understanding HTML5 is no small feat. The most significant challenge is that people use the word *HTML5* to refer to a dozen or more separate standards. (As you'll learn, this problem is the result of HTML5's evolution. It began as a single standard and was later broken into more manageable pieces.) In fact, HTML5 has come to mean "HTML5 and all its related standards" and, even more broadly, "the next generation of web-page-writing technologies." That's the version of HTML5 that you'll explore in this book: everything from the HTML5 core language to a few new features are lumped in with HTML5 even though they were *never* a part of the standard.

This brings you to the second challenge of HTML5: browser support. Different browsers support different parts of HTML5, and there are some painfully new features that still don't work in any browser, anywhere.

Despite these difficulties, there's one fact that no one challenges: *HTML5 is the future*. Huge software companies like Apple and Google have lent it support; the W3C (World Wide Web Consortium) has given up its work on XHTML to formalize and endorse it; and every browser maker now supports a significant part of it. And if you read this book, you too can join the HTML5 party while it's still fun and exciting, and create cool pages like the one shown in Figure I-1.

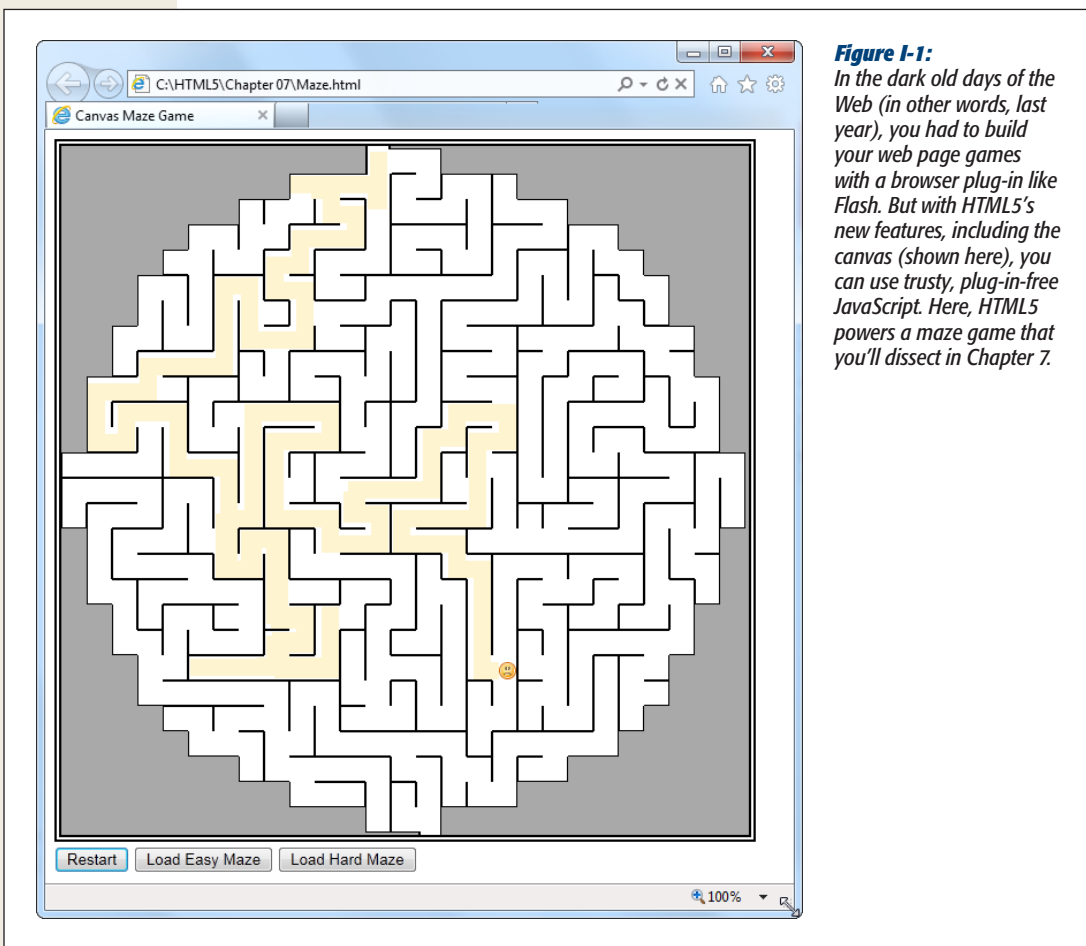

Figure I-1:

In the dark old days of the Web (in other words, last year), you had to build your web page games with a browser plug-in like Flash. But with HTML5's new features, including the canvas (shown here), you can use trusty, plug-in-free JavaScript. Here, HTML5 powers a maze game that you'll dissect in Chapter 7.

What You Need to Get Started

This book covers HTML5, the latest and greatest version of the HTML standard. And while you don't need to be a markup master to read it, you *do* need some previous web design experience. Here's the official rundown:

- **Web page writing.** This book assumes you've written at least a few web pages before (or at the very least, you understand how to use HTML elements to structure content into headings, paragraphs, and lists). If you're new to web design,

you're better off with a gentler introduction, like my own *Creating a Website: The Missing Manual*. (But don't worry, you won't be trapped in the past, as all the examples in *Creating a Website* are valid HTML5 documents.)

- **Style sheet experience.** No modern website is possible without CSS (the Cascading Style Sheet standard), which supplies the layout and formatting for web pages. To follow along in this book, you should know the basics of style sheets—how to create them, what goes inside, and how to attach one to a page. If you're a bit hazy on the subject, you can catch up in Appendix A (“A Very Short Introduction to CSS”). But if you need more help, or if you just want to sharpen your CSS skills to make truly cool layouts and styles, check out a supplementary book like *CSS: The Missing Manual* by David Sawyer McFarland (O'Reilly).
- **JavaScript experience.** No, you don't need JavaScript to create an HTML5 page. However, you do need JavaScript if you want to use many of HTML5's slickest features, like drawing on a canvas or talking to a web server. If you have a smattering of programming experience but don't know much about JavaScript, then Appendix B (“A Very Short Introduction to JavaScript”) can help you get up to speed. But if the idea of writing code sounds about as comfortable as crawling into bed with an escaped python, then you'll either end up skipping a lot of material in this book, or you'll need to fill in the gaps with a supplementary book like *JavaScript & jQuery: The Missing Manual* by David Sawyer McFarland (O'Reilly).

If these requirements made your head spin a bit—well, that's the cost of living on the bleeding edge of web design.

Writing HTML5

You can write HTML5 pages using the same software you use to write HTML pages. That can be as simple as a lowly text editor, like Notepad (on Windows) or TextEdit (on Mac). Many current design tools (like Adobe Dreamweaver and Microsoft Expression Web) have templates that let you quickly create new HTML5 documents. However, the basic structure of an HTML5 page is so simple that you can use any web editor to create one, even if your web editor wasn't specifically designed for HTML5.

Note: And of course, it doesn't matter whether you do your surfing and web page creation on a Windows PC or the latest MacBook—HTML5 supports operating systems of all stripes.

Viewing HTML5

The question everyone likes to ask is, “Which browsers support HTML5?” Sadly, it's a question with no clear-cut answer. As you'll discover in this book, HTML5 is really a collection of independent standards. Some of it is already supported; some of it

won't be supported for several years (and may never be). All the rest falls somewhere in the middle—which means that HTML5 works in some versions of some browsers.

Here are some browsers that support some significant portion of HTML5 without requiring workarounds:

- Internet Explorer 9 and later
- Firefox 3.5 and later
- Google Chrome 8 and later
- Safari 4 and later
- Opera 10.5 and later

Support improves with later releases. For example, Firefox 5 has far better HTML5 support than Firefox 3.5.

Before encouraging you to use a new HTML5 feature, this book clearly indicates that feature's current level of browser support. Of course, browser versions change relatively quickly, so you'll want to perform your own up-to-date research before you embrace any feature that might cause problems. The website <http://caniuse.com> lets you look up specific features and tells you exactly which browser versions support it. (You'll learn more about this useful tool on page 4.)

Note: This book discusses features that are known not to work in some browsers. Don't panic. It's perfectly fine if you just want to dip a toe into the waters of HTML5 and focus on the bits you can use today. Think of the rest as a sneak peek into the future of the Web.

When Will HTML5 Be Ready?

The short answer is “now.” Even the despised Internet Explorer 6, which is 10 years old and chock-full of website-breaking quirks, can display HTML5 documents. That's because the HTML5 standard was intentionally created in a way that embraces and extends traditional HTML.

The more detailed answer is “it depends.” As you've already learned, HTML5 is a collection of different standards with different degrees of browser support. So although every web developer can switch over to HTML5 documents today (and some big sites, like Google, YouTube, and Wikipedia, already have), it may be years before it's safe to use the bulk of HTML5's fancy new features—at least without adding some sort of fallback mechanism for less-enlightened browsers.

Note: It really doesn't matter whether a given feature is part of one specification or another—what matters is its current web browser support (and the likelihood that nonsupporting browsers will add support in the future). When this book introduces a new feature, it carefully points out where it's defined and how well it's supported.

As a standards-minded developer, you also might be interested in knowing how far the various standards are in their journey toward official status. This is complicated by the fact that the people who dreamt up HTML5 have a slightly subversive philosophy, and they often point out that what browsers support is more important than what the official standard says. (In other words, go ahead and use everything that you want right now, if you can get it to work.) But web developers, big companies, governments, and other organizations often take their cue about whether a language is ready to use by looking at the status of its standard.

Technically, the HTML5 language is now in the hands of the W3C as a *working draft*. This designation indicates it's a fairly mature standard, but one that could still change as it passes through the *candidate recommendation* stage (probably sometime in 2012). The actual *recommendation* stage, which involves plenty of testing, could be many years later. But that isn't as important, because there'll be few changes at that point, and everyone who wants to use HTML5 will already be on the bandwagon.

About the Outline

This book crams a comprehensive HTML5 tutorial into 12 chapters. Here's what you'll find:

Part One: Meet the New Language

- **Chapter 1 (“Introducing HTML5”)** explains how HTML turned into HTML5. You'll take your first look at an HTML5 document, see how the language has changed, and take a look at browser support.
- **Chapter 2 (“A New Way to Structure Pages”)** tackles HTML5's *semantic elements*—a group of elements that can inject meaning into your markup. Used properly, this extra information can help browsers, screen readers, web design tools, and search engines work smarter.
- **Chapter 3 (“Meaningful Markup”)** goes deeper into the world of semantics with add-on standards like *microdata*. And while it may seem a bit theoretical, there's a fat prize for the web developers who understand it best: better, more detailed listings in search engines like Google.

Part Two: Creating Modern Web Pages

- **Chapter 4 (“Web Forms, Refined”)** explores HTML5's changes to the web form elements—the text boxes, lists, checkboxes, and other widgets that you use to collect information from your visitors. HTML5 adds a few frills and some basic tools for catching data-entry errors.
- **Chapter 5 (“Audio and Video”)** hits one of HTML5's most exciting new features: its support for audio and video playback. You'll learn how to survive Web Video Codec Wars to create playback pages that work in every browser, and you'll even see how to create your own customized player.

- **Chapter 6 (“Basic Drawing with the Canvas”)** introduces the two-dimensional drawing surface called the canvas. You’ll learn how to paint it with shapes, pictures, and text, and even build a basic drawing program (with a healthy dose of JavaScript code).
- **Chapter 7 (“Deeper into the Canvas”)** pumps up your canvas skills. You’ll learn about shadows and fancy patterns, along with more ambitious canvas techniques like clickable, interactive shapes and animation.
- **Chapter 8 (“Boosting Styles with CSS3”)** introduces the latest version of the CSS3 standard, which complements HTML5 nicely. You’ll learn how to jazz up your text with fancy fonts, adapt your page to different types of mobile devices, and add eye-catching effects with transitions.

Part Three: Building Web Apps with Desktop Smarts

- **Chapter 9 (“Data Storage”)** covers the new web storage feature that lets you store small bits of information on the visitor’s computer. (It’s like a super-convenient version of the cookie feature.) You’ll also learn about ways to process a user-selected file in your web page JavaScript code, rather than on the web server.
- **Chapter 10 (“Offline Applications”)** explores the new HTML5 caching feature that can let a browser keep running a web page, even if it loses the web connection.
- **Chapter 11 (“Communicating with the Web Server”)** dips into the challenging world of web server communication. You’ll start with the time-honored XMLHttpRequest object, which lets your JavaScript code contact the web server and ask for information. Then you’ll move on to two newer features: server-side events and the more ambitious (and not-nearly-finished) web sockets.
- **Chapter 12 (“More Cool JavaScript Tricks”)** covers three miscellaneous features that address challenges in modern web applications. First, you’ll see how geolocation can pin down a visitor’s position. Next, you’ll use web workers to run time-consuming tasks in the background. Finally, you’ll learn about the new browser history feature, which lets you sync up the web page URL to the current state of the page.

There are also two appendixes that can help you catch up with the fundamentals you need to master HTML5. Appendix A gives a stripped-down summary of CSS; Appendix B gives a concise overview of JavaScript.

About the Online Resources

As the owner of a Missing Manual, you’ve got more than just a book to read. Online, you’ll find example files as well as tips, articles, and maybe even a video or two. You can also communicate with the Missing Manual team and tell us what you love (or hate) about the book. Head over to www.missingmanuals.com, or go directly to one of the following sections.

The Missing CD

This book doesn't have a CD pasted inside the back cover, but you're not missing out on anything. Go to <http://missingmanuals.com/cds/html5mm> to download the web page examples discussed and demonstrated in this book. And so you don't wear down your fingers typing long web addresses, the Missing CD page offers a list of clickable links to the websites mentioned in each chapter.

Tip: If you're looking for a specific example, here's a quick way to find it: Look at the corresponding figure in this book. The file name is usually visible at the end of the text in the web browser's address box. For example, if you see the file path `c:\HTML5\Chapter01\SuperSimpleHTML5.html` (Figure 1-1), you'll know that the corresponding example file is `SuperSimpleHTML5.html`.

The Try-Out Site

There's another way to use the examples: on the live example site at www.prosetech.com/html5. There you'll find live versions of every example from this book, which you can run in your browser. This convenience just might save you a few headaches, because HTML5 includes several features that require the involvement of a real web server. (If you're running web pages from the hard drive on your personal computer, these features may develop mysterious quirks or stop working altogether.) By using the live site, you can see how an example is supposed to work before you download the page and start experimenting on your own.

Note: Don't worry—when you come across an HTML5 feature that needs web server hosting, this book will warn you.

Registration

If you register this book at oreilly.com, you'll be eligible for special offers—like discounts on future editions of *Creating a Website: The Missing Manual*. Registering takes only a few clicks. Type <http://tinyurl.com/registerbook> into your browser to hop directly to the Registration page.

Feedback

Got questions? Need more information? Fancy yourself a book reviewer? On our Feedback page, you can get expert answers to questions that come to you while reading, share your thoughts on this Missing Manual, and find groups for folks who share your interest in creating their own sites. To have your say, go to www.missing-manuals.com/feedback.

Errata

To keep this book as up to date and accurate as possible, each time we print more copies, we'll make any confirmed corrections you suggest. We also note such changes on the book's website, so you can mark important corrections into your own copy of the book, if you like. Go to <http://tinyurl.com/3q56k7v> to report an error and view existing corrections.

Newsletter

Our free email newsletter keeps you up to date on what's happening in Missing Manual land. You can meet the authors and editors, see bonus video and book excerpts, and more. Go to <http://tinyurl.com/MMnewsletter> to sign up.

Safari® Books Online

Safari® Books Online is an on-demand digital library that lets you search over 7,500 technology books and videos.

With a subscription, you can read any page and watch any video from our library. Access new titles before they're available in print. Copy and paste code samples, organize your favorites, download chapters, bookmark key sections, create notes, print out pages, and benefit from tons of other time-saving features.

O'Reilly Media has uploaded this book to the Safari Books Online service. To have full digital access to this book and others on similar topics from O'Reilly and other publishers, sign up for free at <http://my.safaribooksonline.com>.

Part One: Meet the New Language

Chapter 1: Introducing HTML5

Chapter 2: A New Way to Structure Pages

Chapter 3: Meaningful Markup

Introducing HTML5

If HTML were a movie, HTML5 would be its surprise twist.

HTML wasn't meant to survive into the 21st century. The official web standards organization, called the W3C (short for World Wide Web Consortium), left HTML for dead way back in 1998. The W3C pinned its future plans on a modernized successor called XHTML. It took a group of disenfranchised rebels to resuscitate HTML and lay the groundwork for the features that you'll explore in this book.

In this chapter, you'll get the scoop on why HTML died, and how it came back to life. You'll learn about HTML5's philosophy and features, and you'll consider the thorny issue of browser support. You'll also get your first look at a bona fide HTML5 document—both in its simplest form, and as a more practical template that you can use as a starting point for any website.

The Story of HTML5

As you know, HTML is the language you use to write web pages. The basic idea of HTML—that you use *elements* to structure your content—hasn't changed since the Web's earliest days. In fact, even the oldest web pages still work perfectly well in the most modern web browsers (including several browsers that didn't exist at the time, like Firefox and Chrome).

Being old and successful also carries some sizable risks—namely, everyone wants to replace you. In 1998, the W3C stopped working on HTML and attempted to improve it with an XML-powered successor called XHTML 1.0.

XHTML 1.0: Getting Strict

XHTML has most of the same syntax conventions as HTML, but it enforces stricter rules. Much of the sloppy markup that traditional HTML permitted just isn't acceptable in XHTML.

For example, suppose you want to italicize the last word in a heading, like so:

```
<h1>The Life of a <i>Duck</i></h1>
```

And you accidentally swap the final two tags:

```
<h1>The Life of a <i>Duck</h1></i>
```

When a browser encounters this slightly messed-up markup, it can figure out what you really want. It italicizes the last word, without even a polite complaint. However, the mismatched tags break the official rules of XHTML. If you plug your page into an XHTML validator (or use a web design tool like Dreamweaver), you'll get a warning that points out your mistake. From a web design point of view, this is helpful—it lets you catch minor mistakes that might cause inconsistent results on different browsers, or might cause bigger problems when you edit and enhance the page.

At first, XHTML was a success story. Professional web developers, who were frustrated with browser quirks and the anything-goes state of web design, flocked to XHTML. Along the way, they were forced to adopt better habits and give up a few of the half-baked formatting features found in HTML. However, many of XHTML's imagined benefits—like interoperability with XML tools, easier page processing for automated programs, portability to mobile platforms, and extensibility of the XHTML language itself—never came to pass.

Still, XHTML became the standard for most serious web designers. And while everyone seemed pretty happy, there was one dirty secret: Although browsers understood XHTML markup, they didn't enforce the strict error-checking that the standard required. That means a page could break the rules of XHTML, and the browsers wouldn't blink. In fact, there was nothing to stop a web developer from throwing together a mess of sloppy markup and old-fashioned HTML content, and calling it an XHTML page. There wasn't a single browser on the planet that would complain. And *that* made the people in charge of the XHTML standard deeply uncomfortable.

XHTML 2: The Unexpected Failure

The solution was supposed to be XHTML 2. It was set to tighten up the error-handling rules, forcing browsers to reject invalid XHTML 2 pages. XHTML 2 also threw out many of the quirks and conventions it had inherited from HTML. For example, the system of numbered headings (`<h1>`, `<h2>`, `<h3>`, and so on) was superseded by a new `<h>` element, whose significance depended on its position in a web page. Similarly, the `<a>` element was eclipsed by a feature that let web developers transform any element into a link, and the `` element lost its `alt` attribute in favor of a new way to supply alternate content.

These changes were typical of XHTML 2. From a theoretical point of view, they were cleaner and made more sense. From a practical point of view, they forced everyone to change the way they wrote web pages (to say nothing of updating the web pages they already had), without adding new functionality to make all the work worthwhile. And along the way, XHTML 2 dumped a few well-worn elements that some web designers still loved, like `` (for bold text), `<i>` (for italics), and `<iframe>` (for embedding one web page inside another).

But perhaps the worst problem was the glacial pace of change. Development on XHTML 2 dragged on for five years, and developer enthusiasm slowly leaked away.

HTML5: Back From the Dead

At about the same time (starting in 2004), a group of people started looking at the future of the Web from a different angle. Instead of trying to sort out what was wrong (or just “philosophically impure”) in HTML, they focused on what was missing, in terms of the things web developers wanted to get done.

After all, HTML began its life as a tool for displaying documents. With the addition of JavaScript, it had morphed into a system for developing web applications, like search engines, e-commerce stores, mapping tools, email readers, and a whole lot more. And while a crafty web application can do a lot of impressive things, creating one isn’t easy. Most rely on a soup of handwritten JavaScript, one or more popular JavaScript toolkits, and a web application that runs on the web server. It’s a challenge to get all these pieces to interact consistently on different browsers. Even when you get it to work, you need to mind the duct tape and staples that hold everything together.

The people creating browsers were particularly concerned about this situation, and a group of forward-thinking individuals from Opera Software (the creators of the Opera browser) and the Mozilla Foundation (the creators of Firefox) lobbied to get XHTML to introduce more developer-oriented features. When they failed, Opera, Mozilla, and Apple formed the loosely knit WHATWG (Web Hypertext Application Technology Working Group) to think of new solutions.

The WHATWG wasn’t out to replace HTML, but to *extend* it, in a seamless, backward-compatible way. In fact, the earliest version of its work had two add-on specifications called Web Applications 1.0 and Web Forms 2.0. Eventually, these standards evolved into HTML5.

Note: The number 5 in the HTML5 specification name is supposed to indicate that the standard picks up where HTML left off (that’s HTML version 4.01, which predates XHTML). Of course, this isn’t really accurate, because HTML5 supports everything that’s happened to web pages in the decade since HTML 4.01 was released, including strict XHTML-style syntax (if you choose to use it) and a slew of JavaScript innovations. However, the name still makes a clear point: HTML5 may support the *conventions* of XHTML, but it enforces the *rules* of HTML.

By 2007, all the excitement was in the WHATWG camp. After some painful reflection, the W3C decided to disband the group that was working on XHTML 2 and work on formalizing the HTML5 standard instead. At this point, the original HTML5 was broken into more manageable pieces, and many of the features that had originally been called HTML5 became separate standards (see the box on this page).

Tip: You can read the official W3C version of the HTML5 standard at www.w3.org/TR/html5.

UP TO SPEED

What Does HTML5 Include?

There's no such thing as a browser that "supports" HTML5. Instead, every browser supports a gradually expanding subset of HTML5-related features. This approach is both good and bad. It's good because the browsers can quickly implement mature parts of the HTML5 standard while other features continue to evolve. It's bad because it forces web page writers to worry about checking whether a browser supports each feature they want to use. (You'll learn about the painful and not-so-painful techniques to do so in this book.)

Here are the major feature categories that fall under the umbrella of HTML5:

- **Core HTML5.** This part of HTML5 makes up the official W3C's version of the specification. It includes the new semantic elements (see Chapter 2 and Chapter 3), new and enhanced web form widgets (Chapter 4), audio and video support (Chapter 5), and the canvas for drawing with JavaScript (Chapter 6 and Chapter 7). This category includes most of the features that have the best browser support.
- **Features that were once HTML5.** These are the features that sprang from the original HTML5 specification,

as prepared by the WHATWG. Most of these are specifications for features that require JavaScript and support rich web applications. The most significant include local data storage (Chapter 9), offline applications (Chapter 10), and messaging (Chapter 11), but you'll learn about several more in this book.

- **Features that are sometimes called HTML5.** These are next-generation features that are often lumped together with HTML5, even though they weren't ever a part of the HTML5 standard. This category includes CSS3 (Chapter 8) and geolocation (Chapter 12).

Oddly enough, it's not just clueless managers and technology writers causing the standards confusion. Even the W3C is blurring the boundaries between the "real" HTML5 (according to the standard) and the "marketing" version (which includes everything new and the kitchen sink). For example, the official W3C logo website (www.w3.org/html/logo) encourages you to generate HTML5 logos that promote CSS3 and SVG—two standards that were under development well before HTML5 appeared.

HTML: The Living Language

The switch from the W3C to the WHATWG and back to the W3C again has led to a rather unusual arrangement. Technically, the W3C in charge of determining what is and isn't official HTML5. But at the same time, the WHATWG continues its work dreaming up future HTML features. Only now, they no longer refer to their work as HTML5. They simply call it HTML, explaining that HTML will continue as a *living language*.

Because HTML is a living language, an HTML page will never become obsolete and stop working. HTML pages will never need a version number (even in the doctype), and web developers will never need to “upgrade” their markup from one version to another to get it to work on new browsers.

Because HTML is a living language, new features (and new elements) may be added to the HTML standard at any time. Some web pages may choose to take advantage of these features, and some browsers may choose to support them. But features won’t be tied to a specific version number.

When web developers hear about this plan, their first reaction is usually unmitigated horror. After all, who wants to deal with a world of wildly variable standards support, where developers need to pick and choose the features they use based on the likelihood these features will be supported? However, on reflection, most web developers come to a grudging realization: for better or worse, this is exactly the way browsers work today, and the way they’ve worked since the dawn of the Web.

As explained earlier, today’s browsers are happy with any mishmash of supported features. You can take a state-of-the-art XHTML page and add something as scandalously backward as the `<marquee>` element (an obsolete feature for creating scrolling text), and no browser will complain. Similarly, browsers have well-known holes in their support for even the oldest standards. For example, browser makers started implementing CSS3 before CSS2 support was finished, and many CSS2 features were later dropped. The only difference is that now HTML5 makes the “living language” status official. Still, it’s no small irony that just as HTML is embarking on a new, innovative chapter, it has finally returned full circle to its roots.

Tip: To see the current, evolving draft of HTML that includes the stuff we call HTML5 and a small but ever-evolving set of new, unsupported features, go to <http://whatwg.org/html>. To follow the latest HTML news in a less formal setting, check out the WHATWG blog at <http://blog.whatwg.org>.

Three Key Principles of HTML5

By this point, you’re probably eager to get going with a real HTML5 page. But first, it’s worth climbing into the minds of the people who built HTML5. Once you understand the philosophy behind the language, the quirks, complexities, and occasional headaches that you’ll encounter in this book will make a whole lot more sense.

1. Don’t Break the Web

“Don’t break the Web” means that a standard shouldn’t introduce changes that make other people’s web pages stop working. This rarely happens.

“Don’t break the Web” *also* means that a standard shouldn’t casually change the rules, and in the process deem perfectly good current-day web pages to be obsolete (even if

they still work). For example, XHTML 2 broke the Web because it demanded an immediate, dramatic shift in the way web pages were written. Yes, old pages would still work—thanks to the backward compatibility that’s built into browsers. But if you wanted to prepare for the future and keep your website up to date, you’d be forced to waste countless hours correcting the “mistakes” that XHTML 2 had banned.

HTML5 has a different viewpoint. Everything that was valid before HTML5 remains valid in HTML5. In fact, everything that was valid in HTML 4.01 also remains valid in HTML 5.

Note: Unlike previous standards, HTML5 doesn’t just tell browser makers what to support—it also documents and formalizes the way they *already work*. Because the HTML5 standard documents reality, rather than just setting out a bunch of ideal rules, it may become the best-supported web standard ever.

UP TO SPEED

How HTML5 Handles Obsolete Elements

Because HTML5 supports all of HTML, it supports many features that are considered obsolete. These includes formatting elements like ``, despised special-effect elements like `<blink>` and `<marquee>`, and the awkward system of HTML frames.

This open-mindedness is a point of confusion for many new HTML5 apprentices. On the one hand, HTML5 should by all rights ban these outdated elements, which haven’t appeared in an official specification for years (if ever). On the other hand, modern browsers still quietly support these elements, and HTML5 is supposed to reflect how web browsers really work. So what’s a standard to do?

To solve this problem, the HTML5 specification has two separate parts. The first part—which is what you’ll consider in this book—targets web developers. They need to avoid the bad habits and discarded elements of the past. You can make sure you’re following this part of the HTML5 standard by using an HTML5 validator.

The second, much longer part of the HTML5 specification targets browser makers. They need to support everything that’s ever existed in HTML, for backward compatibility.

Ideally, the HTML5 standard should have enough information that someone could build a browser from scratch, and make it completely compatible with the modern browsers of today, whether it was processing new or old markup. This part of the standard tells browsers how to deal with obsolete elements that are officially discouraged, but still supported.

Incidentally, the HTML5 specification also formalizes how browsers should deal with a variety of errors (for example, missing or mismatched tags). This point is important, because it ensures that a flawed page will work the same on different browsers, even when it comes to subtle issues like the way a page is modeled in the DOM (that’s the Document Object Model, the tree of in-memory objects that represents the page and is made available to JavaScript code). To create this long, tedious part of the standard, the creators of HTML5 performed exhaustive tests on modern browsers to figure out their undocumented error-handling behavior. Then, they wrote it down.

2. Pave the Cowpaths

A cowpath is the rough, heavily trodden track that gets people from one point to another. A cowpath exists because it's being used. It might not be the best possible way to move around, but at some point it was the most practical working solution.

HTML5 aims to standardize these unofficial (but widely used) techniques. It may not be as neat as laying down a nicely paved expressway with a brand-new approach, but it has a better chance of succeeding. That's because switching over to new techniques may be beyond the ability or interest of the average website designer. And worse, new techniques may not work for visitors who are using older browsers. XHTML 2 tried to drive people off the cowpaths, and it failed miserably.

Note: Paving the cowpaths has an obvious benefit: It uses established techniques that already have some level of browser support. If you give a web developer a choice between a beautifully designed new feature that works on 70 percent of the web browsers out there and a messy hack that works everywhere, they'll choose the messy hack and the bigger audience every time.

The “pave the cowpaths” approach also requires some compromises. Sometimes it means embracing a widely supported but poorly designed feature. One example is HTML5's drag-and-drop ability (see page 299), which is based entirely on the behavior Microsoft created for IE5. Although this drag-and-drop feature is now supported in all browsers, it's universally loathed for being clumsy and overly complicated. This has led some web designers to complain that “HTML5 not only encourages bad behavior, it defines it.”

3. Be Practical

This principle is simple: Changes should have a practical purpose. And the more demanding the change, the bigger the payoff needs to be. Web developers may prefer nicely designed, consistent, quirk-free standards, but that isn't a good enough reason to change a language that's already been used to create several billion documents. Of course, it's still up to someone to decide whose concerns are the most important. A good clue is to look at what web pages are already doing—or trying to do.

For example, the world's third most popular website (at the time of this writing) is YouTube. But because HTML had no real video features before HTML5, YouTube has had to rely on the Flash browser plug-in. This solution works surprisingly well because the Flash plug-in is present on virtually all web-connected computers. However, there are occasional exceptions, like locked-down corporate computers that don't allow Flash, or Apple-designed devices (like the iPhone and iPad) that don't support it. And no matter how many computers have Flash, there's a good case for extending the HTML standard so that it directly supports one of the most fundamental ways people use web pages today—to watch video.

There's a similar motivation behind HTML5's drive to add more interactive features—drag-and-drop support, editable HTML content, two-dimensional drawing on a canvas, and so on. You don't need to look far to find web pages that use all of these features right now, some with plug-ins like Adobe Flash and Microsoft Silverlight, and others with JavaScript libraries or (more laboriously) with pages of custom-written JavaScript code. So why not add official support to the HTML standard, and make sure these features work consistently on all browsers?

Note: Browser plug-ins like Flash won't go away overnight (or even in the next few years). Despite its many innovations, it still takes far more work to build complex, graphical applications in HTML5 (for example, see the browser-hosted games at www.flasharcade.com). But HTML5's ultimate vision is clear: to allow websites to offer video, rich interactivity, and piles of frills without requiring a plug-in.

Your First Look at HTML5 Markup

Here's one of the simplest HTML5 documents you can create. It starts with the HTML5 doctype (a special code that's explained on page 20), followed by a title, and then followed by some content. In this case, the content is a single paragraph of text:

```
<!DOCTYPE html>
<title>A Tiny HTML Document</title>
<p>Let's rock the browser, HTML5 style.</p>
```

You already know what this looks like in a browser, but if you need reassuring, check out Figure 1-1.

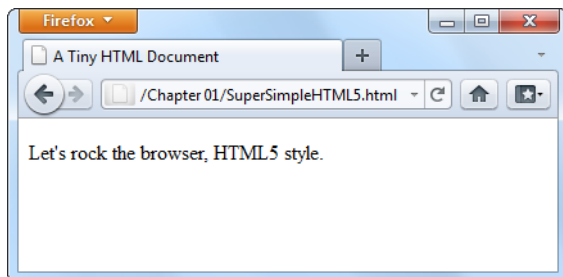

Figure 1-1:
This super-simple HTML5 document holds a single line of text.

You can pare down this document a bit more. For example, the HTML5 standard doesn't really require the final `</p>` tag, since browsers know to close all open elements at the end of the document (and the HTML5 standard makes this behavior official). However, shortcuts like these create confusing markup and can lead to unexpected mistakes.

The HTML5 standard also lets you remove the `<title>` element if the title information is provided by another mechanism. For example, if you're sending an HTML document in an email message, you could put the title in the title of the email message and put the rest of the markup—the doctype and the content—into the body of the message. But this is obviously a specialized scenario.

More commonly, you'll want to flesh out this bare-bones HTML5 document. Most web developers agree that using the traditional `<head>` and `<body>` sections can prevent confusion, by cleanly separating the information about your page (the head) and its actual content (the body). This structure is particularly useful when you start adding scripts, style sheets, and meta elements:

```
<!DOCTYPE html>
<head>
  <title>A Tiny HTML Document</title>
</head>
<body>
  <p>Let's rock the browser, HTML5 style.</p>
</body>
```

As always, the indenting (at the beginning of lines three and six) is purely optional. This example uses it to make the structure of the page easier to see at first glance.

Finally, you can choose to wrap the entire document (not including the doctype) in the traditional `<html>` element. Here's what that looks like:

```
<!DOCTYPE html>
<html>
  <head>
    <title>A Tiny HTML Document</title>
  </head>
  <body>
    <p>Let's rock the browser, HTML5 style.</p>
  </body>
</html>
```

Up until HTML5, every version of the official HTML specification had demanded that you use the `<html>` element, despite the fact that it has no effect on browsers. However, HTML5 makes this detail completely optional.

Note: The use of the `<html>`, `<head>`, and `<body>` elements is simply a matter of style. You can leave them out, and your page will work perfectly well, even on old browsers that don't know a thing about HTML5. In fact, the browser will automatically assume these details. So if you use JavaScript to peek at the DOM (the set of programming objects that represents your page), you'll find objects for the `<html>`, `<head>`, and `<body>` elements, even if you didn't add them yourself.

Currently, this example is somewhere between the simplest possible HTML5 document and the fleshed-out starting point of a practical HTML5 web page. In the following sections, you'll fill in the rest of what you need, and dig a little deeper into the markup.

The HTML5 Doctype

The first line of every HTML5 document is a special code called *doctype*. It clearly announces to anyone who's reading the document markup that HTML5 content follows:

```
<!DOCTYPE html>
```

The first thing you'll notice about the HTML5 doctype is its striking simplicity. Compare it, for example, to the ungainly doctype that web developers need when using XHTML 1.0 strict:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN"  
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">
```

Even professional web developers were forced to copy-and-paste the XHTML doctype from one document to another. But the HTML5 doctype is short and snappy, so you won't have much trouble typing it in by hand.

The HTML5 doctype is also notable for the fact that it doesn't include the official specification version (that's the 5 in HTML5). Instead, the doctype simply indicates that the page is HTML. This is in keeping with the new vision of HTML5 as a living language (page 14). When new features are added to the HTML language, they'll automatically be available in your page, without requiring you to edit the doctype.

All of this raises a good question—if HTML5 is a living language, why does your web page require any doctype at all?

The answer is that the doctype remains for historical reasons. Without a doctype, most browsers (including Internet Explorer and Firefox) will lapse into *quirks mode*. In this mode, they'll attempt to render pages according to the slightly buggy rules that they used in older versions. The problem is that one browser's quirks mode differs from the next, so pages designed for one browser are likely to get inconsistently sized fonts, scrambled layouts, and other glitches on another browser.

When you add a doctype, the browser recognizes that you want to use the stricter *standards mode*, which ensures that the web page is displayed with consistent formatting and layout on every modern browser. The browser doesn't even care *what* doctype you use (with just a few exceptions). Instead, it simply checks that you have *some* doctype. The HTML5 doctype is simply the shortest valid doctype, so it triggers standards mode.

Tip: The HTML5 doctype triggers standards mode on all browsers that have a standards mode, including browsers that don't know anything about HTML5. For that reason, you can start using the HTML5 doctype now, in all your pages, even if you need to hold off on many of HTML5's less-supported features.

Although the doctype is primarily intended to tell web browsers what to do, other agents can also check it. This includes HTML5 validators, search engines, design tools, and other human beings (when they're trying to figure out what flavor of markup you've chosen for your page).

Character Encoding

The *character encoding* is the standard that tells a computer how to convert your text into a sequence of bytes when it's stored in a file (and how to convert it back again when the file is opened). For historical reasons, there are many different character encodings in the world. Today, virtually all English websites use an encoding called UTF-8, which is compact, fast, and supports all the non-English characters you'll ever need.

Often, the web server that hosts your pages is configured to tell browsers that it's serving out pages with a certain kind of encoding. However, because you can't be sure that your web server will take this step (unless you own it), and because browsers can run into an obscure security issue when they attempt to guess a page's encoding, you should always add encoding information to your markup.

HTML5 makes that easy to do. All you need to do is add the meta element shown below at the very beginning of your <head> section (or right after the doctype, if you don't define the <head> element):

```
<head>
  <meta charset="utf-8">
  <title>A Tiny HTML Document</title>
</head>
```

Design tools like Dreamweaver or Expression Web add this detail automatically when you create a new page. They also make sure that your files are being saved with UTF encoding. However, if you're using an ordinary text editor, you might need an extra step to make sure your files are being saved correctly. For example, when editing an HTML file in Notepad (on Windows), you must choose UTF-8 from the Encoding list at the bottom of the Save As dialog box. In TextEdit (on Mac OS), you need to first choose Format→Make Plain Text to make sure the program saves your page as an ordinary text file, and you must then choose “Unicode (UTF-8)” from the Plain Text Encoding pop-up menu in the Save As dialog box.

The Language

It's considered good style to indicate your web page's *natural language*. This information is occasionally useful to other people—for example, search engines can use it to filter search results so they include only pages that match the language of the searcher.

To specify the language of some content, you use the *lang* attribute on any element, along with the appropriate language code. That's *en* for plain English, but you can find more exotic language codes at <http://people.w3.org/rishida/utls/subtags>.

The easiest way to add language information to your web page is to use the <html> element with the lang attribute:

```
<html lang="en">
```

This detail can also help screen readers if a page has text from multiple languages. In this situation, you use the `lang` attribute to indicate the language of different sections of your document (for example, by applying it to different `<div>` elements that wrap different content). Then, screen readers can determine which sections they can read aloud.

Adding a Style Sheet

Virtually every web page in a properly designed, professional website uses style sheets. You specify the style sheets you want to use by adding `<link>` elements to the `<head>` section of an HTML5 document, like this:

```
<head>
  <meta charset="utf-8">
  <title>A Tiny HTML Document</title>
  <link href="styles.css" rel="stylesheet">
</head>
```

This method is more or less the same way you attach style sheets to a traditional HTML document, but slightly simpler. Because CSS is the only style sheet language around, there's no need to add the `type="text/css"` attribute that web pages used to require.

Adding JavaScript

JavaScript started its life as a time-wasting way to add glitter and glamour to hum-drum web pages. Today, JavaScript is less about user interface frills and more about novel web applications, including super-advanced email clients, word processors, and mapping engines that run right in the browser.

You add JavaScript to an HTML5 page in much the same way that you add it to a traditional HTML page. Here's an example that references an external file with JavaScript code:

```
<head>
  <meta charset="utf-8">
  <title>A Tiny HTML Document</title>
  <script src="scripts.js"></script>
</head>
```

There's no need to include the `language="JavaScript"` attribute. The browser assumes you want JavaScript unless you specify otherwise (and because JavaScript is the only HTML scripting language with broad support, you never will). However, you *do* still need to remember the closing `</script>` tag, even when referring an external JavaScript file. If you leave it out or attempt to shorten your markup using the empty element syntax, your page won't work.

If you spend a lot of time testing your JavaScript-powered pages in Internet Explorer, you may also want to add a special comment called the *mark of the Web* to your `<head>` section, right after the character encoding. It looks like this:

```
<head>
  <meta charset="utf-8">
  <!-- saved from url=(0014)about:internet -->
  <title>A Tiny HTML Document</title>
  <script src="scripts.js"></script>
</head>
```

This comment tells Internet Explorer to treat the page as though it has been downloaded from a remote website. Otherwise, IE switches into a special locked-down mode, pops up a security warning in a message bar, and won't run any JavaScript code until you explicitly click, "Allow blocked content."

All other browsers ignore the "mark of the Web" comment and use the same security settings for remote websites and local files.

The Final Product

If you've followed these steps, you'll have an HTML5 document that looks something like this:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>A Tiny HTML Document</title>
  <link href="styles.css" rel="stylesheet">
  <script src="scripts.js"></script>
</head>

  <body>
    <p>Let's rock the browser, HTML5 style.</p>
  </body>
</html>
```

Although it's no longer the shortest possible HTML5 document, it's a reasonable starting point for any web page you want to build. And while this example seems wildly dull, don't worry—in the next chapter, you'll step up to a real-life page that's full of carefully laid-out content, and all wrapped up in CSS.

Note: All the HTML5 syntax you've learned about in this section—the new doctype, the meta element for character encoding, the language information, and the style sheet and JavaScript references, work in browsers both new and old. That's because they rely on defaults and built-in error-correcting practices that all browsers use.

A Closer Look at HTML5 Syntax

As you’ve already learned, HTML5 loosens some of the rules. That’s because the creators of HTML5 wanted the language to more closely reflect web browser reality—in other words, they wanted to narrow the gap between “web pages that work” and “web pages that are considered valid, according to the standard.” In the next section, you’ll take a closer look at how the rules have changed.

Note: Of course there are still plenty of obsolete practices that browsers support but that the HTML5 standard strictly discourages. For help catching these, you’ll need an HTML5 validator (page 25).

The Loosened Rules

In your first walk through an HTML5 document, you discovered that HTML5 makes the `<html>`, `<head>`, and `<body>` elements optional (although they can still be pretty useful). But HTML5’s relaxed attitude doesn’t stop there.

HTML5 ignores capitalization, allowing you to write markup like this:

```
<P>Capital and lowercase letters <EM>don't matter</em> in tag names.</p>.
```

HTML5 also lets you omit the closing slash from a *void element*—that’s an element with no nested content, like an `` (image), a `
` (line break), or an `<hr>` (horizontal line). Here are three equivalent ways to add a line break:

```
I cannot<br />
move backward<br>
or forward.<br/>
I am caught
```

HTML5 also changes the rules for attributes. Attribute values don’t need quotation marks anymore, as long as the value doesn’t include a restricted character (typically `>`, `=`, or a space). Here’s an example of an `` element that takes advantage of this ability:

```
<img alt="Horsehead Nebula" src=Horsehead01.jpg>
```

Attributes with no values are also allowed. So while XHTML required the somewhat redundant syntax to put a checkbox in the checked state...

```
<input type="checkbox" checked="checked" />
```

...you can now revive the shorter HTML 4.01 tradition of including the attribute name on its own.

```
<input type="checkbox" checked>
```

What’s particularly disturbing to some people isn’t the fact that HTML5 allows these things. It’s the fact that inconsistent developers can casually switch back and forth between the stricter and the looser styles, even using both in the same document. But this really isn’t different from XHTML. In both cases, good style is the responsibility of the web designer, and the browser tolerates whatever you can throw at it.

Here's a quick summary of what constitutes good HTML5 style (and what conventions the examples in this book follow, even if they don't have to):

- **Including the optional `<html>`, `<body>`, and `<head>` elements.** The `<html>` element is a handy place to define the page's natural language (page 21); and the `<body>` and `<head>` elements help to keep page content separate from the other page details.
- **Using lowercase tags.** They're not necessary, but they're far more common, easier to type (because you don't need the Shift key), and not nearly as shouty.
- **Using quotation marks around attribute values.** The quotation marks are there for a reason—to protect you from mistakes that are all too easy to make. Without quotation marks, one invalid character can break your whole page.

On the other hand, there are some old conventions that this book ignores (and you can, too). The examples in this book don't close empty elements, because most developers don't bother to add the extra slash (/) when they switch to HTML5. Similarly, there's no reason to favor the long attribute form when the attribute name and the attribute value are the same.

HTML5 Validation

HTML5's new, relaxed style may suit you fine. Or, the very thought that there could be inconsistent, error-ridden markup hiding behind a perfectly happy browser may be enough to keep you up at night. If you fall into the latter camp, you'll be happy to know that a validation tool can hunt down markup that doesn't conform to the recommended standards of HTML5, even if it doesn't faze a browser.

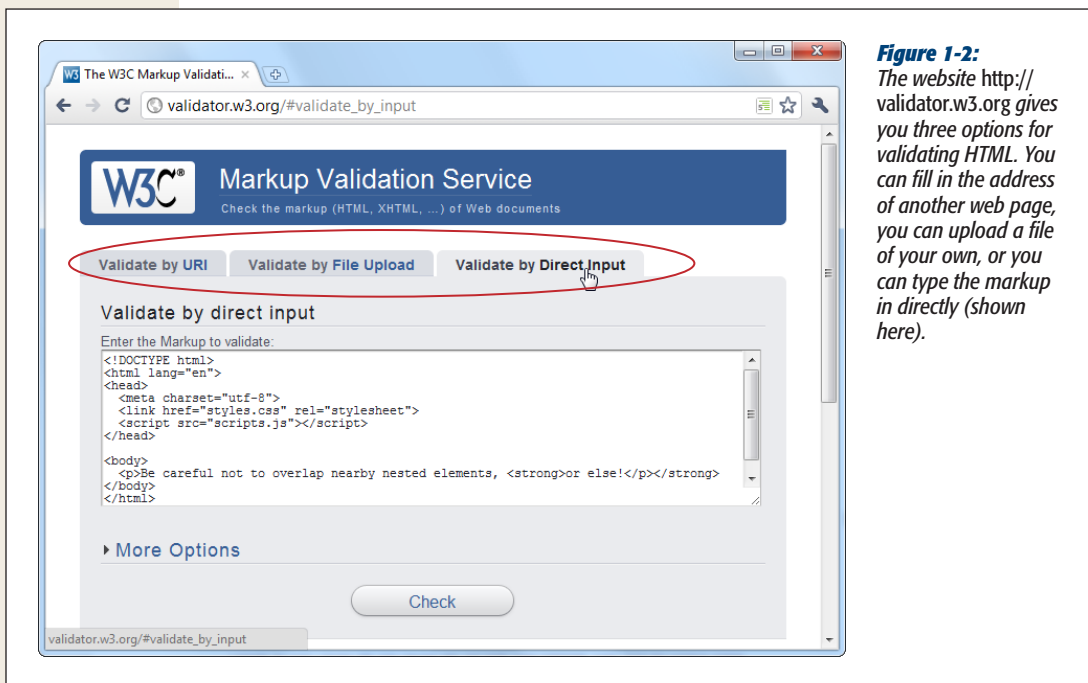

Here are some potential problems that a validator can catch:

- Missing mandatory elements (for example, the `<title>` element)
- A start tag without a matching end tag
- Incorrectly nested tags
- Tags with missing attributes (for example, an `` element without the `src` attribute)
- Elements or content in the wrong place (for example, text that's placed directly in the `<head>` section)

Web design tools like Dreamweaver and Expression Web have their own validators, but only the very latest versions have support for HTML5. In the meantime, you can use an online validation tool. Here's how to use the popular validator provided by the W3C standards organization:

1. **In your web browser, go to <http://validator.w3.org> (Figure 1-2).**

The W3C validator gives you three choices, represented by three separate tabs: “Validate by URI” (for a page that's already online), “Validate by File Upload” (for a page that's stored in a file on your computer), and “Validate by Direct Input” (for a bunch of markup you type in yourself).

2. Click the tab you want, and supply your HTML content.

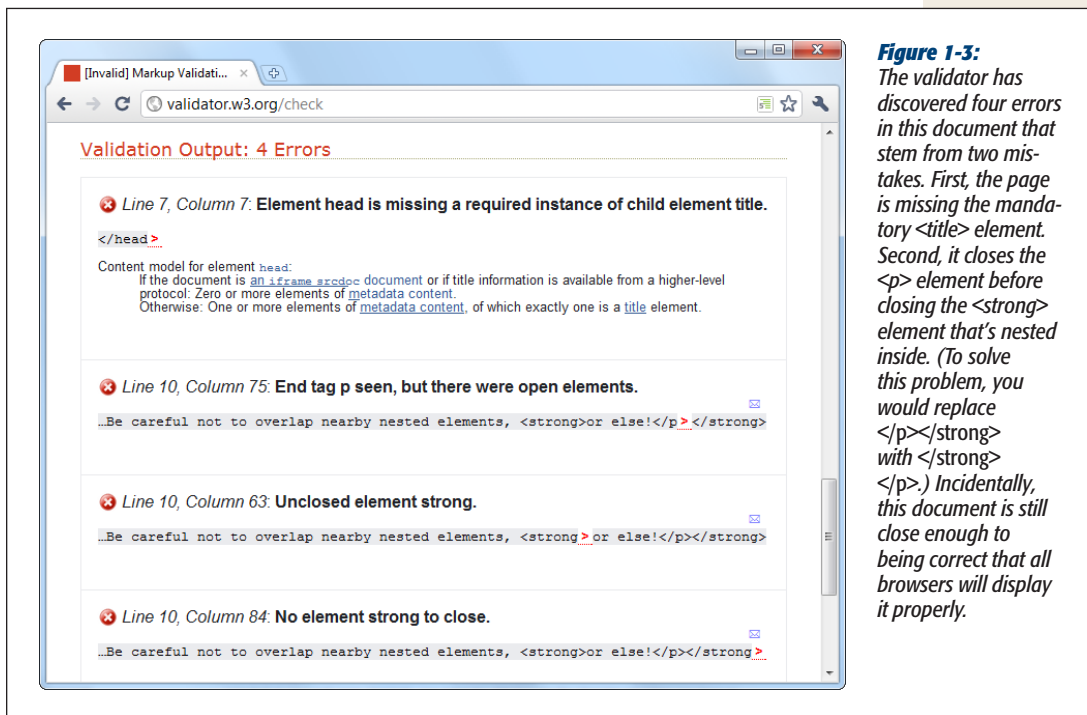

- “Validate by URI” lets you validate an existing web page. You just need to type the page’s URL in the Address box (for example, <http://www.MySloppySite.com/FlawedPage.html>).
- “Validate by File Upload” lets you upload any file from your computer. First, click the Browse button (in Chrome, click Choose File). In the Open dialog box, select your HTML file and then click Open.
- “Validate by Direct Input” lets you validate any markup—you just need to type it into a large box. The easiest way to use this option is to copy the markup from your text editor and paste it into the box on the W3C validation page.

Before continuing, you can click More Options to change some settings, but you probably won’t. For example, it’s best to let the validator automatically detect the document type—that way, the validator will use the doctype specified in your web page. Similarly, use automatic detection for the character set unless you have an HTML page that’s written in another language and the validator has trouble determining the correct character set.

3. Click the Check button.

This sends your HTML page to the W3C validator. After a brief delay, the report appears. You'll see whether your document passed the validation check and, if it failed, what errors the validator detected (see Figure 1-3).

Note: Even in a perfectly valid HTML document, you may get a few harmless warnings, including that the character encoding was determined automatically and that the HTML5 validation service is considered to be an experimental, not-fully-finished feature.

The Return of XHTML

As you've already learned, HTML5 spells the end for the previous king of the Web—XHTML. However, reality isn't quite that simple, and XHTML fans don't need to give up all the things they loved about the past generation of markup languages.

First, remember that XHTML syntax lives on. The rules that XHTML enforced either remain as guidelines (for example, nesting elements correctly) or are still supported as optional conventions (for example, including the trailing slash on empty elements).

But what if you want to *enforce* the XHTML syntax rules? Maybe you're worried that you (or the people you work with) will inadvertently slip into the looser conventions of ordinary HTML. To stop that from happening, you need to use XHTML5—a less common standard that is essentially HTML5 with the XML-based restrictions slapped on top.

To turn an HTML5 document into an XHTML5 document, you need to explicitly add the XHTML namespace to the `<html>` element, close every element, make sure you use lowercase tags, and so on. Here's an example of a web page that takes all these steps:

```
<!DOCTYPE html>
<html lang="en" xmlns="http://www.w3.org/1999/xhtml">
<head>
  <meta charset="utf-8"/>
  <title>A Tiny HTML Document</title>
  <link href="styles.css" rel="stylesheet"/>
  <script src="scripts.js"></script>
</head>

<body>
  <p>Let's rock the browser, XHTML5 style.</p>
</body>
</html>
```

Now you can use an XHTML5 validator to get stricter error checking that enforces the old-style XHTML rules. The W3C validator won't do it, but the validator at <http://validator.nu> will, provided you click the More Options button and choose XHTML5 from the Preset list. (You'll also need to choose the "Be lax about HTTP Content-Type" option, unless you're using the direct input approach, and pasting your markup into a text box.)

If you follow these steps, you'll be able to create and validate an XHTML document. However, *browsers* will still process your page as an HTML5 document—one that just happens to have a XML inferiority complex. They won't attempt to apply any extra rules.

If you want to go XHTML5 all the way, you need to configure your web server to serve your page with the MIME type *application/xhtml+xml* or *application/xml*, instead of the standard *text/html*. (See page 153 for the lowdown on MIME types.) But before you call your web hosting company, be warned that this change will prevent your page from being displayed by any version of Internet Explorer before IE 9. For that reason, true XHTML5 is an immediate deal-breaker in the browser.

Incidentally, browsers that do support XHTML5 deal with it differently than ordinary HTML5. They attempt to process the page as an XML document, and if that process fails (because you've left a mistake behind), the browser gives up on the rest of the document.

Bottom line? For the vast majority of web developers, from ordinary people to serious pros, XHTML5 isn't worth the hassle. The only exception is developers who have a specific XML-related goal in mind (for example, developers who want to manipulate the content in their pages with XML-related standards like XQuery and XPath).

Tip: If you're curious, you can trick your browser into switching into XHTML mode. Just rename your file so that it ends with .xhtml or .xht. Then open it from your hard drive. Most browsers (including Firefox, Chrome, and IE 9) will act as though you downloaded the page from a web server with an XML MIME type. If there's a minor error in the page, the browser window will show a partially processed page (IE 9), an XML error message (Firefox), or a combination of the two (Chrome).

HTML5's Element Family

So far, this chapter has focused on the changes to HTML5's syntax. But more important are the additions, subtractions, and changes to the *elements* that HTML supports. In the following sections, you'll get an overview of how they've changed.

Added Elements

In the following chapters, you'll spend most of your time learning about new elements—ingredients that haven't existed in web pages up until now. Table 1-1 has a preview of what's in store (and where you can read more about it).

Table 1-1. New HTML5 elements

Category	Elements	Discussed in...
Semantic elements for structuring a page	<article>, <aside>, <figcaption>, <figure>, <footer>, <header>, <hgroup>, <nav>, <section>, <details>, <summary>	Chapter 2
Semantic elements for text	<mark>, <time> <wbr> (previously supported, but now an official part of the language)	Chapter 3
Web forms and interactivity	<input> (not new, but has many new subtypes) <datalist>, <keygen>, <meter>, <progress>, <command>, <menu>, <output>	Chapter 4
Audio, video, and plug-ins	<audio>, <video>, <source> <embed> (previously supported, but now an official part of the language)	Chapter 5
Canvas	<canvas>	Chapter 6
Non-English language support	<bdo>, <rp>, <rt>, <ruby>	HTML5 specification at http://dev.w3.org/html5/markup

Removed Elements

Although HTML5 adds new elements, it also boots a few out of the official family. These elements will keep working in browsers, but any decent HTML5 validator will smoke them out of their hiding places and complain loudly (page 25).

Most obviously, HTML5 keeps the philosophy (first cooked up with XHTML) that *presentational elements* are not welcome in the language. Presentational elements are elements that are simply there to add formatting to web pages, and even the greenest web designer knows that's a job for style sheets. Rejects include elements that professional developers haven't use in years (like `<big>`, `<center>`, ``, `<tt>`, and `<strike>`). HTML's presentational attributes died the same death, so there's no reason to rehash them all here.

Additionally, HTML5 kicks more sand on the grave where web developers buried the HTML frames feature. When it was first created, HTML frames seemed like a great way to show multiple web pages in a single browser window. But now, frames are better known as an accessibility nightmare that causes problems with search engines, assistive software, and mobile devices. Interestingly, the `<iframe>` element—which lets developers put one page inside another—squeaks through. That's because web applications use the `<iframe>` for a range of integration tasks, like incorporating YouTube windows, ad units, and Google search boxes in a web page.

A few more elements were kicked out because they were redundant or the cause of common mistakes, including `<acronym>` (use `<abbr>` instead) and `<applet>` (because `<object>` is preferred). But the vast majority of the element family lives on in HTML5.

Note: For those keeping count, HTML5 includes a family of just over 100 elements. Out of these, almost 30 are new and about 10 are significantly changed. You can browse the list of elements (and review which ones are new or changed) at <http://dev.w3.org/html5/markup>.

Adapted Elements

HTML5 has another odd trick: sometimes it adapts an old feature for a new purpose. For example, consider the `<small>` element, which had fallen out of favor as a clumsy way to shrink the font size of a block of text (a task more properly done with style sheets). But unlike the discarded `<big>` element, the HTML5 keeps the `<small>` element, with a change. Now, the `<small>` element represents “small print”—for example, the legalese that no one wants you to read at the bottom of a contract:

```
<small>The creators of this site will not be held liable for any injuries that  
may result from unsupervised unicycle racing.</small>
```

Text inside the `<small>` element is still displayed as it always was, using a smaller font size, unless you override that setting with a style sheet.

Note: Opinions on this `<small>` technique differ. On the one hand, it's great for backward compatibility, because old browsers already support the `<small>` element, and so they'll continue to support it in an HTML5 page. On the other hand, it introduces a potentially confusing change of meaning for old pages. They may be using the `<small>` element for presentational purposes, without wanting to suggest "small print."

Another changed element is `<hr>` (short for horizontal rule), which draws a separating line between sections. In HTML5, `<hr>` represents a thematic break—for example, a transition to another topic. The default formatting stays, but now a new meaning applies.

Similarly, `<s>` (for struck text), isn't just about crossing out words anymore—it now represents text that is no longer accurate or relevant, and has been "struck" from the document. Both of these changes are subtler than the `<small>` element's shift in meaning, because they capture ways that the `<hr>` and `<s>` elements are commonly used in traditional HTML.

Bold and italic formatting

The most important adapted elements are the ones for bold and italic formatting. Two of HTML's most commonly used elements—that's `` for bold and `<i>` for italics—were partially replaced when the first version of XHTML introduced the look-alike `` and `` elements. The idea was to stop looking at things from a formatting point of view (bold and italics), and instead substitute elements that had a real logical meaning (strong importance or stress emphasis). The idea made a fair bit of sense, but the `` and `<i>` tags lived on as shorter and more familiar alternatives to the XHTML fix.

HTML5 takes another crack at solving the problem. Rather than trying to force developers away from `` and `<i>`, it assigns new meaning to both elements. The idea is to allow all four elements to coexist in a respectable HTML5 document. The result is the somewhat confusing set of guidelines listed here:

- Use **``** for text that has *strong importance*. This is text that needs to stand out from its surroundings.
- Use **``** for text that should be presented in bold but doesn't have greater importance than the rest of your text. This could include keywords, product names, and anything else that would be bold in print.
- Use **``** for text that has *emphatic stress*—in other words, text that would have a different inflection if read out loud.
- Use **`<i>`** for text that should be presented in italics but doesn't have extra emphasis. This could include foreign words, technical terms, and anything else that you'd set in italics in print.

And here's a snippet of markup that uses all four of these elements in the appropriate way:

```
<strong>Breaking news!</strong> There's a sale on <i>leche quemada</i> candy
at the <b>El Azul</b> restaurant. Don't delay, because when the last candy
is gone, it's <em>gone</em>.
```

In the browser, the text looks like this:

Breaking news! There's a sale on *leche quemada* candy at the **El Azul** restaurant. Don't delay, because when the last candy is gone, it's *gone*.

It remains to be seen if web developers will follow HTML's well-intentioned rules, or just stick with the most familiar elements for bold and italic formatting.

Tweaked Elements

HTML5 also shifts the rules of a few elements. Usually, these changes are minor details that only HTML wonks will notice, but occasionally they have deeper effects. One example is the rarely used `<address>` element, which is not suitable (despite the name) for postal addresses. Instead, the `<address>` element has the narrow purpose of providing contact information for the creator of the HTML document, usually as an email address or website link:

```
Our website is managed by:
<address>
<a href="mailto:jsolo@mysite.com">John Solo</a>,
<a href="mailto:lcheng@mysite.com">Lisa Cheng</a>, and
<a href="mailto:rpavane@mysite.com">Ryan Pavane</a>.
</address>
```

The `<cite>` element has also changed. It can still be used to cite some work (for example, a story, article, or television show), like this:

```
<p>Charles Dickens wrote <cite>A Tale of Two Cities</cite>.</p>
```

However, it's not acceptable to use `<cite>` to mark up a person's name. This restriction has turned out to be surprisingly controversial, because this usage was allowed before. Several guru-level web developers are on record urging people to disregard the new `<cite>` rule, which is a bit odd, because you can spend a lifetime editing web pages without ever stumbling across the `<cite>` element in real life.

A more significantly tweak affects the `<a>` element for creating links. Past versions of HTML have allowed the `<a>` element to hold clickable text or a clickable image. In HTML5, the `<a>` element allows anything and everything, which means it's perfectly acceptable to stuff entire paragraphs in there, along with lists, images, and so on. (If you do, you'll see that all the text inside becomes blue and underlined, and all the images inside sport blue borders.) Web browsers have supported this behavior for years, but it's only HTML5 that makes it an official, albeit not terribly useful, part of the HTML standard.

There are also some tweaks that don't work yet—in any browser. For example, the `` element (for ordered lists) now gets a *reversed* attribute, which you can set to count backward (either toward 1, or toward whatever starting value you set with the *start* attribute), but no browsers recognize this setting yet.

You'll learn about a few more tweaks as you make your way through this book.

Standardized Elements

HTML5 also adds supports for a few elements that were supported but weren't officially welcome in the HTML or XHTML language. One of the best-known examples is `<embed>`, which is used all over the Web as an all-purpose way to shoehorn a plug-in into a page.

A more exotic example is `<wbr>`, which indicates an optional word break—in other words, a place where the browser can split a line if the word is too long to fit in its container:

```
<p>Many linguists remain unconvinced that
  <b>supercali<wbr>fragilistic<wbr>expialidocious</b> is indeed a word.</p>
```

The `<wbr>` element is useful when you have long names (sometimes seen in programming terminology) in small places, like table cells or tiny boxes. Even if the browser supports `<wbr>`, it will break the word only if it doesn't fit in the available space. In the previous example, that means the browser may render the word in one of the following ways:

Many linguists remain
unconvinced that
supercalifragilisticexpialidocious
is indeed a word.

Many linguists remain
unconvinced that
**supercalifragilistic
expialidocious** is indeed a
word.

Many linguists
remain
unconvinced
that **supercali
fragilistic
expialidocious**
is indeed a
word.

The `<wbr>` element pairs naturally with the standard `<noabr>` element (which you can use to prevent a term from being split where there's a space). But until HTML5, the `<wbr>` existed as a nonstandard extension that was supported in only some browsers.

Using HTML5 Today

As you’ve seen, HTML5 is an odd mix. At the same time that it revives (and standardizes) some of the old *laissez-faire* rules of HTML, it also introduces bleeding-edge features that won’t work in anything but the newest browsers around.

As far as browser compatibility is concerned, you can think of HTML5 features in three categories:

- **Features that already work.** This includes features that are well supported but weren’t an official part of HTML in the past (like drag-and-drop). It also includes features that can work on older browsers with very little extra work, like the semantic elements described in Chapter 2.
- **Features that degrade gracefully.** For example, the new `<video>` element has a fallback mechanism that lets you supply something else to older browsers, like a video player that uses the Flash plug-in. (Supplying an error message is somewhat rude, and definitely not an example of degrading gracefully.) This category also includes nonessential frills that older browsers can safely ignore, like some of the web form features (like placeholder text) and some of the formatting properties from CSS3 (like rounded corners and drop shadows).
- **Features that require a JavaScript workaround.** Many of HTML5’s new features are inspired by the stuff web developers are already doing the hard way. Thus, it should come as no surprise that you can duplicate many of HTML5’s features using a good JavaScript library (or, in the worst-case scenario, by writing a whack-load of your own custom JavaScript). Creating JavaScript workarounds can be a lot of work, and if you decide a feature is essential and needs a workaround, you may simply decide to use that workaround for everybody, and save the HTML5 approach for the future.

This book assumes that you want to use the HTML5 approach when it’s completely safe—that’s the first feature category in the list above. If a feature falls into one of the other categories (and many do), it’s up to you to determine if you want to put the work into developing an old-browser solution, or whether you’re just here to bide your time and prepare for the greener pastures ahead. If a good JavaScript workaround exists on the Web, this book will point it out. However, many times you’ll face a murky choice between fancy new features and universal compatibility.

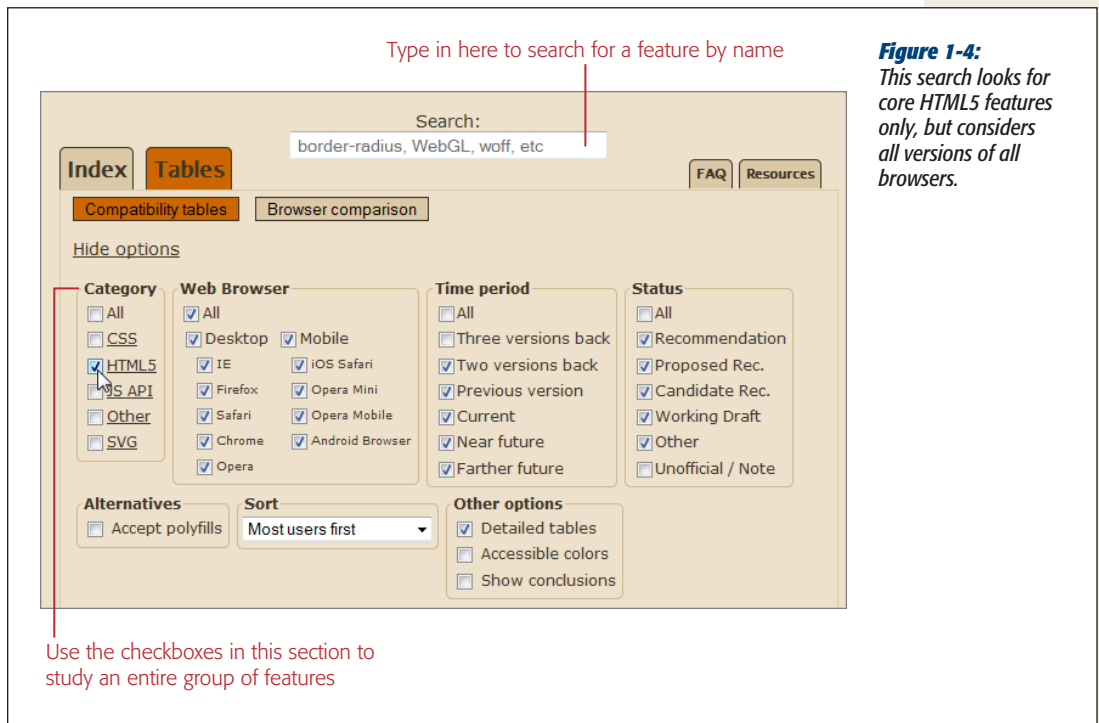

Evaluating Browser Support

The people who have the final word on how much HTML5 you use are the browser vendors. If they don’t support a feature, there’s not much point in attempting to use it, no matter what the standard says. Today, there are four or five major browsers (not including mobile browsers designed for web-connected devices like smartphones and iPads). A single web developer has no chance of testing each prospective feature on every browser—not to mention evaluating support in older versions that are still widely used.

Fortunately, there's a website named <http://caniuse.com> that can help you out. It details the HTML5 support found in *every* mainstream browser. Best of all, it lets you focus on exactly the features you need. Here's how it works:

1. First, at the top of the page, pick the feature (or group of features) that you're interested in using in the checkboxes (Figure 1-4).

You can search for a specific feature by typing its name into the Search box near the top of the page. Or, you can look at a whole category of features (in which case, you'll get a separate compatibility table for each subfeature) by using the checkboxes in the Category box. For example, click HTML5 and clear the other checkboxes to see only those features that are considered a part of the HTML5 standard. Choose JS API to see many of the JavaScript-powered features that began as part of HTML5 but have since been split off. And choose CSS to explore support for fancy new CSS3 features.

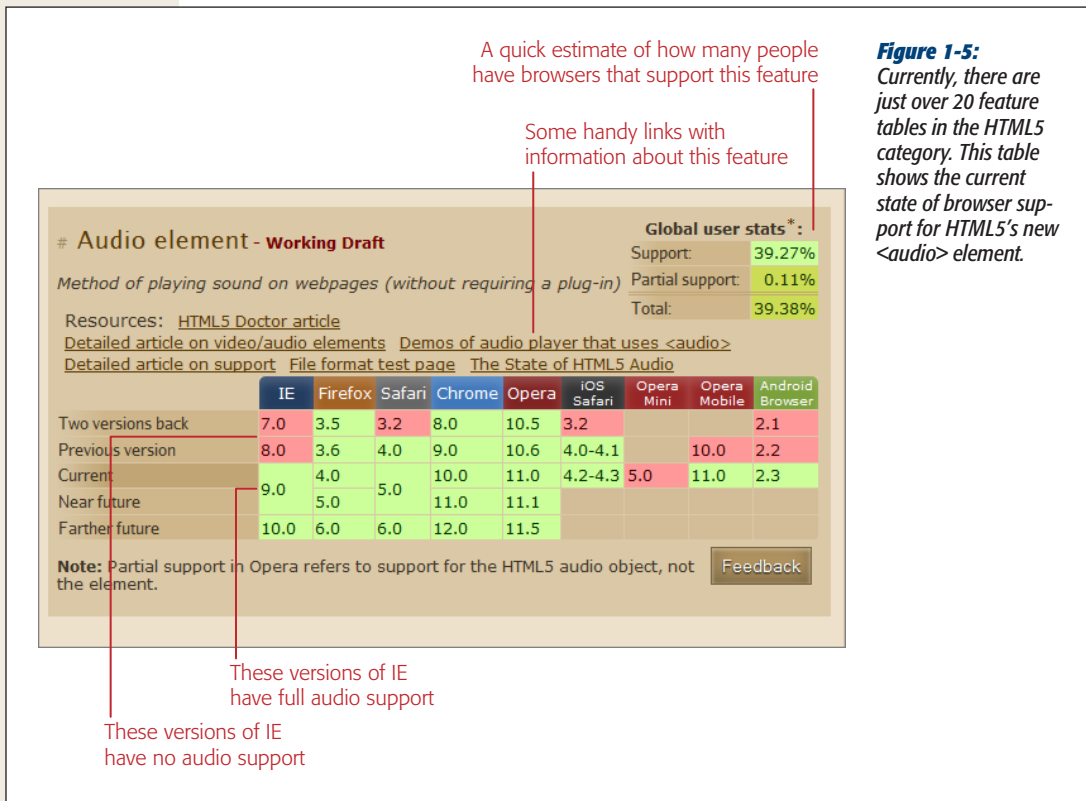

2. Optionally, pick your other options using the other checkboxes.

You can refine your tables by removing some details. For example, you may not want to see compatibility information for mobile browsers or for browsers that are still in development and not officially released. However, it's usually easiest to just keep all these options switched on, since the tables are still easy to read.

3. Scroll down to see your results (Figure 1-5).

If you're looking at a large batch of features, you'll see only 20 tables at a time. You can move from one page to the next by clicking the "Show next 20" link at the bottom of the page.

Each feature table shows a grid of different browser versions. The tables indicate support with the color of the cell, which can be red (no support), bright green (full support), olive green (partial support), or gray (undetermined, usually because this version of the browser is still under development and the feature hasn't been added yet).

Browser Adoption Statistics

Browser adoption statistics fill in the last piece of the puzzle. They tell you what portion of your audience has a browser that supports the features you plan to use. One good place to get a look is the popular GlobalStats site <http://gs.statcounter.com>. Once you get there, choose Browser Version in the Statistic list box (under the chart). This chart lets you consider not just which browsers are being used, but which *versions* of each browser. You can also pick a geographic region, like North America, from the Country/Region list box.

UP TO SPEED

Is IE Being Left Behind?

As you explore HTML5, you'll quickly find that one browser stands out with the weakest HTML5 support (and the slowest upgrade rate). This laggard is Internet Explorer. Although Microsoft took a giant step forward with Internet Explorer 9, IE's HTML5 support still trails every other modern browser.

Microsoft isn't ignoring the newest developments in the HTML5 universe, but it *is* holding off on implementing features that aren't finished. For some of these features, Microsoft provides experimental IE extensions (called HTML5 "labs"), which you can download at <http://html5labs.interoperabilitybridges.com>. This is a great if you simply want to play around with some new, still-evolving HTML5 features. But it's no help if you actually want to start

implementing them in a real web application. (Of course, implementing some of these features borders on foolhardy, but that's a completely different subject.)

But there's an even more significant issue in IE's support for HTML5. As explained earlier, IE 9 is the first version of IE to support any HTML5 features. It requires Windows 7 or Windows Vista. People using Windows XP (which still ranks as the world's most popular operating system, despite its age) can't use IE 9, and so they can't get *any* HTML5 support. And while these abandoned computer users aren't totally left out—they can still use a competing browser—it'll be a long time before web developers can switch over to HTML5 without worrying about feature detection and fallbacks.

Lastly, you can pick the chart type using the option buttons that are just to the right of the chart box. Pick Bar to see a bar chart that shows a snapshot of the current situation. Pick Line to see a line chart that shows the trend in browser adoption over time. By default, line charts show the entire previous year (Figure 1-6), but you can tweak the date range to focus on the time period that interests you.

Figure 1-6: This chart shows that HTML5 support is a gamble. The world's current most popular browser, IE 8, has none.

GlobalStats compiles its statistics daily using tracking code that's present on millions of websites. And while that's a large number of pages and a huge amount of data, it's still just a small fraction of the total Web, which means you can't necessarily assume that your website visitors will have the same browsers.

Furthermore, browser-share results change depending on the web surfer's country and the type of website. For example, in Germany, Firefox is the top browser with 60 percent of web surfers, while in Belarus, Opera wins the day with a 49 percent share. And on the TechCrunch website (a popular news site for computer nerds), barely 16 percent use any version of the world's most popular web browser, Internet Explorer. So if you want to design a website that works for your peeps, review the web statistics generated by your own pages. (And if you aren't already using a web tracking service for your site, check out the top-tier and completely free Google Analytics, at www.google.com/analytics.)

Feature Detection with Modernizr

For the next few years, it'll be a fact of life that some of your visitors' browsers won't support HTML5. That doesn't need to stop you from using these features, if you're willing to put in some work to create a workaround or degrade gracefully. Either way, you'll probably need the help of some JavaScript code. The typical pattern is this: Your page loads and a script runs to check whether a specific feature is available.

Unfortunately, because HTML5 is, at its heart, a loose collection of related standards, there's no single support test. Instead, you need dozens of different tests to check for dozens of different features—and sometimes even to check if a specific *part* of a feature is supported, which gets ugly fast.

Checking for support usually involves looking for a property on a programming object, or creating an object and trying to use it a certain way. But think twice before you write this sort of feature-testing code, because it's so easy to do it badly. For example, your feature-testing code might fail on certain browsers for some obscure reason or another, or quickly become out of date. Instead, consider using Modernizr (www.modernizr.com), a small, constantly updated tool that tests the support of a wide range of HTML5 and related features. It also has a cool trick for implementing fallback support when you're using new CSS3 features, which you'll see on page 240.

Here's how to use Modernizr in one of your web pages:

1. Look for the “Download Modernizr” box. In it, click the Development button to download the Modernizr JavaScript file.

Typically, this file has a name like *modernizr-2.0.6.js*. The exact name depends on the version you're using. Some developers rename the file so it doesn't include the version number (say, *modernizr.js*). That way you can update the Modernizr script file in the future without needing to modify the script reference in the web pages that use it.

Tip: The full Modernizr script is a bit bulky. It's intended for testing purposes while you're still working on your website. Once you've finished development and you're ready to go live, you can create a slimmed-down version of the Modernizr script that tests only for the features you need. To do so, click the Production button in the "Download Modernizr" box. This takes you to a page where you can pick and choose the features you want to detect (by clicking the appropriate checkboxes) and then create your custom version (by clicking the Generate button).

2. Place the file in the same folder as your web page.

Or, place it in a subfolder, and modify the path in the JavaScript reference (see the next step) accordingly.

3. Add a reference to the JavaScript file in the <head> section of your web page.

Here's an example of what your markup might look like:

```
<head>
  <meta charset="utf-8">
  <title>HTML5 Feature Detection</title>
  <script src="modernizr-2.0.6.js"></script>
  ...
</head>
```

Now, when your page loads, the Modernizr script runs. It tests for a couple of dozen new features, in mere milliseconds, and then creates a JavaScript object called Modernizr that contains the results. You can test the properties of this object to check the browser's support for a specific feature.

Tip: For the full list of features that Modernizr tests, and for the JavaScript code that you need to examine each one, refer to the documentation at www.modernizr.com/docs.

4. Write some script code that tests for the feature you want and then carries out the appropriate action.

For example, here's how you might test whether Modernizr supports the HTML5 drag-and-drop feature, and show the result in the page:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>HTML5 Feature Detection</title>
  <script src="modernizr-2.0.6.js"></script>
</head>

<body>
  <p>The verdict is... <span id="result"></span></p>

  <script>
    // Find the element on the page (named result) where you can show
    // the results.
    var result = document.getElementById("result");
```

```

if (Modernizr.draganddrop) {
    result.innerHTML = "Rejoice! Your browser supports drag-and-drop.";
}
else {
    result.innerHTML = "Your feeble browser doesn't support drag-and-drop.";
}
</script>
</body>

</html>

```

Figure 1-7 shows the result.

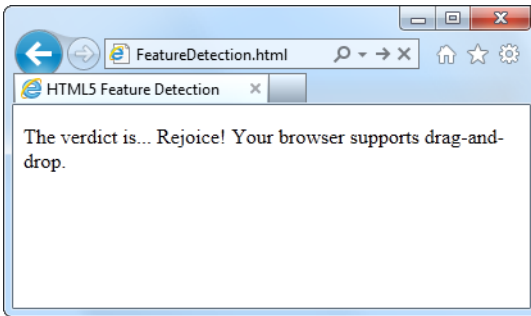

Figure 1-7:

Although this example shows the right way to test for features, it shows a less-than-ideal approach for dealing with them. Instead of telling your website visitor about a missing feature, it's far, far better to implement some sort of workaround (even if it's not as neat or fully featured as the HTML5 equivalent) or simply ignore the problem altogether (if the missing feature is a minor frill that's not necessary for the visitor to enjoy the page).

Tip: This example uses basic and time-honored JavaScript techniques—looking up an element by ID and changing its content. If you find it a bit perplexing, you can brush up with the JavaScript review in Appendix B.

Feature “Filling” with Polyfills

Modernizr helps you spot the holes in browser support. It alerts you when a feature won't work. However, it doesn't do anything to patch these problems. That's where *polyfills* come in. Basically, polyfills are a hodgepodge collection of techniques for filling the gaps in HTML5 support on aging browsers. The word *polyfills* is borrowed from the product polyfiller, a compound that's used to fill in drywall holes before painting (also known as spackling paste). In HTML5, the ideal polyfill is one you can drop into a page without any extra work. It takes care of backward compatibility in a seamless, unobtrusive way, so you can work with pure HTML5 while someone else worries about the workarounds.

But polyfills aren't perfect. Some rely on other technologies that may be only partly supported. For example, one polyfill allows you to emulate the HTML5 <canvas> on old versions of Internet Explorer using the Silverlight plug-in. But if the web visitor isn't willing or able to install Silverlight, you need to fall back on something else. Other polyfills may have fewer features than the real HTML5 feature, or poorer performance.

GEM IN THE ROUGH

Retrofitting IE with Google Chrome Frame

The biggest polyfill of them all is Google Chrome Frame, a browser plug-in for Internet Explorer versions 6, 7, 8, and 9. It works by asking the Chrome browser to run inside the IE browser, and process HTML5 pages. However, Chrome Frame doesn't go to work on all HTML5 pages. Instead, it only kicks in if the website creator has added some information to the page that explicitly allows it.

The obvious limitation to Chrome Frame is that users need to have it installed in order for websites to use it—and if they're willing to do that, why not just run the full Chrome browser? But if you'd like to learn more about Chrome Frame, you can read Google's documentation at <http://code.google.com/chrome/chromeframe>.

Occasionally, this book will point you to a potential polyfill. If you want more information, you can find the closest thing there is to a comprehensive catalog of HTML5 polyfills on GitHub at <http://tinyurl.com/polyfill>. But be warned—polyfills differ greatly in quality, performance, and support.

Tip: Remember, it's not enough to simply know that a polyfill exists for a given HTML5 feature. You must test it and check how well it works on various old browsers *before* you risk incorporating the corresponding feature into your website.

With tools like browser statistics, feature detection, and polyfills, you're ready to think long and hard about integrating HTML5 features into your own web pages. In the next chapter, you'll take the first step, with some HTML5 elements that can function in browsers both new and old.

A New Way to Structure Pages

Over the nearly two decades that the Web's been around, websites have changed dramatically. But the greatest surprise isn't how much the Web has changed, but how well ancient HTML elements have held up. In fact, web developers use the same set of elements to build today's modern sites that they used to build their predecessors 10 years ago.

One element in particular—the humble `<div>` (or *division*)—is the cornerstone of nearly every modern web page. Using `<div>` elements, you can carve an HTML document into headers, side panels, navigation bars, and more. Add a healthy pinch of CSS formatting, and you can turn these sections into bordered boxes or shaded columns, and place each one exactly where it belongs.

This `<div>`-and-style technique is straightforward, powerful, and flexible—but it's not *transparent*. That means when you look at someone else's markup, it takes some effort to figure out what each `<div>` represents and how the whole page fits together. To make sense of it all, you need to jump back and forth among the markup, the style sheet, and the actual page in the browser. And you'll face this confusion every time you crack open anyone else's halfway-sophisticated page, even though you're probably using the same design techniques in your own websites.

This situation got people thinking. What if there were a way to replace `<div>` with something better? Something that worked like `<div>`, but conveyed a bit more meaning. Something that might help separate the sidebars from the headers and the ad bars from the menus. HTML5 fulfills this dream with a set of new elements for structuring pages.

Tip: If your CSS skills are so rusty that you need a tetanus shot before you can crack open a style sheet, then you're not quite ready for this chapter. Fortunately, Appendix A has a condensed introduction that covers the CSS essentials you need to know.

Introducing the Semantic Elements

To improve the structure of your web pages, you need HTML5's new *semantic elements*. These elements give extra meaning to the content they enclose.

For example, the new `<time>` element flags a valid date or time in your web page. Here's an example of the `<time>` element at its very simplest:

```
Registration begins on <time>2012-11-25</time>.
```

And this is what someone sees when viewing the page:

```
Registration begins on 2012-11-25.
```

The important thing to understand is that the `<time>` element doesn't have any built-in formatting. In fact, the web page reader has no way of knowing that there's an extra element wrapping the date. You can add your own formatting to the `<time>` element using a style sheet, but by default, it's indistinguishable from ordinary text.

The `<time>` element is designed to wrap a single piece of information. However, most of HTML5's semantic elements are different: They're designed to identify larger sections of content. For example, the `<nav>` element identifies a set of navigation links. The `<footer>` element wraps the footer that sits at the bottom of a page. And so on, for a dozen (or so) new elements.

Note: Although semantic elements are the least showy of HTML5's new features, they're one of the largest. In fact, the majority of the new elements in HTML5 are semantic elements.

All the semantic elements share a distinguishing feature: They don't really do anything. By contrast, the `<video>` element, for example, embeds a fully capable video player in your page (page 148). So why bother using a new set of elements that doesn't change the way your web page looks?

There are several good reasons:

- **Easier editing and maintenance.** It can be difficult to interpret the markup in a traditional HTML page. To understand the overall layout and the significance of various sections, you'll often need to scour a web page's style sheet. But by using HTML5's semantic elements, you provide extra structural information in the markup. That makes your life easier when you need to edit the page months later, and it's even more important if someone else needs to revise your work.

- **Accessibility.** One of the key themes of modern web design is making *accessible* pages—that is, pages that people can navigate using screen readers and other assistive tools. Right now, the companies that create accessibility tools are still scrambling to catch up to HTML5. When they do, they’ll be able to provide a far better browsing experience for disabled visitors. (For just one example, imagine how a screen reader can home in on the <nav> sections to quickly find the navigation links for a website.)

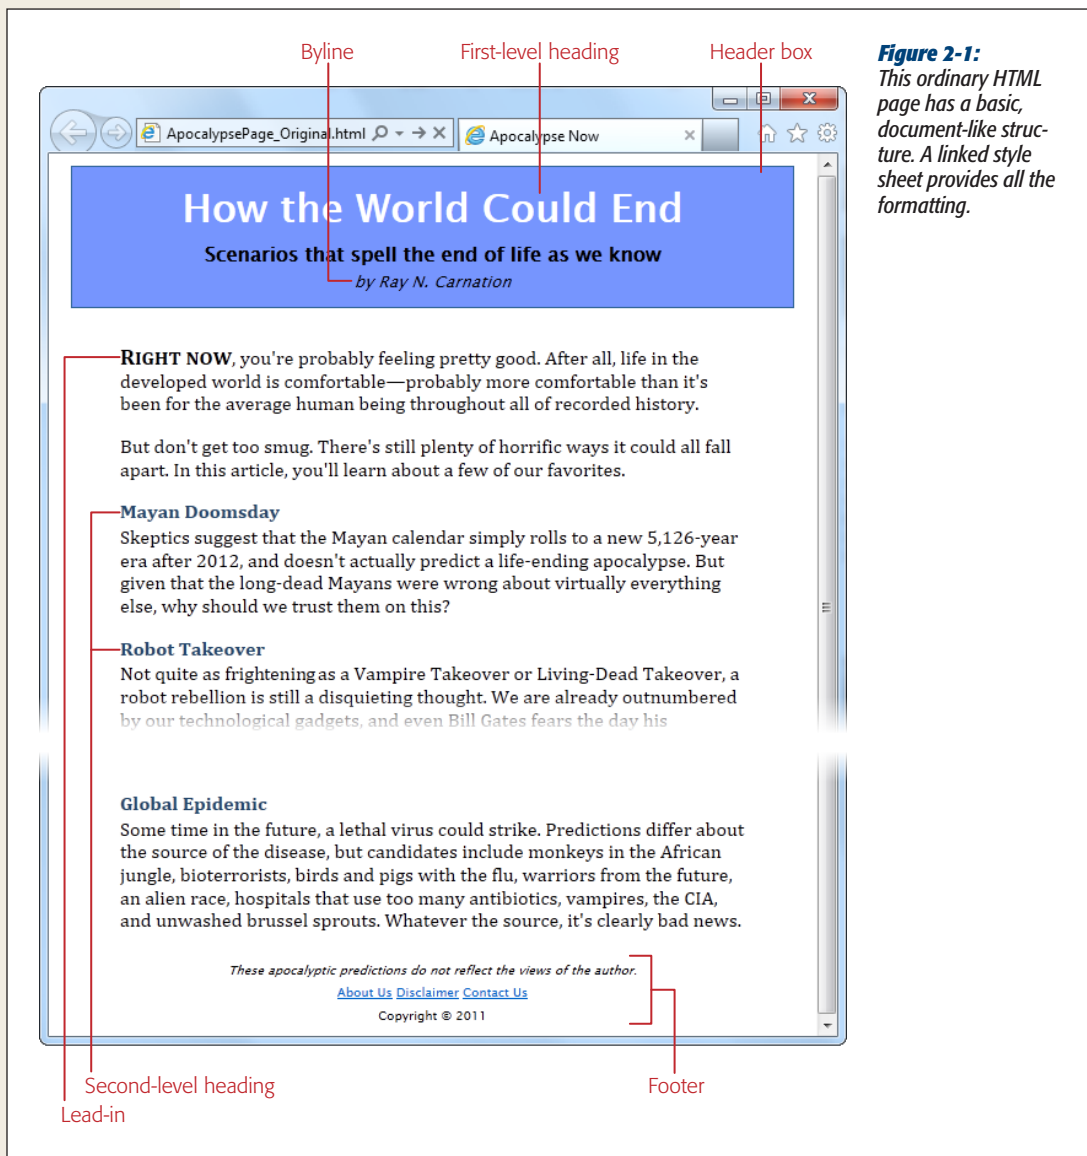

Tip: To learn more about the best practices for web accessibility, you can visit the WAI (Web Accessibility Initiative) website at www.w3.org/WAI. Or, to get a quick look at what life is like behind a screen reader (and to learn why properly arranged headings are so important), check out the YouTube video at <http://tinyurl.com/6bu4pe>.

- **Search-engine optimization.** Search engines like Google use powerful *search bots*—automated programs that crawl the Web and fetch every page they can—to scan your content and index it in their search databases. The better Google understands your site, the better the chance that it can match a web searcher’s query to your content, and the better the chance that your website will turn up in someone’s search results. Search bots already check for some of HTML5’s semantic elements to glean more information about the pages they’re indexing.
- **Future features.** New browsers and web editing tools are sure to take advantage of semantic elements in ways both small and large. For example, a browser could provide an outline that lets visitors jump to the appropriate section in a page, like the Navigation Pane in Microsoft Word 2010. (In fact, Chrome already has a plug-in that does exactly that—see page 71.) Similarly, web design tools might include features that let you build or edit navigation menus, by managing the content you’ve placed in the <nav> section.

The bottom line is this: If you can apply the semantic elements correctly, you can create cleaner, clearer pages that are ready for the next wave of browsers and web tools. But if your brain is still tied up with the old-fashioned practices of traditional HTML, the future just might pass you by.

Retrofitting a Traditional HTML Page

The easiest way to introduce yourself to the new semantic elements—and to learn how to use them to structure a page—is to take a classic HTML document and inject it with some HTML5 goodness. Figure 2-1 shows the first example you’ll tackle. It’s a simple, standalone web page that holds an article, although other types of content (like a blog posting, a product description, or a short story) would work equally well.

Tip: You can view or download the example in Figure 2-1 from the try-out site at www.prosetech.com/html5, along with all the examples for this chapter. Start with `ApocalypsePage_Original.html` if you'd like to try to remodel the HTML yourself, or `ApocalypsePage_Revised.html` if you want to jump straight to the HTML5-improved final product.

Page Structure the Old Way

There are a number of ways to format a page like the one shown in Figure 2-1. Happily, this example uses HTML best practices, which means the markup doesn't have a lick of formatting logic. There are no bold or italic elements, no inline styles, and certainly nothing as hideous as the obsolete `` element. Instead, it's a neatly formatted document that's bound to an external style sheet.

Here's a shortened version of the markup, which highlights where the document plugs into its style sheet:

```
<div class="Header">
  <h1>How the World Could End</h1>
  <p class="Teaser">Scenarios that spell the end of life as we know</p>
  <p class="Byline">by Ray N. Carnation</p>
</div>

<div class="Content">
  <p><span class="LeadIn">Right now</span>, you're probably ...</p>
  <p>...</p>

  <h2>Mayan Doomsday</h2>
  <p>Skeptics suggest ...</p>
  ...
</div>

<div class="Footer">
  <p class="Disclaimer">These apocalyptic predictions ...</p>
  <p>
    <a href="AboutUs.html">About Us</a>
    ...
  </p>
  <p>Copyright © 2011</p>
</div>
```

UP TO SPEED

What Are These Dots (...)?

This book can't show you the full markup for every example—at least not without expanding itself to 12,000 pages and wiping out an entire old-growth forest. But it *can* show you basic structure of a page, and all its important elements. To do that, many of the examples in this book use an ellipsis (a series of three dots) to show where some content has been left out.

For example, consider the markup shown on this page. It includes the full body of the page shown in Figure 2-2, but it leaves out the full text of most paragraphs, most of the article after the “Mayan Doomsday” heading, and the full list of links in the footer. But as you know, you can pore over every detail by examining the sample files for this chapter on the try-out site (www.prosetech.com/html5).

In a well-written, traditional HTML page (like this one), most of the work is farmed out to the style sheet using the `<div>` and `` containers. The `` lets you format snippets of text inside another element. The `<div>` allows you to format entire sections of content, and it establishes the overall structure of the page (Figure 2-2).

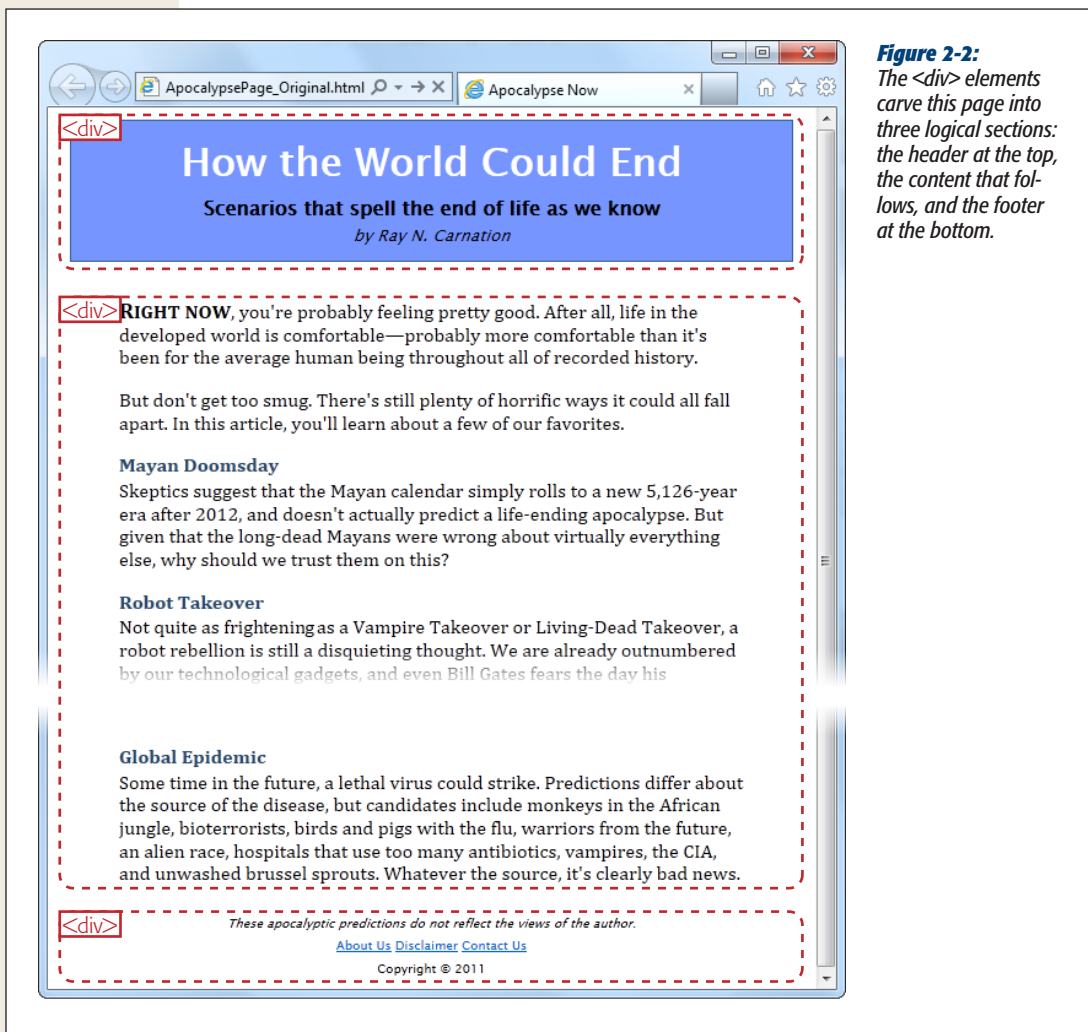

Figure 2-2:
The `<div>` elements
carve this page into
three logical sections:
the header at the top,
the content that fol-
lows, and the footer
at the bottom.

Here, the style-sheet formatting tasks are simple. The entire page is given a maximum width (800 pixels) to prevent really long text lines on widescreen monitors. The header is put in a blue bordered box. The content is padded on either side, and the footer is centered at the bottom of the page.

Thanks to the `<div>`, formatting is easy. For example, here are the style sheet rules that format the header box and the content inside:

```
/* Format the <div> that represents the header (as a blue, bordered box). */
.Header {
  background-color: #7695FE;
  border: thin #336699 solid;
  padding: 10px;
  margin: 10px;
  text-align: center;
}

/* Format any <h1> headings in the header <div> (that's the article title). */
.Header h1 {
  margin: 0px;
  color: white;
  font-size: xx-large;
}

/* Format the subtitle in the header <div>. */
.Header .Teaser {
  margin: 0px;
  font-weight: bold;
}

/* Format the byline in the header <div>. */
.Header .Byline {
  font-style: italic;
  font-size: small;
  margin: 0px;
}
```

You'll notice that this example makes good use of contextual selectors (page 387). For example, it uses the selector `.Header h1` to format all `<h1>` elements in the header box.

Tip: This example is also described in the CSS review in Appendix A. If you'd like to take a detailed walk through the style sheet rules that format each section, flip to page 391.

Page Structure with HTML5

The `<div>` element is a staple of current-day web design. It's a straightforward, all-purpose container that can apply formatting anywhere you want in a web page. The limitation of the `<div>` is that it doesn't provide any information about the page. When you (or a browser, or a design tool, or a screen reader, or a search bot) come across a `<div>`, you know that you've found a separate section of the page, but you don't know the purpose of that section.

To improve this situation in HTML5, you can replace some of your `<div>` elements with more descriptive semantic elements. The semantic elements behave exactly like a `<div>` element: They group a block of markup, they don't do anything on their own, and they give you a styling hook that allows you to apply formatting. However, they also add a little bit more semantic smarts to your page.

Here's a quick revision of the article shown in Figure 2-1. It removes two `<div>` elements and adds two semantic elements from HTML5: `<header>` and `<footer>`.

```
<header class="Header">
  <h1>How the World Could End</h1>
  <p class="Teaser">Scenarios that spell the end of life as we know</p>
  <p class="Byline">by Ray N. Carnation</p>
</header>

<div class="Content">
  <p><span class="LeadIn">Right now</span>, you're probably ...</p>
  <p>...</p>

  <h2>Mayan Doomsday</h2>
  <p>Skeptics suggest ...</p>
  ...
</div>

<footer class="Footer">
  <p class="Disclaimer">These apocalyptic predictions ...</p>
  <p>
    <a href="AboutUs.html">About Us</a>
    ...
  </p>
  <p>Copyright © 2011</p>
</footer>
```

In this example, the `<header>` and `<footer>` elements take the place of the `<div>` elements that were there before. Web developers who are revising a large website might start by wrapping the existing `<div>` elements in the appropriate HTML5 semantic elements.

You'll also notice that the `<header>` and `<footer>` elements still use class names. This way, there's no immediate need to change the style sheet. However, the class names seem a bit redundant, so you might prefer to leave them out, like this:

```
<header>
  <h1>How the World Could End</h1>
  <p class="Teaser">Scenarios that spell the end of life as we know</p>
  <p class="Byline">by Ray N. Carnation</p>
</header>
```

Because the page has just a single header, you can target it by element name. Here's the revised style sheet that applies its formatting to all <header> elements:

```
/* Format the <header> (as a blue, bordered box.) */
header {
    ...
}

/* Format any <h1> headings in the <header> (that's the article title). */
header h1 {
    ...
}

/* Format the subtitle in the <header>. */
header .Teaser {
    ...
}

/* Format the byline in the <header>. */
header .Byline {
    ...
}
```

Both approaches are equally valid. As with many design decisions in HTML5, there are plenty of discussions but no hard rules.

You'll notice that the <div> section for the content remains. This is perfectly acceptable, as HTML5 web pages often contain a mix of semantic elements and the more generic <div> container. Because there's no HTML5 "content" element, an ordinary <div> still makes sense.

Note: Left to its own devices, this web page won't display correctly on versions of Internet Explorer before IE 9. To fix this issue, you need the simple workaround discussed on page 59. But first, check out a few more semantic elements that can enhance your pages.

Finally, there's one more element worth adding to this example. HTML5 includes an <article> element that represents a complete, self-contained piece of content, like a blog posting or a news story. The <article> element includes the whole shebang, including the title, author byline, and main content. Once you add the <article> element to the page, you get this structure:

```
<article>
  <header>
    <h1>How the World Could End</h1>
    ...
  </header>

  <div class="Content">
    <p><span class="LeadIn">Right now</span>, you're probably ...</p>
    <p>...</p>
```

```

    <h2>Mayan Doomsday</h2>
    <p>Skeptics suggest ...</p>
    ...
  </div>
</article>

<footer>
  <p class="Disclaimer">These apocalyptic predictions ...</p>
  ...
</footer>

```

Figure 2-3 shows the final structure.

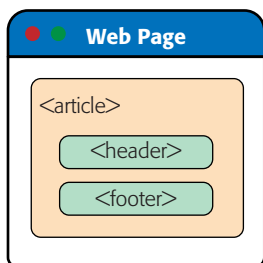

Figure 2-3:

After the redesign, the page uses three of HTML5's semantic elements. If the old structure said, "Here is a page with three sections," then the new structure says, "Here is an article with a header and a footer."

Although the web page still looks the same in the browser, there's a fair bit of extra information lurking behind the scenes. For example, a search bot that stops by your site can quickly find the content on the page (that's your article) and the title of that content (that's the header). It won't pay as much attention to the footer.

Note: Sometimes articles are split over several web pages. The current consensus of webheads is that each part of the article should be wrapped in its own `<article>` element, even though it's not complete and self-contained. This messy compromise is just one of many that occur when semantics meet the practical, presentational considerations of the Web.

Subtitles with `<hgroup>`

The previous example puts the `<header>` to good use. However, HTML5 actually adds two heading-related elements: `<header>` and `<hgroup>`. Here are the official guidelines about how to use them.

First, if you have an ordinary title, all on its own with no special content, a numbered heading element (like `<h1>`, `<h2>`, `<h3>`, and so on) will do fine on its own:

```
<h1>How the World Could End</h1>
```

If you have a title and a subtitle, you can wrap the two of them in an `<hgroup>`. But don't try to sneak anything in there other than numbered heading elements (that's `<h1>`, `<h2>`, `<h3>`, and so on):

```
<hgroup>
  <h1>How the World Could End</h1>
  <h2>Scenarios that spell the end of life as we know</h2>
</hgroup>
```

If you have a “fat” header—one that includes the title and some other content (for example, a summary, the publication date, an author byline, an image, or subtopic links)—you should wrap the whole thing in the `<header>` element:

```
<header>
  <h1>How the World Could End</h1>
  <p class="Byline">by Ray N. Carnation</p>
</header>
```

Finally, if you have a fat header that *also* has a subtitle, you need to throw a `<header>` around your `<hgroup>` to mark up the extra content, like this:

```
<header>
  <hgroup>
    <h1>How the World Could End</h1>
    <h2>Scenarios that spell the end of life as we know</h2>
  </hgroup>
  <p class="Byline">by Ray N. Carnation</p>
</header>
```

This, of course, is the content from the previous example, with a slight change: The subtitle is marked up with the `<h2>` element instead of `<p>`.

At first glance, this markup seems potentially confusing. It could, structurally speaking, imply that all the content that follows is part of a subsection that starts with the level 2 heading, which doesn't make much sense. After all, who wants an article that consists entirely of one big subsection? And even though setup this doesn't affect the way the page appears in a browser, it does change the way browsers and other tools build a *document outline* for your page (as you'll see on page 70).

Fortunately, the `<hgroup>` element solves the problem automatically. Structurally speaking, it pays attention to the top-level heading *only* (in this case, that's the `<h1>`). Other headings are shown in the browser, but they don't become part of the document outline. This behavior makes perfect sense, because these headings are meant to indicate subtitles, not subsections.

Adding a Figure with `<figure>`

Plenty of pages have images. But the concept of a *figure* is a bit different. The HTML5 specification suggests that you think of them much like figures in a book—in other words, a picture that's separate from the text, yet referred to in the text.

Generally, you let figures *float*, which means you put them in the nearest convenient spot alongside your text (rather than lock them in place next to a specific word or element). Often, figures have captions that float with them.

The following example shows some HTML markup that adds a figure to the apocalyptic article. (It also includes the paragraph that immediately precedes the figure and the one that follows it, so you can see exactly where the figure is placed in the markup.)

```
<p><span class="LeadIn">Right now</span>, you're probably ...</p>

<div class="FloatFigure">
  
  <p>Will you be the last person standing if one of these apocalyptic
    scenarios plays out?</p>
</div>

<p>But don't get too smug ...</p>
```

This markup assumes that you've created a style sheet rule that positions the figure (and sets margins, controls the formatting of the caption text, and optionally draws a border around it). Here's an example:

```
/* Format the floating figure box. */
.FloatFigure {
  float: left;
  margin-left: 0px;
  margin-top: 0px;
  margin-right: 20px;
  margin-bottom: 0px;
}

/* Format the figure caption text. */
.FloatFigure p {
  max-width: 200px;
  font-size: small;
  font-style: italic;
  margin-bottom: 5px;
}
```

Figure 2-4 shows this example at work.

If you've created this sort of figure before, you'll be interested to know that HTML5 provides new semantic elements that are tailor-made for this pattern. Instead of using a boring `<div>` to hold the figure box, you use a `<figure>` element. And if you have any caption text, you put that in a `<figcaption>` element inside the `<figure>`:

```
<figure class="FloatFigure">
  
  <figcaption>Will you be the last person standing if one of these
    apocalyptic scenarios plays out?</figcaption>
</figure>
```

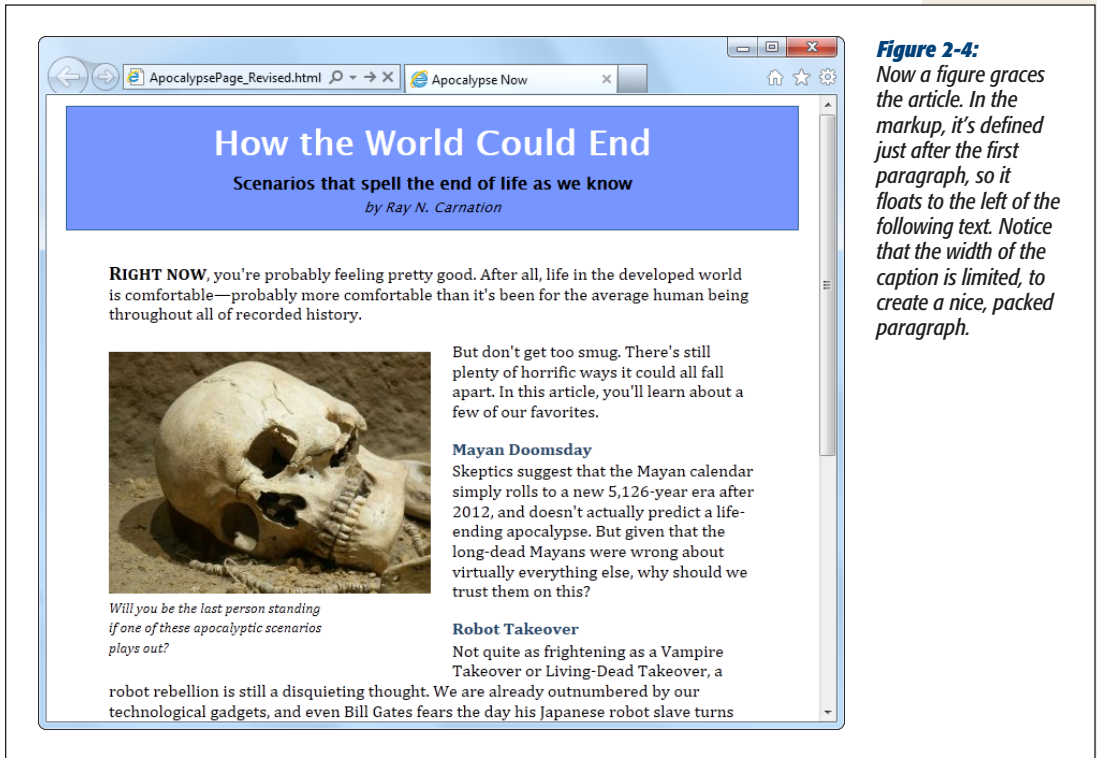

Figure 2-4: Now a figure graces the article. In the markup, it's defined just after the first paragraph, so it floats to the left of the following text. Notice that the width of the caption is limited, to create a nice, packed paragraph.

Of course it's still up to you to use a style sheet to position and format your figure box. (In this example, that means you need to change the style rule selector that targets the caption text. Right now it uses `.FloatFigure p`, but the revised example requires `.FloatFigure figcaption`.)

Tip: Note that the `<figure>` element still gets its formatting based on its class name (`FloatFigure`), not its element type. That's because you're likely to format figures in more than one way. For example, you might have figures that float on the left, figures that float on the right, ones that need different margin or caption settings, and so on. To preserve this sort of flexibility, it makes sense to format your figures with classes.

In the browser, the figure still looks the same. The difference is that the purpose of your figure markup is now perfectly clear. (Incidentally, `<figcaption>` isn't limited to holding text—you can use any HTML elements that make sense. Other possibilities include links and tiny icons.)

Finally, it's worth noting that in some cases the figure caption may include a complete description of the image, rendering the alt text redundant. In this situation, you can remove the *alt* attribute from the `` element:

```
<figure class="FloatFigure">
  
  <figcaption>A human skull lies on the sand</figcaption>
</figure>
```

Just make sure you don't set the alternate text with an empty string, because that means your image is purely presentational and screen readers should avoid it altogether.

Adding a Sidebar with `<aside>`

The new `<aside>` element represents content that is tangentially related to the text that surrounds it. For example, you can use an `<aside>` in the same way you use a sidebar in print—to introduce a related topic or to expand on a point that's raised in the main document. (See, for instance, the box on page 58.) The `<aside>` element also makes sense if you need somewhere to stash a block of ads, some related content links, or even a pull-quote like the one shown in Figure 2-5.

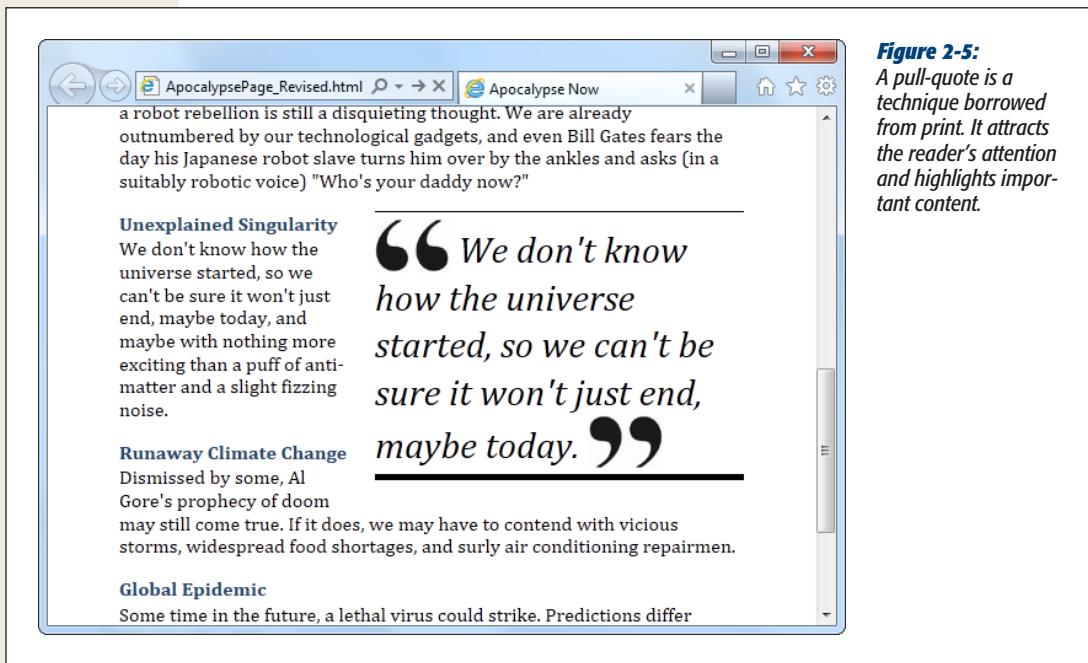

Figure 2-5:
A pull-quote is a technique borrowed from print. It attracts the reader's attention and highlights important content.

You can easily create this effect with the well-worn `<div>` element, but the `<aside>` element gives you a more meaningful way to mark up the same content:

```
<p>... (in a suitably robotic voice) "Who's your daddy now?"</p>

<aside class="PullQuote">
  
  We don't know how the universe started, so we can't be sure it won't
  just end, maybe today.
  
</aside>

<h2>Unexplained Singularity</h2>
```

This time, the style sheet rule floats the pull-quote to the right. Here are the styling details, just in case you're curious:

```
.PullQuote {
  float: right;
  max-width: 300px;
  border-top: thin black solid;
  border-bottom: thick black solid;
  font-size: 30px;
  line-height: 130%;
  font-style: italic;
  padding-top: 5px;
  padding-bottom: 5px;
  margin-left: 15px;
  margin-bottom: 10px;
}

.PullQuote img {
  vertical-align: bottom;
}
```

Browser Compatibility for the Semantic Elements

So far, this exercise has been a lot of fun. But the results aren't as cheering if you fire this page up on older browsers. Before we get to those, it's worth checking out the browser requirements for pure, uncomplicated semantic element support. Table 2-1 tells the story.

Table 2-1. Browser support for the semantic elements

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	9	4	8	5	11.1	4	2.1

Fortunately, this is one missing feature that's easy to patch up. After all, the semantic elements don't actually do anything. To support them, a browser simply needs to treat them like an ordinary `<div>` element. And to make that happen, you need to tackle two challenges.

UP TO SPEED

How the Semantic Elements Were Chosen

Before inventing HTML5, its creators took a long look at the current crop of web pages. And they didn't just browse through their favorite sites; instead, they reviewed the Google-crunched statistics for over a *billion* web pages. (You can see the results of this remarkable survey at <http://code.google.com/webstats>, which is best viewed in a non-IE browser, as Internet Explorer won't show the nifty charts and graphs.)

The Google survey analyzed the markup and compiled a list of the class names web authors were using in their pages. Their idea was that the class name might betray the purpose of the element and give a valuable clue about the way people were structuring pages. For example, if everyone has a `<div>` element that uses a class named *header*, then it's logical to assume everyone is putting headers at the tops of their web pages.

The first thing that Google found is that the vast majority of pages didn't use class names (or style sheets at all). Next, they compiled a short list of the most commonly used class names. Some of the most popular names were footer, header, title, menu, nav—which correspond well to HTML5's new semantic elements `<footer>`, `<header>`, and `<nav>`. A few others suggest possible semantic elements that haven't been created yet, like search and copyright.

In other words, the Web is awash with the same basic designs—for example, pages with headers, footers, sidebars, and navigation menus. But everyone has a slightly different way of doing more or less the same thing. From this realization, it's just a small leap to decide that the HTML language could be expanded with a few new elements that capture the semantics of what everyone is already doing. And this is exactly the insight that inspired HTML5's semantic elements.

First, you need to fight the browser's built-in habit of treating all unrecognized elements as inline elements. Most of HTML5's semantic elements (including all the ones you've seen in this chapter, except `<time>`) are block elements, which means they should be rendered on a separate line, with a little bit of space between them and the preceding and following elements.

Web browsers that don't recognize the HTML5 elements won't know to display some of them as block elements, so they're likely to end up in a clumped-together mess. To fix this problem, you simply need to add a new rule to your style sheet. Here's a super-rule that applies block display formatting to the nine HTML5 elements that need it in one step:

```
article, aside, figure, figcaption, footer, header, hgroup, nav, section,
summary {
  display: block;
}
```

This style sheet rule won't have any effect for browsers that already recognize HTML5, because the *display* property is already set to *block*. And it won't affect any style rules you already use to format these elements. They will still apply in addition to this rule.

That first technique is enough to solve the problem in most browsers, but “most” doesn’t include Internet Explorer 8 and older. Old versions of IE introduce a second challenge: They refuse to apply style sheet formatting to elements they don’t recognize. Fortunately, there is a workaround: You can trick IE into recognizing a foreign element by registering it with a JavaScript command. For example, here’s a script block that gives IE the ability to recognize and style the `<header>` element:

```
<script>
  document.createElement('header')
</script>
```

Rather than write this sort of code yourself, you can make use of a ready-made script that does it for you (described at <http://tinyurl.com/nlcjxm>). To use this script, you simply add a reference to it in the `<head>` section of your page, like this:

```
<head>
  <title>...</title>
  <script src="http://html5shim.googlecode.com/svn/trunk/html5.js"></script>
  ...
</head>
```

This code grabs the script from the *html5shim.googlecode.com* web server and runs it before the browser starts processing the rest of the page. The script is short and to the point—it uses the JavaScript described above to create all the new HTML5 elements. This allows you to format them with style sheet rules. Add the super-rule shown above to your style sheet, and the new elements will display as proper block elements. The only remaining task is for you to use the elements, and to add your own style sheet rules to format them.

Incidentally, the *html5.js* script code is conditional—it runs only if it detects you’re running an old version of Internet Explorer. But if you want to avoid the overhead of requesting the JavaScript file at all, you can make the script reference conditional, like so:

```
<!--[if lt IE 9]>
  <script src="http://html5shim.googlecode.com/svn/trunk/html5.js"></script>
<![endif]-->
```

That way, other browsers (and IE 9 or later) will ignore this instruction, saving your page a few milliseconds of time.

Finally, it’s worth pointing out that when you test a web page on your own computer, Internet Explorer will usually lock it down. That means you’ll see the infamous IE security bar at the top of the page, warning you that it’s disabled the script. To run it, you need to explicitly click the security bar and choose to allow active content.

This problem disappears once you upload the page to a website, but it can be a hassle when testing your work. The solution is to add the “mark of the Web” comment to the beginning of your web page, as described on page 23.

Tip: There's one alternate solution to the semantic styling problem: Use Modernizr (page 38). It automatically takes care of the problem without the need for the `html5.js` script or the style rule. So if you're already using Modernizr to test for feature support, consider the problem solved.

Designing a Site with the Semantic Elements

Adding the semantic elements to a simple, document-like page is easy. Adding them to a complete website isn't any harder, but it does raise a whole lot more questions. And because HTML5 is essentially virgin territory, there are a small number of settled conventions (but a large number of legitimate disagreements). That means when you have a choice between two markup approaches, and the HTML5 standard says they're both perfectly acceptable, it's up to you to decide which one makes the most sense for your content.

Figure 2-6 shows the more ambitious example that you'll consider next.

Figure 2-6: Here, the single-page article you considered previously has been placed in a complete content-based website. A site header caps the page; the content is underneath; and a sidebar on the left provides navigation controls, "About Us" information, and an image ad.

Deeper into Headers

There are two similar, but subtly different, ways to use the `<header>` element. First, you can use it to title some content. Second, you can use it to title your web page. Sometimes, these two tasks overlap (as with the single article example shown in Figure 2-1). But other times, you'll have a web page with both a page header and one or more pieces of headered content. Figure 2-6 is this sort of example.

What makes this situation a bit trickier is that the conventions for using the `<header>` element change based on its role. If you're dealing with content, you probably won't use a header unless you need it. And you need it only if you're creating a "fat" header—one that has some extra content besides the title. If all you need is an ordinary title, you're probably best to use the `<h1>` element on its own. Similarly, if all you need is a title with one or more subtitles, you can use `<hgroup>` on its own. But if you need to add other details, it makes sense to wrap the whole package in a `<header>` (as explained on page 50). But when creating a header for a website, most people elect to wrap it in a `<header>` element, even if there's nothing there but a title in a big CSS-formatted box. After all, it's a major design point of your website, and who knows when you might need to crack it open and add something new?

Here's the takeaway: Pages can have more than one `<header>` element (and they often will), even though these headers play different roles on the page.

UP TO SPEED

Turning a Web Page into a Website

Figure 2-6 shows a single page from a fictional website.

In a real website, you'd have the same layout (and the same side panel) on *dozens* of different pages or more. The only thing that would change as the visitor clicks around the page is main page content—in this case, the article.

HTML5 doesn't have any special magic for turning web pages into websites. Instead, you need to use the same tricks and technologies that web developers rely on in traditional HTML. Those are:

- **Server-side frameworks.** The idea is simple: When a browser requests a page, the web server assembles the pieces, including the common elements (like a navigation bar) and the content. This approach is by far the most common, and it's the only way to go on big, professional websites. Countless different technologies implement this approach in different ways, from the old-fashioned server-side include feature

to rich web application platforms (like ASP.NET and PHP) and content management systems (like Drupal and WordPress).

- **Page templates.** High-powered web page editors like Dreamweaver and Expression Web include a page template feature. You begin by creating a template that defines the structure of your web pages and includes the repeating content you want to appear on every page (like the header and the sidebar). Then you use that template to create all your site pages. Here's the neat part: When you update the template, your web page editor automatically updates all the pages that use it.

Of course, you're free to use either technique, so this book focuses on the final result: the pasted-together markup that forms a complete page and is shown in the web browser.

The apocalyptic site (Figure 2-6) adds a website header. The content for that header is a single banner image, which combines graphical text and a picture. Here's the `<header>` element that the site uses:

```
<header class="SiteHeader">
  
  <h1 style="display:none">Apocalypse Today</h1>
</header>
```

Right away, you'll notice that this header adds a detail that you don't see on the page: a `<h1>` heading that duplicates the content that's in the picture. However, an inline style setting hides this heading.

This example raises a clear question—what's the point of adding a heading that you can't see? There are actually several reasons. First, all `<header>` elements require some level of heading inside, just to satisfy the rules of HTML5. Second, this design makes the page more accessible for people who are navigating it with screen readers, because they'll often jump from one heading to the next without looking at the content in between. And third, it establishes a heading structure that you may use in the rest of the page. That's a fancy way of saying that if you start with an `<h1>` for your website header, you may decide to use `<h2>` elements to title the other sections of the page (like “Articles” and “About Us” in the sidebar). For more about this design decision, see the box on page 63.

Note: Of course, you could simplify your life by creating an ordinary text header. (And if you want fancy fonts, the new CSS3 embedded font feature, described on page 244, can help you out.) But for the many web pages that put the title in a picture, the hidden heading trick is the next best solution.

Navigation Links with `<nav>`

The most interesting new feature in the apocalyptic website is the sidebar on the left, which provides the website's navigation, some extra information, and an image ad. (Typically, you'd throw in a block of JavaScript that fetches a randomly chosen ad using a service like Google AdSense. But this example just hard-codes a picture to stand in for that.)

In a traditional HTML website, you'd wrap the whole sidebar in a `<div>`. In HTML5, you almost always rely on two more specific elements: `<aside>` and `<nav>`.

The `<aside>` element is a bit like the `<header>` element in that it has a subtle, slightly stretchable meaning. You can use it to mark up a piece of unrelated content, as you did with the pull-quote on page 56. Or, you can also use it to designate an entirely separate section of the page—one that's offset from the main flow.

FREQUENTLY ASKED QUESTIONS

The Heading Structure of a Site

Is it acceptable to have more than one level-1 heading on a page? Is it a good idea?

According to the official rules of HTML, you can have as many level-1 headings as you want. However, website creators often strive to have just a single level-1 heading per page, because it makes for a more accessible site. (That's because people using screen readers might miss a level-1 heading as they skip from one level-2 heading to the next.) There's also a school of webmaster thought that says every page should have exactly one level-1 heading, which is unique across the entire website and clearly tells search engines what content awaits.

The example in Figure 2-6 uses this style. The “Apocalypse Today” heading that tops the site is the only `<h1>` on the page. The other sections on the page, like “Articles” and “About Us” in the sidebar, use level-2 headings. The article title also uses a level-2 heading. (With a little bit of extra planning, you could vary the text of the level-1 heading to match the current article—after all, this heading isn't actually visible, and it could help the page match more focused queries in a search engine like Google.)

But there are other, equally valid approaches. For example, you could use level-1 headings to title each major section of your page, including the sidebar, the article, and so on.

Or, you could give the website a level-1 site heading and put level-2 headings in the sidebar (as in the current example) but make the article title into a second level-1 heading. This works fine in HTML5, because of its new outlining system. As you'll learn on page 73, some elements, including `<article>`, are treated as separate sections, with their own distinct outlines. So it makes perfect sense for these sections to start the heading hierarchy over again with a brand new `<h1>`. (However, HTML5 says it's fine to start with a different heading level, too.)

In short, there's no clear answer about how to structure your website. It seems likely that the multiple-`<h1>` approach will become increasingly popular as HTML5 conquers the Web. But for now, many web developers are sticking with the single-`<h1>` approach to keep screen readers happy.

The `<nav>` element wraps a block of links. These links may point to topics on the current page, or to other pages on the website. Most pages will have multiple `<nav>` sections in them. But not all links need a `<nav>` section—instead, it's generally reserved for the largest and most important navigational sections on a page. For example, if you have a list of articles (as in Figure 2-6), you definitely need a `<nav>` section. But if you have just a couple of links at the bottom of the page with licensing and contact information, a full-blown `<nav>` isn't necessary.

With these two elements in mind, it's a good time to try a practice exercise. First, review the sidebar in Figure 2-6. Next, sketch out on a piece of paper how you would mark up the structure of this content. Then, read on to find out the best possible solution.

In fact, there are at least two reasonably good ways to structure this sidebar, as shown in Figure 2-7.

Figure 2-7:

Left: You can think of the entire side panel as a navigation bar, with some other content wedged in. In this case, the whole panel can be a `<nav>`, and the other content sections require an `<aside>` (because they aren't related to the sidebar's main content, the links).

Right: Alternatively, consider the entire side panel to be a separate web page section that serves several purposes. In this case, the sidebar becomes an `<aside>` while the navigational content inside is wrapped in a `<nav>`.

The apocalyptic site uses the second approach (Figure 2-7, right). That's because the sidebar seems to serve several purposes, with none clearly being dominant. But if you have a lengthy and complex navigational section (like a collapsible menu) followed by a short bit of content, the first approach just might make more sense.

Here's the markup that shapes the sidebar, dividing it into three sections:

```
<aside class="NavSidebar">
  <nav>
    <h2>Articles</h2>
    <ul>
      <li><a href="...">How The World Could End</a></li>
      <li><a href="...">Would Aliens Enslave or Eradicate Us</a></li>
      ...
    </ul>
  </nav>

  <section>
    <h2>About Us</h2>
    <p>Apocalypse Today is a world leader in conspiracy theories ...</p>
  </section>

  <div>
    
  </div>
</aside>
```

Here are the key points you don't want to miss:

- **The title sections (“Articles” and “About Us”) are level-2 headings.** That way, they are clearly subordinate to the level-1 website heading, which makes the page more accessible to screen readers.
- **The links are marked up in an unordered list using the `` and `` elements.** Website designers agree that a list is the best, most accessible way to deal with a series of links. However, you may need to use style sheet rules to remove the indent (as done here) and the bullets (not in this example).

- **The “About Us” section is wrapped in a `<section>` element.** That’s because there’s no other semantic element that suits this content. A `<section>` is slightly more specific than a `<div>`—it’s suitable for any block of content that starts with a heading. If there were a more specific element to use (for example, a hypothetical `<about>` element), that would be preferable to a basic `<section>`, but there isn’t.
- **The image ad is wrapped in a `<div>`.** The `<section>` element is appropriate only for content that starts with a title, and the image section doesn’t have a heading. (Although if it did—say, “A Word from Our Sponsors”—a `<section>` element would be the better choice.) Technically, it’s not necessary to put any other element around the image, but the `<div>` makes it easier to separate this section, style it, and throw in some JavaScript code that manipulates it, if necessary.

There are also some details that this sidebar *doesn’t* have, but many others do. For example, complex sidebars may start with a `<header>` and end with a `<footer>`. They may also include multiple `<nav>` sections—for example, one for a list of archived content, one with a list of late-breaking news, one with a blogroll or list of related sites, and so on. For an example, check out the sidebar of a typical blog, which is packed full of sections, many of which are navigational.

The style sheet rules you use to format the `<aside>` sidebar are the same as the ones you’d use to format a traditional `<div>` sidebar. They place the sidebar in the correct spot, using absolute positioning, and set some formatting details, like padding and background color:

```
aside.NavSidebar
{
    position: absolute;
    top: 179px;
    left: 0px;
    padding: 5px 15px 0px 15px;
    width: 203px;
    min-height: 1500px;
    background-color:#eee;
    font-size: small;
}
```

This rule is followed by contextual style sheet rules that format the `<h2>`, ``, ``, and `` elements in the sidebar. (As always, you can get the sample code from www.prosetech.com/html5, and peruse the complete style sheet.)

Now that you understand how the sidebar is put together, you’ll understand how it fits into the layout of the entire page, as shown in Figure 2-8.

Note: As you’ve learned, the `<nav>` is often found on its own, or in an `<aside>`. There’s one more common place for it to crop up: in the `<header>` element that tops a web page.

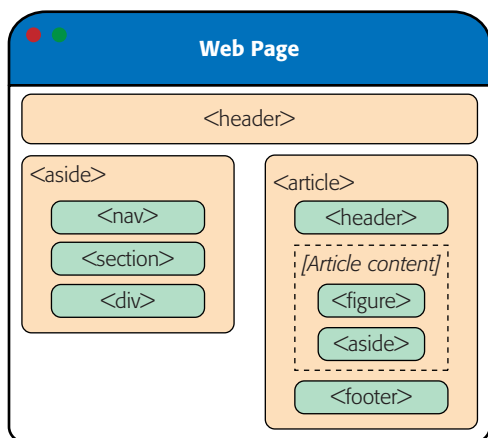

Figure 2-8:
Here are all the semantic elements that you'll find in the
apocalyptic web page (shown in Figure 2-6).

GEM IN THE ROUGH

Collapsible Boxes with `<details>` and `<summary>`

You've no doubt seen collapsible boxes on the Web: sections of content that you can show or hide by clicking a heading. Collapsible boxes are one of the easiest feats to pull off with basic JavaScript. You simply need to react when the heading is clicked, and then change a style setting to hide your box:

```
var box = document.getElementById("myBox");
box.style.display = "none";
```

And then back again to make it reappear:

```
var box = document.getElementById("myBox");
box.style.display = "block";
```

Interestingly, HTML5 adds two semantic elements that aim to make this behavior automatic. The idea is that you wrap your collapsible section in a `<details>` element, and wrap the heading inside in a `<summary>` element. The final result is something like this:

```
<details>
  <summary>Section #1</summary>
  <p>If you can see this content, the
    section is expanded</p>
</details>
```

Browsers that support these elements (currently, that's just Chrome), will show just the heading, possibly with some sort of visual adornment (like a tiny triangle icon next to the heading). Then, if the user clicks the heading, the full content expands into view. Browsers that don't support the `<details>` and `<summary>` elements will show the full content right from the start, without giving the user any way to collapse it.

The `<details>` and `<summary>` elements are somewhat controversial. Many web developers feel that they aren't really semantic, because they're more about visual style than logical structure.

For now, it's best to avoid the `<details>` and `<summary>` elements because they have such poor browser support. Although you could write a workaround that uses JavaScript on browsers that don't support them, writing this workaround is more effort than just using a few lines of JavaScript to perform the collapsing on your own, on any browser.

Deeper into Footers

HTML5 and fat headers were meant for each other. Not only can you stuff in subtitles and bylines, but you can also add images, navigational sections (with the `<nav>` element), and virtually anything else that belongs at the top of your page.

Oddly, HTML5 isn't as accommodating when it comes to footers. The footer is supposed to be limited to a few basic details about the website's copyright, authorship, legal restrictions, and links. Footers aren't supposed to hold long lists of links, important pieces of content, or extraneous details like ads, social media buttons, and website widgets.

This raises a question. What should you do if your website design calls for a fat footer? After all, fat footers are wildly popular in website design right now (see Figure 2-9 for an example). They incorporate a number of fancy techniques, sometimes including:

- **Fixed positioning**, so that they are always attached to the bottom of the browser window, no matter where the visitor scrolls (as with the example in Figure 2-9).
- **A close button**, so the user can close them and reclaim the space after reading the footer (as with the example in Figure 2-9). To make this work, you use a simple piece of JavaScript that hides whatever element wraps the footer (like the code shown in the box on page 66).
- **A partially transparent background**, so that you can see the page content *through* the footer. This works well if the footer is advertising breaking news or an important disclaimer, and it's usually used in conjunction with a close button.
- **Animation**, so that they spring or slide into view (for example, see the related article box that pops up when you reach the bottom of an article at www.ny-times.com).

If your site includes this sort of footer, you have a choice. The simple approach is to disregard the rules. This approach not as terrible as it sounds, because other website developers are sure to commit the same mistake, and over time the official rules may be loosened, allowing fancier footers. But if you want to be on the right side of the standard right now, you need to adjust your markup. Fortunately, it's not too difficult.

Figure 2-9:
This absurdly fat footer is stuffed with garish extras, like an award picture and social media buttons. It uses fixed positioning to lock itself to the bottom of the browser window, like a toolbar. Fortunately, this footer has one redeeming quality: the close button in the top-right corner that lets anyone banish it from view.

The trick is to split the standard footer details from the extras. In the browser, these can appear to be a single footer, but in the markup, they won't all belong to the `<footer>` element. For example, here's the structure of the fat footer in Figure 2-9:

```
<div id="FatFooter">
  <!-- Fat footer content goes here. -->
  
  ...

  <footer>
    <!-- Standard footer content goes here. -->
    <p>The views expressed on this site do not ... </p>
  </footer>
</div>
```

The outer `<div>` has no semantic meaning. Instead, it's a convenient package that bundles the extra “fat” content with the bare-bones footer details. It also lets you apply the style sheet formatting rule that locks the fat footer into place:

```
#FatFooter {
  position: fixed;
  bottom: 0px;
  height: 145px;
  width: 100%;
  background: #ECD672;
  border-top: thin solid black;
  font-size: small;
}
```

Note: In this example, the style sheet rule applies its formatting by ID name (using the `#FatFooter` selector) rather than by class name (for example, using a `.FatFooter` selector). That's because the fat footer already needs a unique ID, so the JavaScript code can find it and hide it when someone clicks the close button. It makes more sense to use this unique ID in the style sheet than to add a class name for the same purpose.

You could also choose to put the footer in an `<aside>` element, to clearly indicate that the footer content is a separate section, and tangentially related to the rest of the content on the page. Here's what that structure looks like:

```
<div id="FatFooter">
  <aside>
    <!-- Fat footer content goes here. -->
    
    ...
  </aside>
</footer>
<!-- Standard footer content goes here. -->
<p>The views expressed on this site do not ... </p>
</footer>
</div>
```

The important detail here is that the `<footer>` is not placed inside the `<aside>` element. That's because the `<footer>` doesn't apply to the `<aside>` but to the entire website. Similarly, if you have a `<footer>` that applies to some piece of content, your `<footer>` needs to be placed inside the element that wraps that content.

Note: The rules and guidelines for the proper use of HTML5's semantic elements are still evolving. Questions about the proper way to mark up large, complex sites stir ferocious debate in the HTML community. The best advice is this: If something doesn't seem true to your content, don't do it. Or you can discuss it online, where you can get feedback from dozens of super-smart HTML gurus. (One particularly good site is <http://html5doctor.com>, where you can see these ongoing debates unfolding in the comments section of most articles.)

Deeper into Sections

As you've already learned, the `<section>` is the semantic element of last resort. If you have a titled block of content, and the other semantic elements aren't appropriate, then the `<section>` element is generally a better choice than `<div>`.

So what goes in a typical section? Depending on your perspective, the `<section>` element is either a flexible tool that fits many needs, or a loose and baggy monster with no clear identity. That's because sections play a variety of different web page roles. They can mark up any of the following:

- Small blocks of content that are displayed alongside the main page, like the "About Us" paragraph in the apocalyptic website.

- Self-contained content that can't really be described as an article, like a customer billing record or a product listing.
- Groups of content—for example, a collection of articles on a news site.
- A *portion* of a longer document. For example, in the apocalyptic article, you could mark up each separate end-of-the-world scenario as a distinct section. Sometimes you'll use sections in this way to ensure a correct outline for your document, as explained in the next section.

The last two items in the list are the most surprising. Many web developers find it's a bit of a stretch to use the same element to deal with a small fragment of an article and an entire group of articles. Some think that HTML5 should have at least two different elements to deal with these different scenarios. But the creators of HTML5 decided to keep things simple (by limiting the number of new elements) while making the new elements as flexible and practical as possible.

There's one last consideration. The `<section>` element also has an effect on a web page's outline, which is the concept you'll explore next.

The HTML5 Outlining System

HTML5 defines a set of rules that dictate how you can create a *document outline* for any web page. A web page's outline can come in handy in a lot of ways. For example, a browser could let you jump from one part of an outline to another. A design tool could let you rearrange sections by dragging and dropping them in an outline view. A search engine could use the outline to build a better page preview, and screen readers could benefit the most of all, by using outlines to guide users with vision difficulties through a deeply nested hierarchy of sections and subsections.

However, none of these scenarios is real yet, because almost no one uses HTML5 outlines today—except for the small set of developer tools you'll consider in the next section.

Note: It's hard to get excited about a feature that doesn't affect the way the page is presented in a browser and isn't used by other tools. However, it's still a good idea to review the outline of your web pages (or at least the outline of a typical page from your website) to make sure that its structure makes sense and that you aren't breaking any HTML5 rules.

How to View an Outline

To really understand outlines, you need to take a look at the outlines produced by your own pages. Right now, no browser implements the rules of HTML5 outlines (or gives you a way to peek at one). However, there are several tools that fill the gap:

- **Online HTML outliner.** Just visit <http://gsnedders.html5.org/outliner> and tell the outliner what page you want to outline. As with the HTML5 validator you used in Chapter 1 (page 25), you can submit the page you want to outline in three ways: by uploading a file from your computer, by supplying a URL, or by pasting the markup into a text box.
- **Chrome extension.** You can use the h5o plug-in to analyze page outlines from inside the Chrome browser. Just install it from <http://code.google.com/p/h5o> and surf to an HTML5 page somewhere on the Web (sadly, at this writing h5o doesn't work with files that are stored on your computer). An outline icon will appear in the address bar, which reveals the structure of the page when clicked (Figure 2-10). The h5o page also provides a *bookmarklet*—a piece of JavaScript code that you can add to your web browser's bookmark list—which allows you to display page outlines in Firefox and Internet Explorer, albeit with a few quirks.
- **Opera extension.** There's an Opera version of the h5o Chrome extension. Get it at <http://tinyurl.com/3k3ecdy>.

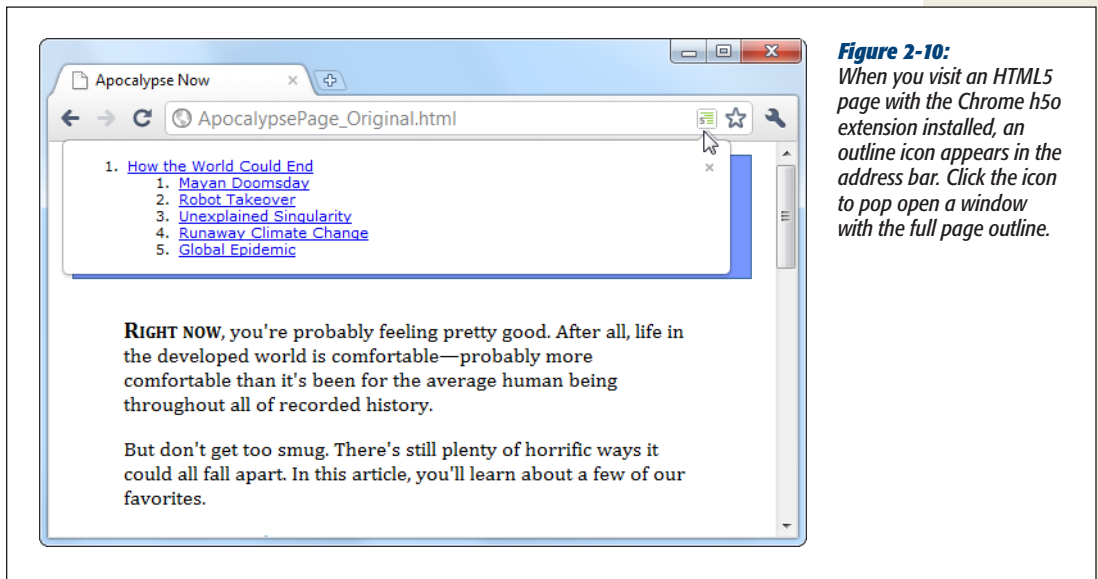

Figure 2-10: When you visit an HTML5 page with the Chrome h5o extension installed, an outline icon appears in the address bar. Click the icon to pop open a window with the full page outline.

Basic Outlines

To visualize the outline of your web page, imagine it stripped of all content except for the text in a numbered heading element (<h1>, <h2>, <h3>, and so on). Then, indent those headings based on their place in your markup, so more deeply nested headings are indented more in the outline.

For example, consider the apocalypse article in its initial, pre-HTML5 state:

```
<body>
  <div class="Header">
    <h1>How the World Could End</h1>
    ...
  </div>
  ...
  <h2>Mayan Doomsday</h2>
  ...
  <h2>Robot Takeover</h2>
  ...
  <h2>Unexplained Singularity</h2>
  ...
  <h2>Runaway Climate Change</h2>
  ...
  <h2>Global Epidemic</h2>
  ...
  <div class="Footer">
    ...
  </div>
</body>
```

This simple structure leads to an outline like this:

1. How the World Could End
 1. Mayan Doomsday
 2. Robot Takeover
 3. Unexplained Singularity
 4. Runaway Climate Change
 5. Global Epidemic

Two levels of headings (<h1> and <h2>) create a two-level outline. This scheme is similar to the outline features in many word processing programs—for example, you can see much the same thing in Word 2010's Navigation pane.

On the other hand, markup like this:

```
<h1>Level-1 Heading</h1>
<h2>Level-2 Heading</h2>
<h2>Level-2 Heading</h2>
<h3>Level-3 Heading</h3>
<h2>Level-2 Heading</h2>
```

Gets an outline like this:

- 1. Level-1 Heading
 - 1. Level-2 Heading
 - 2. Level-2 Heading
 - 1. Level-3 Heading
 - 3. Level-2 Heading

Again, there are no surprises.

Finally, the outline algorithm is smart enough to ignore skipped levels. For example, if you write this slightly wobbly markup, which skips from `<h1>` directly to `<h3>`:

```
<h1>Level-1 Heading</h1>  
<h2>Level-2 Heading</h2>  
<h1>Level-1 Heading</h2>  
<h3>Level-3 Heading</h3>  
<h2>Level-2 Heading</h2>
```

You get this outline:

- 1. Level-1 Heading
 - 1. Level-2 Heading
 - 2. Level-1 Heading**
 - 1. Level-3 Heading**
 - 2. Level-2 Heading

Now the level-3 heading has level-2 status in the outline, based on its position in the document. This might seem like one of those automatic error corrections browsers love to make, but it actually serves a practical purpose. In some situations, a web page may be assembled out of separate pieces—for example, it might contain a copy of an article that’s published elsewhere. In this case, the heading levels of the embedded content might not line up perfectly with the rest of the web page. But because the outlining algorithm smooths these differences out, it’s unlikely to be a problem.

Sectioning Elements

Sectioning elements are elements that create a new, nested outline inside your page. These elements are `<article>`, `<aside>`, `<nav>`, and `<section>`. To understand how sectioning elements work, imagine a page that contains two `<article>` elements. Because `<article>` is a sectioning element, this page has (at least) three outlines—the outline of the overall page, and one nested outline for each article.

To get a better grasp of this situation, consider the structure of the apocalypse article, after it's been revised with HTML5:

```
<body>
  <article>
    <header>
      <h1>How the World Could End</h1>
      ...
    </header>

    <div class="Content">
      ...
      <h2>Mayan Doomsday</h2>
      ...
      <h2>Robot Takeover</h2>
      ...
      <h2>Unexplained Singularity</h2>
      ...
      <h2>Runaway Climate Change</h2>
      ...
      <h2>Global Epidemic</h2>
      ...
    </div>
  </article>

  <footer>
    ...
  </footer>
</body>
```

Plug this into an outline viewer like <http://gsnedders.html5.org/outliner>, and you'll see this:

1. *Untitled Section*
 1. How the World Could End
 1. Mayan Doomsday
 2. Robot Takeover
 3. Unexplained Singularity
 4. Runaway Climate Change
 5. Global Epidemic

Here, the outline starts with an untitled section, which is the root `<body>` element. The `<article>` element starts a new, nested outline, which contains a single `<h1>` and several `<h2>` elements.

Sometimes, the “Untitled Section” note indicates a mistake. Although it’s considered acceptable for `<aside>` and `<nav>` elements to exist without titles, the same leniency isn’t usually given to `<article>` or `<section>` elements. In the previous example, the untitled section is the main section for the page, which belongs to the `<body>` element. Because the page contains a single article, there’s no reason for the page to have a separate heading, and you can ignore this quirk.

Now consider what happens with a more complex example, like the apocalypse site with the navigation sidebar (page 60). Put that through an outliner, and you’ll get this outline:

1. *Apocalypse Today*
 1. *Untitled Section*
 1. Articles
 2. About Us
 2. How the World Could End
 1. Mayan Doomsday
 2. Robot Takeover
 3. *Untitled Section*
 4. Unexplained Singularity
 5. Runaway Climate Change
 6. Global Epidemic

Here, there are two sectioning elements, and two nested outlines: one for the sidebar, and one for the article. There are also two untitled sections, both of which are legitimate. The first is the `<aside>` element for the sidebar, and the second is the `<aside>` element that represents the pull-quote in the article.

Note: In addition to sectioning elements, some elements are called *section roots*. These elements aren’t just branches of an existing outline; they start a new outline of their own that doesn’t appear in the main outline of the containing page. The `<body>` element that contains your web page content is a sectioning root, which makes sense. But HTML5 also considers the following elements to be sectioning roots: `<blockquote>`, `<td>`, `<fieldset>`, `<figure>`, and `<details>`.

GEM IN THE ROUGH

How Sectioning Elements Help Complex Pages

Sectioning is a great help with *syndication* and *aggregation*—two examples of the fine art of taking content from one web page and injecting it into another.

For example, imagine you have a web page that includes excerpts from several articles, all of which are drawn from other sites. Now imagine that this page has a deeply nested structure of headings, and somewhere inside—let’s say under an `<h4>` heading—there’s an article with content pulled from another web page.

In traditional HTML, you’d like the first heading in this content to use the `<h5>` element, because it’s nested under an `<h4>`. But this article was originally developed to be placed somewhere else, on a different page, with less nesting, so it probably starts with an `<h2>` or an `<h1>`. This doesn’t stop the page from working, but it does mean that the hierarchy is

scrambled, and the page could be more difficult for screen readers, search engines, and other software to process.

In HTML5, this page isn’t a problem. As long as you wrap the nested article in an `<article>` element, the extracted content becomes part of its own nested outline. That outline can start with any heading—it doesn’t matter. What matters is its position in the containing document. So if the `<article>` element falls after an `<h4>`, then the first level of heading in that article behaves like a logical `<h5>`, the second level acts like a logical `<h6>`, and so on.

The conclusion is this: HTML5 has a logical outline system that makes it easier to combine documents. In this outline system, the position of your headings becomes more important, and the exact level of each heading becomes less significant—making it harder to shoot yourself in the foot.

Solving an Outline Problem

So far, you’ve looked at the examples in this chapter, and seen the outlines they generated. And so far, the outlines have made perfect sense. But sometimes, a problem can occur. For example, imagine you create a document with this structure:

```
<body>
  <article>
    <h1>Natural Wonders to Visit Before You Die</h1>
    ...
    <h2>In North America</h2>
    ...
    <h3>The Grand Canyon</h3>
    ...
    <h3>Yellowstone National Park</h3>
    ...
    <h2>In the Rest of the World</h2>
    ...
    <aside>...</aside>
    ...
    <h3>Galapagos Islands</h3>
    ...
    <h3>The Swiss Alps</h3>
    ...
  </article>
</body>
```

You probably expect an outline like this:

1. *Untitled Section for the <body>*
 1. Natural Wonders to Visit Before You Die
 1. In North America
 1. The Grand Canyon
 2. Yellowstone National Park
 2. In the Rest of the World
 3. *Untitled Section for the <aside>*
 1. Galapagos Islands
 2. The Swiss Alps

But the outline you actually get is this:

1. *Untitled Section for the <body>*
 1. Natural Wonders to Visit Before You Die
 1. In North America
 1. The Grand Canyon
 2. Yellowstone National Park
 2. In the Rest of the World
 3. *Untitled Section for the <aside>*
 - 4. Galapagos Islands**
 - 5. The Swiss Alps**

Somehow, the addition of the `<aside>` after the `<h2>` throws off the following `<h3>` elements, making them have the same logical level as the `<h2>`. This clearly isn't what you want.

To solve this problem, you first need to understand that the HTML5 outline system automatically creates a new section every time it finds a numbered heading element (like `<h1>`, `<h2>`, `<h3>`, and so on), *unless* that element is already at the top of a section.

In this example, the outline system doesn't do anything to the initial `<h1>` element, because it's at the top of the `<article>` section. But the outline algorithm does create new sections for the `<h2>` and `<h3>` elements that follow. It's as though you wrote this markup:

```
<body>
  <article>
    <h1>Natural Wonders to Visit Before You Die</h1>
    ...
    <section>
      <h2>In North America</h2>
      ...
```

```

<section>
  <h3>The Grand Canyon</h3>
  ...
</section>
<section>
  <h3>Yellowstone National Park</h3>
  ...
</section>
</section>

<section>
  <h2>In the Rest of the World</h2>
  ...
</section>
<aside>...</aside>
...
<section>
  <h3>Galapagos Islands</h3>
  ...
</section>
<section>
  <h3>The Swiss Alps</h3>
  ...
</section>
</article>
</body>

```

Most of the time, these automatically created sections aren't a problem. In fact, they're usually an asset, because they make sure incorrectly numbered heading are still placed in the right outline level (as you learned on page 76). The cost for this convenience is an occasional glitch, like the one shown here.

As you can see in this listing, everything goes right at first. The top <h1> is left alone (because it's in an <article> already), there's a subsection created for the first <h2>, then a subsection for each <h3> inside, and so on. The problem starts when the outline algorithm runs into the <aside> element. It sees this as a cue to close the current section, which means that when the sections are created for the following <h3> elements, they're at the same logical level as the <h2> elements before.

To correct this problem, you need to take control of the sections and subsections by defining some yourself. In this example, the goal is to prevent the second <h2> section from being closed too early, which you can do by defining it explicitly in the markup:

```

<body>
  <article>
    <h1>Natural Wonders to Visit Before You Die</h1>
    ...
    <h2>In North America</h2>
    ...
    <h3>The Grand Canyon</h3>
    ...
    <h3>Yellowstone National Park</h3>
    ...

```

```
<section>
  <h2>In the Rest of the World</h2>
  ...
  <aside>...</aside>
  ...
  <h3>Galapagos Islands</h3>
  ...
  <h3>The Swiss Alps</h3>
  ...
</section>
</article>
</body>
```

Now, the outline algorithm doesn't need to create an automatic section for the second `<h2>`, and so there's no risk of it closing the section when it stumbles across the `<aside>`. Although you could define the section for every heading in this document, there's no need to clutter your markup, as this single change fixes the problem.

Note: Another solution is to replace the `<aside>` with a `<div>`. The `<div>` is not a sectioning element, so it won't cause a section to close unexpectedly.

Using the `<aside>` element doesn't always cause this problem. The earlier article examples used the `<aside>` element for a pull-quote but worked fine, because the `<aside>` fell between two `<h2>` elements. But if you carelessly plunk a sectioning element between two different heading levels, you should check your outline to make sure it still makes sense.

Tip: If the whole outline concept seems overwhelmingly theoretical, don't worry. Truthfully, it's a subtle concept that many web developers will ignore (at least for now). The best approach is to think of the HTML5 outlining system as a quality assurance tool that can help you out. If you review your pages in an outline generator (like one of the tools listed on page 71), you can catch mistakes that may indicate other problems, and make sure that you're using the semantic elements correctly.

Meaningful Markup

In the previous chapter, you met HTML5's semantic elements. With their help, you can give your pages a clean, logical structure and prepare for a future of super-smart browsers, search engines, and assistive devices.

But you haven't reached the end of the semantic story yet. Semantics are all about adding *meaning* to your markup, and there are several types of information you can inject. In Chapter 2, semantics were all about *page structure*—you used them to explain the purpose of large blocks of content and entire sections of your layout. But semantics can also include *text-level information*, which you add to explain much smaller pieces of content. You can use text-level semantics to point out important types of information that would otherwise be lost in a sea of web page content, like names, addresses, event listings, products, recipes, restaurant reviews, and so on. Then this content can be extracted and used by a host of different services—everything from nifty browser plug-ins to specialized search engines.

In this chapter, you'll start by returning to the small set of semantic elements that are built into the HTML5 language. You'll learn about a few text-level semantic elements that you can use today, effortlessly. Next, you'll look at the companion standards that tackle text-level semantics head-on. That means digging into *microdata*, which began its life as part of the original HTML5 specification, but now lives on as a separate, still-evolving standard managed by the W3C. Along the way, you'll take a look at a few forward-thinking services that are already putting microdata to good use.

The Semantic Elements Revisited

There's a reason you began your exploration into semantics with the page structure elements (see Table 3-1 for a recap). Quite simply, page structure is an easy challenge. That's because the vast majority of websites use a small set of design elements (headers, footers, sidebars, and menus) to create layouts that are—for all their cosmetic differences—very similar.

Table 3-1. *Semantic elements for page structure*

Element	Description
<code><article></code>	Represents whatever you think of as an article—a section of self-contained content like a newspaper article, a forum post, or a blog entry (not including frills like comments or the author bio).
<code><aside></code>	Represents a complete chunk of content that's separate from the surrounding content of the page. For example, it makes sense to use <code><aside></code> to create a sidebar with related content or links next to a main article.
<code><figure></code> and <code><figcaption></code>	Represents a figure. The <code><figcaption></code> element wraps the caption text, and the <code><figure></code> element wraps the <code><figcaption></code> and the <code></code> element for the picture itself. The goal is to indicate the association between an image and its caption.
<code><footer></code>	Represents the footer at the bottom of the page. This is a tiny chunk of content that may include small print, a copyright notice, and a brief set of links (for example, "About Us" or "Get Support").
<code><header></code>	Represents an enhanced heading that includes a standard HTML heading and extra content. The extra content might include a logo, a byline, or a set of navigation links for the content that follows.
<code><hgroup></code>	Represents an enhanced heading that groups two or more heading elements, and nothing else. Its primary purpose is to make a title and a subtitle stand together.
<code><nav></code>	Represents a significant collection of links on a page. These links may point to topics on the current page, or to other pages on the website. In fact, it's not unusual to have a page with multiple <code><nav></code> sections.
<code><section></code>	Represents a section of a document or a group of documents. The <code><section></code> is an all-purpose container with a single rule: The content it holds should begin with a heading. Use <code><section></code> only if the other semantic elements (for example, <code><article></code> and <code><aside></code>) don't apply.

Text-level semantics are a tougher nut to crack. That's because people use a huge number of different types of content. If HTML5 set out to create an element for every sort of information you might add to a page, the language would be swimming in a mess of elements. Complicating the problem is the fact that structured information is also made of smaller pieces that can be assembled in different ways. For example, even an ordinary postal address would require a handful of elements (like `<address>`, `<name>`, `<street>`, `<postalcode>`, `<country>`, and so on) before anyone could use it in a page.

HTML5 takes a two-pronged approach. First, it adds a very small number of text-level semantic elements. But second, and more importantly, HTML5 supports a separate microdata standard, which gives people an extensible way to define any sort of information they want, and then flag it in their pages. You'll cover both of these topics in this chapter. First up are three new text-level semantic elements: `<time>`, `<output>`, and `<mark>`.

Dates and Times with `<time>`

Date and time information appears frequently in web pages. For example, it turns up at the end of most blog postings. Unfortunately, there's no standardized way to tag dates, so there's no easy way for other programs (like search engines) to extract them without guessing. The `<time>` element solves this problem. It allows you to mark up a date, time, or combined date and time. Here's an example:

The party starts `<time>2012-03-21</time>`.

Note: It may seem a little counterintuitive to have a `<time>` element wrapping a date (with no time), but that's just one of the quirks of HTML5. A more sensible element name would be `<datetime>`, but that isn't what they chose.

The `<time>` element performs two roles. First, it indicates where a date or time value is in your markup. Second, it provides that date or time value in a form that any software program can understand. The previous example meets the second requirement using the universal date format, which includes a four-digit year, a two-digit month, and a two-digit day, in that order, with each piece separated by a colon. In other words, the format follows this pattern:

YYYY:MM:DD

However, it's perfectly acceptable to present the date in a different way to the person reading your web page. In fact, you can use whatever text you want, as long as you supply the computer-readable universal date with the *datetime* attribute, like this:

The party starts `<time datetime="2012-03-21">March 21st</time>`.

Which looks like this in the browser:

The party starts March 21st.

The `<time>` element has similar rules about times, which you supply in this format:

HH:MM+00:00

That's a two-digit hour (using a 24-hour clock), followed by a two-digit number of minutes. The part that's tacked on at the end, after the + sign, is the time zone. Time zones are not optional—you can figure yours out at http://en.wikipedia.org/wiki/Time_zone. For example, New York is in the Eastern Time Zone, which is known as UTC-5:00. To indicate 4:30 p.m. in New York, you'd use this markup:

Parties start every night at `<time datetime="16:30-5:00">4:30 p.m.</time>`.

This way, the people reading your page get the time in the format they expect, while search bots and other bits of software get an unambiguous datetime value that they can process.

Finally, you can specify a time on a specific date by combining these two standards. Just put the date first, followed by an uppercase letter *T*, followed by the time information:

```
The party starts <time datetime="2012-03-21T16:30-5:00">March 21<sup>st</sup>
at 4:30 p.m.</time>.
```

The `<time>` element also supports a *pubdate* attribute. You should use this if your date corresponds to the publication date of the current content (for example, the `<article>` in which the `<time>` is placed). Here's an example:

```
Published on <time datetime="2011-03-21" pubdate>March 31, 2011</time>.
```

Note: Because the `<time>` element is purely informational and doesn't have any associated formatting, you can use it with any browser. There are no compatibility issues to worry about. But if you want to style the `<time>` element, you need the Internet Explorer workaround described on page 59.

JavaScript Calculations with `<output>`

HTML5 includes one semantic element that's designed to make certain types of JavaScript-powered pages a bit clearer—the `<output>` element. It's a nothing more than a placeholder that your code can use to show a piece of calculated information.

For example, imagine you create a page like the one shown in Figure 3-1. This figure lets the user enter some information. A script then takes this information, performs a calculation, and displays the result just underneath.

The usual way of dealing with this is to assign a unique ID to the placeholder, so the JavaScript code can find it when it performs the calculation. Typically, web developers use the `` element, which works perfectly but doesn't provide any specific meaning:

```
<p>Your BMI: <span id="result"></span></p>
```

Here's the more meaningful version you'd use in HTML5:

```
<p>Your BMI: <output id="result"></output></p>
```

The actual JavaScript code doesn't need any changes, because it looks up the element by name, and doesn't care about the element type:

```
var resultElement = document.getElementById("result");
```

Note: Before you use `<output>`, make sure you've included the Internet Explorer workaround described on page 59. Otherwise, the element won't be accessible in JavaScript on old versions of IE.

Often, this sort of page will put its controls into a `<form>` element. In this example, that's the three text boxes where people can type in information:

```
<form action="#" id="bmiCalculator">
  <label for="feet inches">Height:</label>
  <input name="feet"> feet<br>
  <input name="inches"> inches<br>

  <label for="pounds">Weight:</label>
  <input name="pounds"> pounds<br><br>
  ...
</form>
```

If you want to make your `<output>` element look even smarter, you can add the *form* attribute (which indicates the ID of the form that has the related controls) and the *for* attribute (which lists the IDs of the related controls, separated by spaces). Here's an example:

```
<p>Your BMI: <output id="result" form="bmiCalculator"
  for="feet inches pounds"></output></p>
```

These attributes don't actually do anything, other than convey information about where your `<output>` element gets its goods. But they will earn you some serious semantic brownie points. And if other people need to edit your page, these attributes could help them sort out how it works.

Tip: If you're a bit hazy about forms, you'll learn more in Chapter 4. If you know more about Esperanto than JavaScript, you can brush up on the programming language in Appendix B. And if you want to try this page out for yourself, you can find the complete example at www.prosetech.com/html5.

Highlighted Text with <mark>

The <mark> element represents a section of text that's highlighted for reference. It's particularly appropriate when you're quoting someone else's text, and you want to bring attention to something:

```
<p>In 2009, Facebook made a bold grab to own everyone's content,
<em>forever</em>. This is the text they put in their terms of service:</p>
<blockquote>You hereby grant Facebook an <mark>irrevocable, perpetual,
non-exclusive, transferable, fully paid, worldwide license</mark> (with the
right to sublicense) to <mark>use, copy, publish</mark>, stream, store,
retain, publicly perform or display, transmit, scan, reformat, modify, edit,
frame, translate, excerpt, adapt, create derivative works and distribute
(through multiple tiers), <mark>any user content you post</mark>
...
</blockquote>
```

The text in a <mark> element gets the yellow background shown in Figure 3-2.

You could also use <mark> to flag important content or keywords, as search engines do when showing matching text in your search results, or to mark up document changes, in combination with (for deleted text) and <ins> (for inserted text).

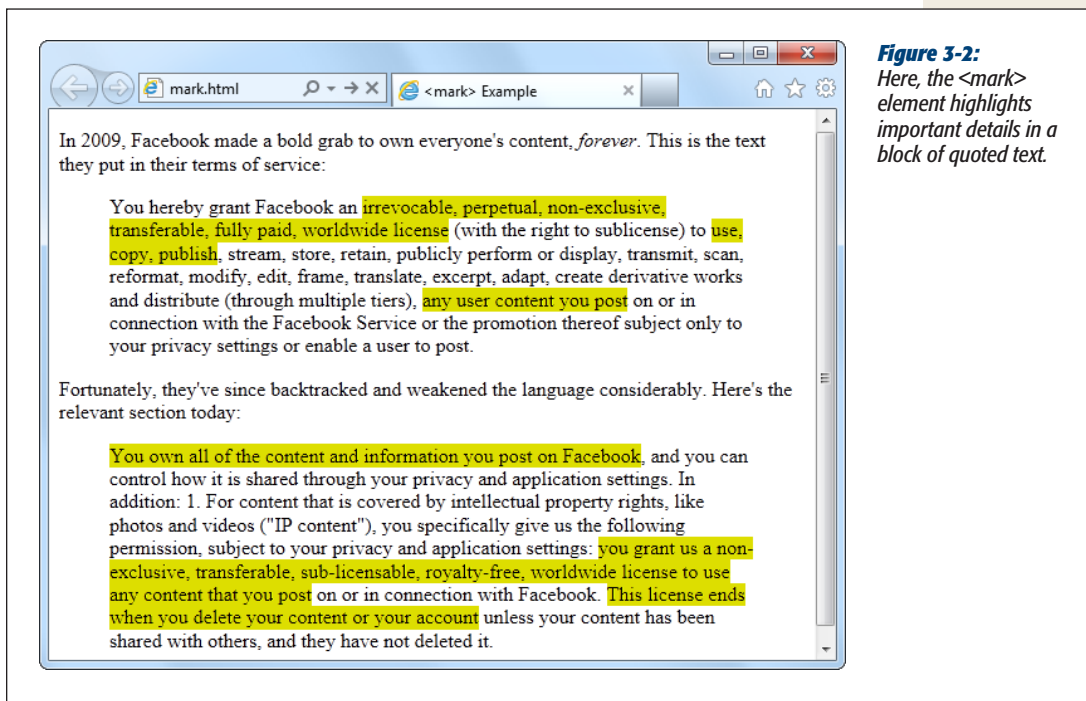

Truthfully, the <mark> element is a bit of a misfit. The HTML5 specification considers it to be a semantic element, but it plays a presentational role that's arguably more important. By default, marked-up text is highlighted with a bright yellow background (Figure 3-2), although you could apply your own style sheet rules to use a different formatting effect.

Tip: The <mark> element isn't really about formatting. After all, there are lots of ways to make text stand out in a web page. Instead, you should use <mark> (coupled with any CSS formatting you like) when it's semantically appropriate. A good rule of thumb is to use <mark> to draw attention to ordinary text that has *become* important, either because of the discussion that frames it, or because of the task the user is performing.

Even if you stick with the default yellow-background formatting, you should add a style sheet fallback for browsers that don't support HTML5. Here's the sort of style rule you need:

```
mark {
  background-color: yellow;
  color: black;
}
```

You'll also need the Internet Explorer workaround described on page 59 to make the <mark> element style-able.

Other Standards that Boost Semantics

At this point, it's probably occurring to you that there are a lot of potential semantic elements that HTML *doesn't* have. Sure, you can flag dates and highlighted text, but what about other common bits of information, like names, addresses, business listings, product descriptions, personal profiles, and so on? HTML5 deliberately doesn't wade into this arena, because its creators didn't want to bog the language down with dozens of specialized elements that would suit some people but leave others bored and unimpressed. To really get to the next level with semantics, you need to broaden your search beyond the core HTML5 language, and consider a few standards that can work with your web pages.

Semantically smart markup isn't a new idea. In fact, way back when HTML5 was still just a fantasy in WHATWG editor Ian Hickson's head, there were plenty of web developers clamoring for ways to make their markup for meaningful. Their goals weren't always the same—some wanted to boost accessibility, some were planning to do data mining, and others just wanted to dial up the cool factor on their resumé's. But none of them could find what they wanted in the standard HTML language, which is why several new standards sprung up to fill the gap.

In the following sections, you'll learn about no fewer than *four* of these standards. First, you'll get the scoop on ARIA, a standard that's all about improving accessibility for screen readers. Then, you'll take a peek at three competing approaches for describing different types of content, whether it's contact details, addresses, business listings, or just about anything else you can fit between the tags of an HTML page.

ARIA (Accessible Rich Internet Applications)

ARIA is a developing standard that lets you supply extra information for screen readers through attributes on any HTML element. For example, ARIA introduces the *role* attribute, which indicates the purpose of a given element. For example, if you have a `<div>` that represents a header:

```
<div class="header">
```

You can announce that fact to screen readers by setting the *aria* role attribute to *banner*:

```
<div class="header" role="banner">
```

Of course, you learned last chapter that HTML5 also gives you a more meaningful way to mark up headers. So what you really should use is something like this:

```
<header role="banner">
```

This example demonstrates two important facts. First, ARIA requires you to use one of a short list of recommended role names. (For the full list, refer to the appropriate section of the specification at www.w3.org/TR/wai-aria/roles#landmark_roles.) Second, parts of ARIA overlap the new HTML5 semantic elements—which makes sense, because ARIA predates HTML5. But the overlap isn't complete. For example, some role names duplicate HTML5 (like “banner” and “article”), while others go further (like “toolbar” and “search”).

ARIA also adds two attributes that work with HTML forms. The *aria-required* attribute in a text box indicates that the user needs to enter a value. The *aria-invalid* attribute in a text box indicates that the current value isn't right. These attributes are helpful, because screen readers are likely to miss the visual cues that sighted users rely on, like an asterisk next to a missing field, or a flashing red error icon.

In order to apply ARIA properly, you need to learn the standard and spend some time reviewing your markup. Web developers are divided over whether it's a worthwhile investment, given that the standard is still developing and that HTML5 provides some of the same benefits with less trouble. However, if you want to create a truly accessible website today, you need to use both, because newer screen readers support ARIA but not yet HTML5.

Note: For more information about ARIA (fully known as WAI-ARIA, because it was developed by the Web Accessibility Initiative group), you can read the specification at www.w3.org/TR/wai-aria.

RDFa (Resource Description Framework)

RDFa is a standard for embedding detailed metadata into your web documents using attributes. RDFa has a significant advantage: Unlike the other approaches discussed in this chapter, it's a stable, settled standard. RDFa also has two significant drawbacks. First, it's complicated. Markup that's augmented with RDFa metadata is far longer and more cumbersome than ordinary HTML. Second, it's designed for XHTML, not HTML5. Right now, a number of super-smart webheads are hammering out the best ways for web developers to adapt RDFa to work with HTML5. However, it's possible that RDFa just won't catch fire in the HTML5 world, because it's more at home with the strict syntax and ironclad rules of XML.

RDFa isn't discussed in this chapter. But if you want to learn more, you can get a solid introduction on Wikipedia at <http://en.wikipedia.org/wiki/RDFa>, or you can visit the Google Rich Snippets page described later (page 98), which has RDFa versions of all its examples.

Microformats

Microformats are a simple, streamlined approach to putting metadata in your pages. Microformats don't attempt to be any sort of official standard. Instead, they are best described as a loose collection of agreed-upon conventions that allow pages to share structured information, without requiring the complexities of a something like RDFa. This approach has given microformats tremendous success, and a recent Google survey found that when a page has some sort of rich metadata, 94 percent of the time it's microformats.

Note: Based on the popularity of microformats, you might assume that the battle for the Semantic Web is settled. But not so fast—there are several caveats. First, the vast majority of pages have no rich semantic data at all. Second, most of the pages that have adopted microformats use them for just two purposes: contact information and event listings. And third, the simplicity of microformats may hold them back from more ambitious tasks, especially when HTML5 catches on. So although microformats aren't going anywhere soon, you can't afford to ignore the competition either.

Before you can mark up any data, you need to choose the microformat you want to use. There are only a few dozen in widespread use, and most are still being tweaked and revised. You can see what's available and read detailed usage information about each microformat at <http://microformats.org/wiki>. But it's most likely that you'll use one of the two most popular microformats: hCard or hCalendar.

Contact details with hCard

The hCard microformat is an all-purpose way to represent the contact details for a person, company, organization, or place. At last count, the Web contained more than 2 billion hCards, making it the most popular microformat by far.

Microformats work in an innovative way—they piggyback on the *class* attribute that's usually used for styling. You mark up your data using certain standardized style names, depending on the type of data. Then, another program can read your markup, extract the data, and check the attributes to figure out what everything means. To create an hCard, you need a root element that sets the class attribute to *vcard*. Inside that element, you need to supply at least a formatted name, in another element. That element needs to set the class attribute to *fn*. Here's some markup that meets these requirements:

```
<div class="vcard">
  <div class="fn">Mike Rowe Formatte</div>
</div>
```

When you use the class attribute for a microformat, you don't need to go to the trouble of creating a matching style with that class name. (In fact, doing so is probably just going to be confusing.) Instead, the class attribute is put to a different use—advertising your data as a nicely structured, meaningful bit of content.

Although an hCard doesn't need anything more than a name, most fill in a few more details, such as a postal and email address, website URL, telephone number, birth date, photo, title, organization name, and so on. As long as you use the right class names, you can put these details in any order in the containing *vcard* element. Here's an example, with the all-important class names highlighted:

```
<div class="vcard">
  <div class="fn">Mike Rowe Formatte</div>
  
  <div class="title">Web Developer</div>
  <div class="org">The Magic Semantic Company</div>
  <a class="url" href="http://www.magicsemantics.com">www.magicsemantics.com</a>
  <div class="tel">641-545-0234</div>
</div>
```

Tip: You can get information about all the supported hCard properties at <http://microformats.org/wiki/hcard>.

So far, this example has shown how to create markup that matches the hCard microformat from scratch. But you'll often need to take an existing web page and retrofit it with microdata support. For example, you might have a page that includes contact information, but you want to mark up that information so it's accessible to any program that understands the hCard microformat. This task is fairly easy, if you keep a few points in mind:

- Often, you'll have important data mixed in with content that you want to ignore. In this case, you can add new elements around each piece of information you want to capture. Use a `<div>` if you want a block-level element or a `` if you want to get a piece of inline content.

- Don't worry about other elements with different class names. When reading a microformat, everything that doesn't have a recognized class name is ignored.
- If you're supplying a picture to a microformat, you can use the `` element. If you're supplying a link, you can use the `<a>` element. The rest of the time, you'll usually be marking up ordinary text.

Here's a more typical example. Imagine you start with an "About Me" page (Figure 3-3) that has content like this:

```
<h1>About Me</h1>

<p>This website is the work of <b>Mike Rowe Formatte</b>.
His friends know him as <b>The Big M</b>.</p>

<p>You can contact him where he works, at
The Magic Semantic Company (phone
641-545-0234 and ask for Mike).</p>

<p>Or, visit him there at:<br>
42 Jordan Gordon Street, 6th Floor<br>
San Francisco, CA 94105<br>
USA<br>
<a href="http://www.magicsemantics.com">www.magicsemantics.com</a>
```

And here's how you can weave the microformat-enhanced elements around this information:

```
<h1>About Me</h1>

<div class="vcard">
  
  <p>This website is the work of
  <span class="title" style="display:none">Web Developer</span>
  <b class="fn">Mike Rowe Formatte</b>.
  His friends know him as <b class="nickname">The Big M</b>.</p>

  <p>You can contact him where he works, at
  <span class="org">The Magic Semantic Company</span> (phone
  <span class="tel">641-545-0234</span> and ask for Mike).</p>

  <p>Or, visit him there at:<br>
  <span class="street-address">42 Jordan Gordon Street, 6th Floor</span><br>
  <span class="locality">San Francisco</span>,
  <span class="region">CA</span>
  <span class="postal-code">94105</span><br>
  <span class="country-name">USA</span><br>
  <a class="url" href="http://www.magicsemantics.com">www.magicsemantics.com</a>
</div>
```

Figure 3-3:

This “About Me” page includes the contact details for the website author.

This example incorporates several tricks:

- It adds new `` elements to wrap the bits of content you need for the vcard.
- It adds the class attribute to existing elements, where doing so makes sense. For example, the `` element wraps the name information, so there's no need to add an additional ``. (Of course, you could. For example, you might prefer to write something like `<b class="KeywordEmphasis">Mike Rowe Formatte` if you want to apply formatting and mark up the name at the same time, but keep your style sheet rules separate from your microformat.
- It uses a hidden piece of content to point out the person's title (as a web developer). There's no need to show this on the page, because that information is already obvious from the sentence, "This website is the work of..." However, this technique is a bit controversial, because some tools (like Google) ignore information that isn't made visible to the web page viewer.

Now that you've gone to this trouble, it's time to see what sort of benefits you can reap. Although no browser recognizes microformats on its own (at least at the time of this writing), there are a variety of plug-ins and scripts that can give browsers these capabilities. And it's not difficult to imagine useful scenarios. For example, a browser could detect the hCards on a page, list them in a side panel, and give you commands that would allow you to add a person to your address book as quickly as you bookmark a page. You can look for a browser plug-in that supports microformats at <http://microformats.org/wiki/browsers>.

One such tool is Oomph (available at <http://oomph.codeplex.com>). You can install Oomph as a browser plug-in for Internet Explorer, in which case it automatically searches every page you visit for three microformats: hCard (for contact information), hCalendar (for event listings), and hMedia (for images, audio, or video). If it finds something, it adds a tiny icon to the top-left corner of the window (see Figure 3-4). Click this icon, and you'll see the contacts, events, and media files it found, complete with handy links.

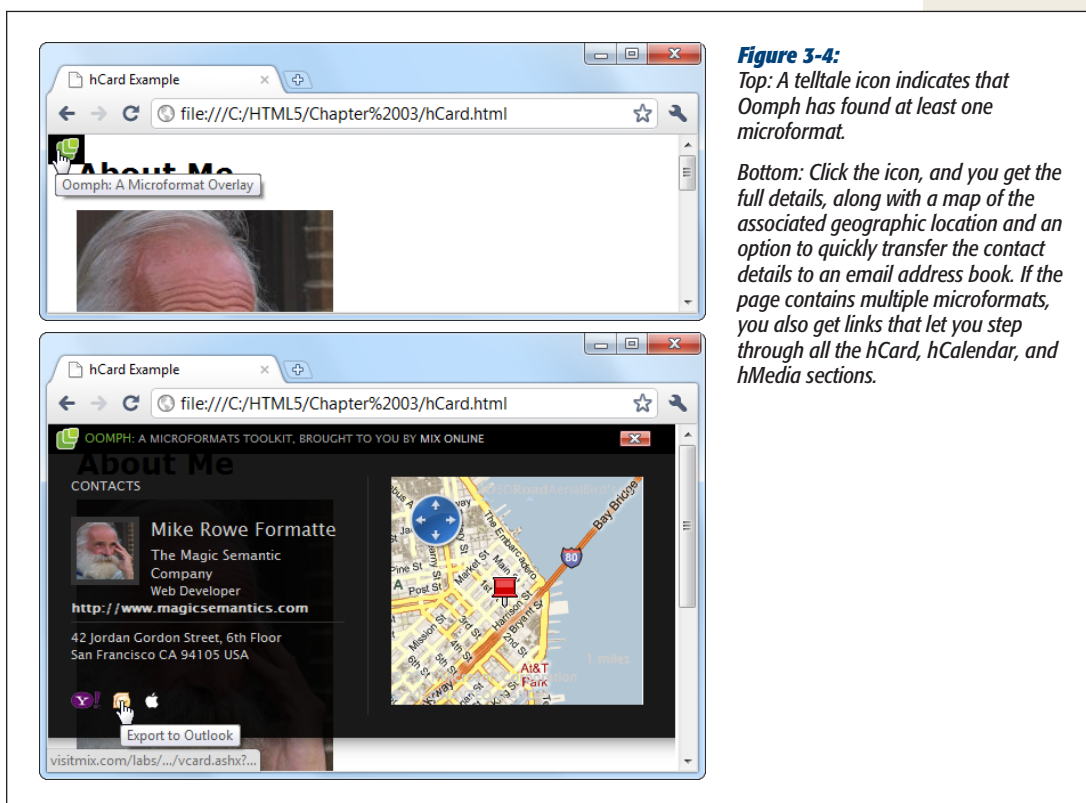

Figure 3-4:
Top: A telltale icon indicates that Oomph has found at least one microformat.

Bottom: Click the icon, and you get the full details, along with a map of the associated geographic location and an option to quickly transfer the contact details to an email address book. If the page contains multiple microformats, you also get links that let you step through all the hCard, hCalendar, and hMedia sections.

But the really interesting thing about Oomph is that there's another way to use it—using a JavaScript library. In this case, all you need to do is add to script references to your page:

```
<head>
  <meta charset="utf-8">
  <title>hCard Example</title>
  <script src="jquery-1.3.2.min.js"></script>
  <script src="oomph.min.js"></script>
</style>
```

Now, all the people who visit your page get the enhanced experience with the pop-up microformat button, no matter what browser they use. In fact, that's what allows the example in Figure 3-4 to work on Google Chrome. To see for yourself, visit the try-out site at www.prosetech.com/html5.

Note: You should think of Oomph as a proof-of-concept demonstration of what's possible with microformats, not a real-life tool. The best bet for a microformats future is for mainstream browsers to incorporate direct support, just like IE, Firefox, and Safari do for RSS feeds. For example, if you visit a blog with Firefox, it automatically detects the RSS feed and allows you to create a “live” bookmark. This is exactly the sort of value-added feature that could make microformats really useful.

Events with hCalendar

The second most popular microformat is hCalendar, a simple way of marking up events. For example, you can use hCalendar to detail appointments, meetings, holidays, product releases, store openings, and so on. Currently, the Web has tens of millions of hCalendar events. Figure 3-5 shows an example.

Once you've worked your way around your first hCard, you'll have no trouble understanding hCalendar. First, you need to wrap the event listing in an element with the class name *vevent*. Inside, you need at least two pieces of information: the start date (marked up with the *dtstart* class) and a description (marked up with the *summary* class). You can also choose from a variety of optional attributes described at <http://microformats.org/wiki/hcalendar>, including an ending date or duration, a location, and a URL with more details. Here's an example:

```
<div class="vevent">
  <h2 class="summary">Web Developer Clam Bake</h2>
  <p>I'm hosting a party!</p>
  <p>It's
    <span class="dtstart" title="2011-10-25T13:30">Tuesday, October 25,
      1:30PM</span>
    at the <span class="location">Deep Sea Hotel, San Francisco, CA</span></p>
</div>
```

When formatting the date, you must use the universal date format described on page 83. However, there's a workaround—you can supply the computer-readable date details using the *title* attribute, and then use whatever text you want. Unfortunately, there's currently no automatic way for a microformat to use the information in the *datetime* attribute of HTML5's `<time>` element (although the microdata standard fixes that, as you'll see on the next page).

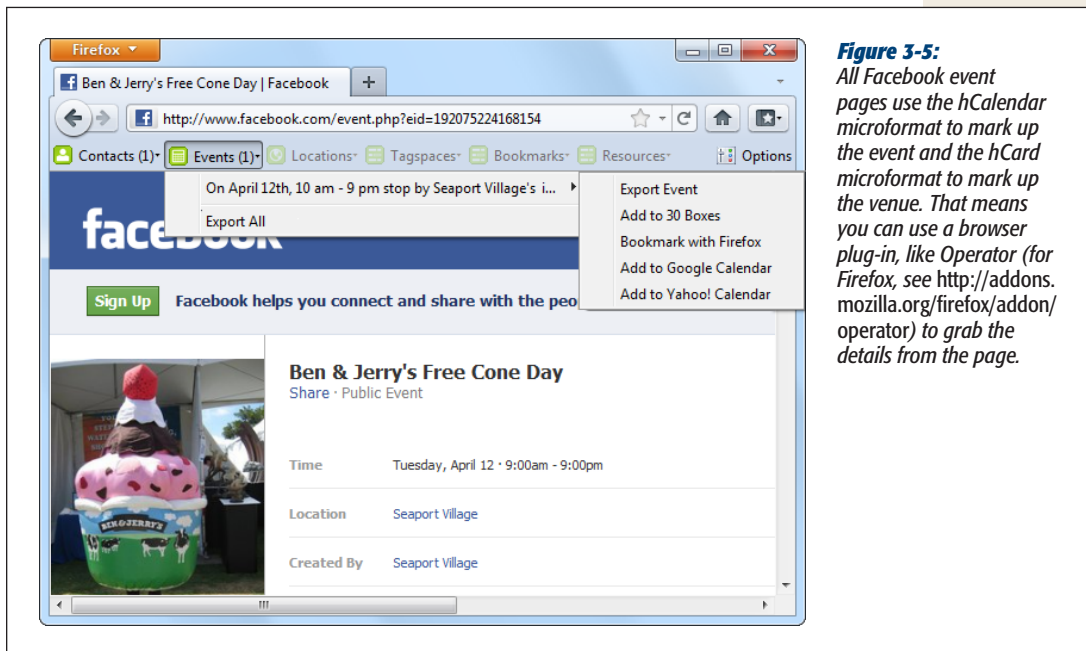

Figure 3-5: All Facebook event pages use the hCalendar microformat to mark up the event and the hCard microformat to mark up the venue. That means you can use a browser plug-in, like Operator (for Firefox, see <http://addons.mozilla.org/firefox/addon/operator>) to grab the details from the page.

Microdata

Microdata is a third take at solving the challenge of semantic markup. It began its life as part of the HTML5 specification, and later split into its own developing standard at <http://dev.w3.org/html5/md>. Microdata uses an approach that's similar to RDFa, but simplified. Unlike microformats, it uses its own attributes, and doesn't risk colliding with style sheet rules (or confusing the heck out of other web developers). This design means microdata is more logical, as well as easier to adapt for your own custom languages. But it also comes at the cost of brevity—microdata-enriched markup can bloat up a bit more than microformat-enriched markup.

Note: As the newest semantic standard, it's still unclear whether microdata will ride in on a wave of HTML5-fueled excitement, or whether it will give way to the other, more established standards (perhaps microformats for simple uses and some adapted form of RDFa for more complex requirements). However, either way, learning about microdata isn't a waste. As you'll see in the next section, it's already supported by Google, and looks a lot like RDFa—close enough that you can switch formats depending on what the future holds.

To begin a microdata section, you add the *itemscope* and *itemtype* attributes to any element (although a `<div>` makes a logical container, if you don't have one already). The *itemscope* attribute indicates that you're starting a new chunk of semantic content. The *itemtype* attribute indicates the specific type of data you're encoding:

```
<div itemscope itemtype="http://data-vocabulary.org/Person">
  ...
</div>
```

To identify the data type, you use a predetermined, unique piece of text called an *XML namespace*. In this example, the XML namespace is `http://data-vocabulary.org/Person`, which is a data format for encoding contact details.

XML namespaces are often URLs. Sometimes, you can even find a description of the corresponding data type by typing the URL into your web browser (as you can with the `http://data-vocabulary.org/Person` data format). However, XML namespaces don't *need* to correlate to real web locations, and they don't need to be URLs at all. It just depends on what the person (or people) chose when creating the format. The advantage of a URL is that it can incorporate a domain name that a person or organization owns. This way, the namespace is more likely to be unique, meaning that no one else will create a different data format that shares the same namespace name and confuses everyone.

Once you have the container element, you're ready to move on to the next step. Inside your container element, you use the *itemprop* attribute to capture the important bits of information. The basic approach is the same as it was for microformats—you use a recognized *itemprop* name, and other pieces of software can grab the information from the associated elements. In fact, the most significant difference between microdata and microformats is that microdata uses the *itemprop* attribute to mark up elements instead of the *class* attribute.

```
<div itemscope itemtype="http://data-vocabulary.org/Person">
  <span itemprop="name">Mike Rowe Formatte</span>.
  ...
</div>
```

Microdata is also a bit more structured than microformats. For example, it's common to have one type of data nested inside another type. In the case of the contact details, you might have a set of address information nestled inside. Technically, the address information all belongs to a separate data type, which is identified with a different XML namespace. So you need a new `<div>` or `` element that uses the *itemscope* and *itemtype* attributes, as shown here:

```
<div itemscope itemtype="http://data-vocabulary.org/Person">
  ...
  <span itemprop="address" itemscope
    itemtype="http://data-vocabulary.org/Address">
    <span itemprop="street-address">42 Jordan Gordon Street,
      6th Floor</span><br>
    <span itemprop="locality">San Francisco</span>,
    <span itemprop="region">CA</span>
  </span>
</div>
```

With these rules in mind, you can retrofit the “About Me” page shown earlier (page 91) to use microdata. Here’s the finished product, with the changes highlighted:

```
<h1>About Me</h1>

<div itemscope itemtype="http://data-vocabulary.org/Person">
  
  <p>This website is the work of
  <span itemprop="title" style="display:none">Web Developer</span>
  <b itemprop="name">Mike Rowe Formatte</b>.
  His friends know him as <b itemprop="nickname">The Big M</b>.</p>

  <p>You can contact him where he works, at
  <span itemprop="affiliation">The Magic Semantic Company</span> (phone
  <span itemprop="tel">641-545-0234</span> and ask for Mike).</p>

  <p>Or, visit him there at:<br>
  <span itemprop="address" itemscope
  itemtype="http://data-vocabulary.org/Address">
    <span itemprop="street-address">42 Jordan Gordon Street,
    6th Floor</span><br>
    <span itemprop="locality">San Francisco</span>,
    <span itemprop="region">CA</span>
    <span itemprop="postal-code">94105</span><br>
    <span itemprop="country-name">USA</span><br>
  </span>
  <a itemprop="url" href="http://www.magicsemantics.com">www.magicsemantics.
  com</a>
</div>
```

As you’ve probably noticed, this example is strikingly similar to the hCard example shown earlier (page 91). Although the property names have shifted from the class attribute to the `itemprop` attribute, this example still uses almost all the same property names (the only changes are *fn* to *name* and *org* to *affiliation*). And if you learned RDFa, you’d find an even greater correspondence, because both microdata and RDFa use the `http://data-vocabulary.org/Person` data format.

Note: The three standards for rich semantic data—RDFa, microdata, and microformats—all share broad similarities. They aren’t quite compatible, but the markup is similar enough that the skills you pick up learning one system are mostly applicable to the others.

Microdata falls short in one notable area: There’s still no browser plug-in or JavaScript magic that can dig these details out of a page. However, microdata works perfectly well if your goal is to enhance web search results, which is the technique you’ll practice next.

Google Rich Snippets

Stuffing your page with semantic details is a great way to win yourself some serious web-nerd cred. But even hardcore web developers need some sort of payoff to make the extra work (and the messier markup) worthwhile. It’s nice to think about a world

of super-smart, semantically aware browsers, but right now the cold, hard reality is that web surfers have little more than a few experimental and little-known browser plug-ins.

Fortunately, there is another reason to embrace rich semantics: *search engine optimization* (SEO). SEO is the art of making your website more visible in a search engine—in other words, making it turn up more often in a results page, helping it get a better ranking for certain keywords, and making it more likely to entice a visitor to click through to your site. Google’s *rich snippets* feature helps with the last part of this equation. All you do is put the right semantic data on your page, and Google will find it and use it to present a fancier search listing, which can help your website stand out from the crowd.

But before you use rich snippets, you need to understand a bit more about the term. *Rich snippets* is the name Google has created to lump together RDFa, microformats, and microdata. As you’ve already learned, these approaches share significant similarities and address the same problem. But Google’s goal is to treat them all equally, so it doesn’t matter which approach you favor. (The following examples use microdata, with the aim of getting onboard with HTML5’s newest semantic standard.)

To learn more about the standards that rich snippets support, you can view Google’s documentation at <http://tinyurl.com/GoogleRichSnippets>. Not only does this page include a decent overview of RDFa, microformats, and microdata, it also shows many different snippet examples (like contact information, events, products, reviews, recipes, and so on). Best of all, Google includes an RDFa, microformat, and microdata version of each example, which can help you translate your semantic skills from one standard to another, if the need arises.

Enhanced Search Results

To see how Google’s rich snippets feature works, you can use Google’s Rich Snippets Testing Tool. This tool checks a page you supply, shows you the semantic data that Google can extract from the page, and then shows you how Google might use that information to customize the way it presents that page in someone’s search results.

Note: The Rich Snippets Testing Tool is useful for two reasons. First, it helps validate your semantic markup. (If Google isn’t able to extract all the information you put in the page, or if some of it is assigned to the wrong property, you know you’ve done something wrong.) Second, it shows you how the semantic data can change your page’s appearance in Google’s search results.

To use the Rich Snippets Testing Tool, follow these simple steps:

1. Go to www.google.com/webmasters/tools/richsnippets.

This simple page includes a single text box (see Figure 3-6).

2. Enter the full URL to your page in the text box.

The only disadvantage is that the Rich Snippets Testing Tool works only on pages that are already online, so you can't use it to check a page that's stored on your computer's hard drive.

3. Click Preview.

You can now review the results (see Figure 3-6). There are two important sections to review. The "Google search preview" section shows how the page may appear in a search result. The "Extracted rich snippet data from the page" shows all the raw semantic data that Google was able to pull out of your markup.

Rich Snippets Testing Tool

Use the Rich Snippets Testing Tool to check that Google can correctly parse your structured data markup and display it in search results.

Test your website

Enter a web page URL to see how it may appear in search results:

Extracted rich snippet data from the page

Item

Type: <http://data-vocabulary.org/person>
 photo = <http://www.sugarbeat.ca/prosetech/face.jpg>
 title = Web Developer
 name = Mike Rowe Formatte
 nickname = The Big M
 affiliation = The Magic Semantic Company
 tel = 641-545-0234
 address = *Item(1)*
 url = <http://www.magicsemantics.com/>

Item 1

Type: <http://data-vocabulary.org/address>
 street-address = 42 Jordan Gordon Street, 6th Floor
 locality = San Francisco
 region = CA
 postal-code = 94105
 country-name = USA

Figure 3-6: Here, Google found the person contact details and address information (from the microdata example shown on page 97). It used this information to add a gray byline under the page title, with some of the personal details.

The page you want Google to examine

Google uses some of the semantic data to create this light gray line

Google also found the address details

Google found the contact details on the page

Tip: If you see the dreaded “Insufficient data to generate the preview” error message, there are three possible causes. First, your markup may be faulty. Review the raw data that Google extracted, and make sure it found everything you put there. If you don’t find a problem here, it’s possible that you’re trying to use a data type that Google doesn’t yet support or you haven’t included the bare minimum set of properties that Google needs. To figure out what the problem is, compare your markup with one of Google’s examples at <http://tinyurl.com/GoogleRichSnippets>.

The method Google uses to emphasize contact details (Figure 3-6) is fairly restrained. However, contact details are only one of the rich data types that Google recognizes. Earlier in this chapter (page 94), you saw how to define events using microformats. Add a list of events to your page, and Google just might include them at the bottom of your search result, as shown in Figure 3-7.

Figure 3-7:

This example page has three events. If you supply a URL with your event listing (as done here), Google turns each event listing into a clickable link.

Google is also interested in business listings (which are treated in much the same way as personal contact details), recipes (which you’ll take a peek at in the next section), and reviews (which you’ll consider next).

The following example shows the markup you need to turn some review text into recognizable review microdata. The data standard is defined at <http://data-vocabulary.org/Review>. Key properties include *itemreviewed* (in this case, a restaurant), *reviewer*, and *description*. You can also supply a one-sentence overview (*summary*), the date when the review was made or submitted (*dtreviewed*, which supports HTML5’s `<time>` element), and a score from 0 to 5 (*rating*).

Here’s an example, with all the microdata details highlighted:

```
<div itemscope itemtype="http://data-vocabulary.org/Review">
  <h1 itemprop="itemreviewed">Jan's Pizza House</h1>
  <p>Reviewed by <span itemprop="reviewer">Jared Elberadi</span> on
  <time itemprop="dtreviewed" datetime="2011-01-26">January 26</time>.<p>
  <p itemprop="summary">Pretty bad, and then the Health Department showed
  up.</p>
  <p itemprop="description">I had an urge to mack on some pizza, and this
  place was the only joint around. It looked like a bit of a dive, but I went
  in hoping to find an undiscovered gem. Instead, I watched a Health
  Department inspector closing the place down. Verdict? I didn't get to
  finish my pizza, and the inspector recommends a Hep-C shot.</p>
  <p>Rating: <span itemprop="rating">0.5</span></p>
</div>
```

Put this data in a page, and Google gives it truly special treatment (Figure 3-8).

Jan's Pizza House

Reviews really stand out in search results. The ranking stars are eye-catching and attract immediate interest.

TROUBLESHOOTING MOMENT**What to Do When Google Ignores Your Semantic Data**

Just because Google *can* show a semantically enriched page in a certain special way doesn't mean it *will*. Google uses its own set of semi-secret rules to determine if the semantic information is valuable to the searcher. But here are some surefire ways to make sure Google ignores your data:

- **The semantic data doesn't represent the main content.** In other words, if you slap your contact details on a page about fly-fishing, Google isn't likely to use your contact information. (After all, the odds are that when web searchers find this page, they're searching for something to do with fishing, and it doesn't make any sense to see a byline with your
- **The semantic data is hidden.** Google won't use any content that's hidden via CSS.
- **Your website uses just a little semantic data.** If your site has relatively few pages that use semantic data, Google might inadvertently overlook the ones that do.

Avoid these mistakes and you stand a good chance of getting an enhanced listing.

The Recipe Search Engine

Enhanced search listings are a neat trick, and they can drive new traffic into your website. But still, it's hard not to want something even more impressive to justify your newfound semantic skills. Happily, the geniuses at Google are busy dreaming up the future of search, and it has semantics all over it.

One brilliant idea is to use the semantic information not to tweak how an item is presented in a search, but to allow smarter search filtering. For example, if people mark up their resumés using RDFa, microformats, or microdata, Google could provide a specialized resumé searching feature that looks at this data, considering resumés from every popular career website and ignoring every other type of web content. This resumé search engine could also provide enhanced filtering options—for example, allowing companies to find candidates who have specific accreditations or have worked for specific companies.

Right now, Google doesn't have a resumé search engine. However, Google has recently released something that's conceptually quite similar, and possibly more practical: a search tool for hunting down recipes.

By now, you can probably guess what recipe data looks like when it's marked up with microdata or a microformat. The entire recipe sits inside a container that uses the recipe data format (that's <http://data-vocabulary.org/Recipe>). There are separate properties for the recipe name, the author, and a photo. You can also add a one-sentence summary and a ranking from user reviews.

Here's a portion of recipe markup:

```
<div itemscope itemtype="http://data-vocabulary.org/Recipe">
  <h1 itemprop="name">Elegant Tomato Soup</h1>
  
  <p>By <span itemprop="author">Michael Chiarello</span></p>
  <p itemprop="summary">Roasted tomatoes are the key to developing the rich
    flavor of this tomato soup.</p>
  ...
```

After this, you can include key details about the recipe, including its prep time, cook time, and yield. You can also add a nested section for nutritional information (with details about serving size, calories, fat, and so on):

```
...
<p>Prep time: <time itemprop="prepTime" datetime="PT30M">30 min</time></p>
<p>Cook time: <time itemprop="cookTime" datetime="PT1H">40 min</time></p>
<p>Yield: <span itemprop="yield">4 servings</span></p>
<div itemprop="nutrition" itemscope
  itemtype="http://data-vocabulary.org/Nutrition">
  Serving size: <span itemprop="servingSize">1 large bowl</span>
  Calories per serving: <span itemprop="calories">250</span>
  Fat per serving: <span itemprop="fat">3g</span>
</div>
...
```

Note: The `prepTime` and `cookTime` properties are meant to represent a *duration* of time, not a single instant in time, and so they can't use the same format as the HTML5 `<time>` element. Instead, they use an ISO format that's detailed at http://en.wikipedia.org/wiki/ISO_8601#Durations.

After this is the recipe's ingredient list. Each ingredient is a separate nested section, which typically includes information like the ingredient name and quantity:

```
...
<ul>
  <li itemprop="ingredient" itemscope
    itemtype="http://data-vocabulary.org/RecipeIngredient">
    <span itemprop="amount">1</span>
    <span itemprop="name">yellow onion</span> (diced)
  </li>
```

```

<li itemprop="ingredient" itemscope
  itemtype="http://data-vocabulary.org/RecipeIngredient">
  <span itemprop="amount">14-ounce can</span>
  <span itemprop="name">diced tomatoes</span>
</li>
...
</ul>
...

```

Writing this part of the markup is tedious. But don't stop yet—the payoff is just ahead.

Finally, the directions are a series of paragraphs or a list of steps. They're wrapped up in a single property, like this:

```

...
<div itemprop="instructions">
  <ol>
    <li>Preheat oven to 450 degrees F.</li>
    <li>Strain the chopped canned tomatoes, reserving the juices.</li>
    ...
  </div>
  ...
</div>

```

For a full recipe example, see <http://tinyurl.com/RichSnippetsRecipe>.

Note: Recipes tend to be long and fairly detailed, so marking them up is a long and involved project. This is a clear case where a good authoring tool could make a dramatic difference. Ideally, this tool would let web authors enter the recipe details in the text boxes of a nicely arranged window. It would then generate semantically correct markup that you could place in your web page.

Once Google indexes your marked-up recipe page, it will make that recipe available through the Recipe View search feature. To try out Recipe View, surf to www.google.com/landing/recipes, type a recipe name in the search box, and then click Search. The interesting part is what comes next. Because Google can *understand* the structure of every recipe, it can ignore web pages that don't have real recipe data, and it can include smarter filtering options (see Figure 3-9). The end result is that semantic data gives web surfers a powerful information-hunting tool—and a more effective way to find your web pages.

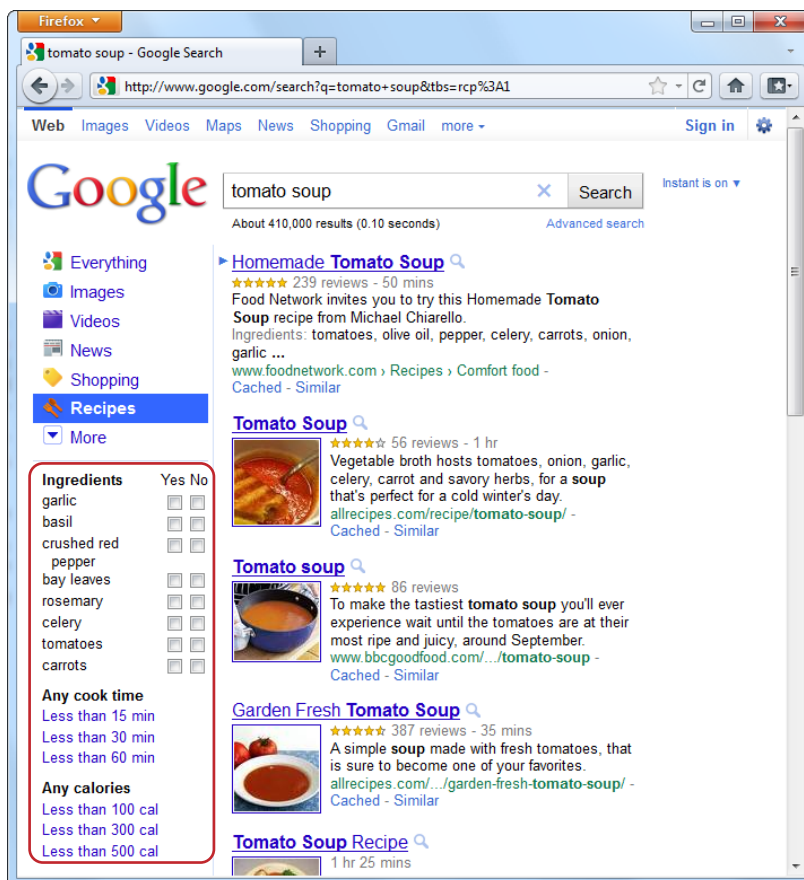

Figure 3-9: After you perform a recipe search, Google lets you filter the results based on some of the rich snippet information that it found in the matching recipes. For example, you can require or eliminate specific ingredients, and set a maximum cook time or calorie count.

Chapter 7: Deeper into the Canvas

Chapter 8: Boosting Styles with CSS3

Web Forms, Refined

*H*TML forms are simple HTML controls you use to collect information from website visitors. They include text boxes people can type into, list boxes they can pick from, checkboxes they can switch on or off, and so on. There are countless ways to use HTML forms, and if you've kicked around the Web for more than a week, you've used them to do everything from getting a stock quote to signing up for an email account.

HTML forms have existed almost since the dawn of HTML, and they haven't changed a wink since last century, despite some serious efforts. Web standards-makers spent years cooking up a successor called XForms, which fell as flat as XHTML 2 (see page 12). Although XForms solved some problems easily and elegantly, it also had its own headaches—for example, XForms code was verbose and assumed that web designers were intimately familiar with XML. But the biggest hurdle was the fact that XForms wasn't compatible with HTML forms in any way, meaning that developers would need to close their eyes and jump to a new model with nothing but a whole lot of nerve and hope. But because mainstream web browsers never bothered to implement XForms—it was too complex and little used—web developers never ended up taking that leap.

HTML5 takes a different approach. It introduces refinements to the existing HTML forms model, which means HTML5-enhanced forms can keep working on older browsers, just without all the bells and whistles. (This is good, because Internet Explorer won't start supporting the new form features until IE 10.) HTML5 forms also focus on adding features that developers are already using today. The difference is that HTML5 makes them easily accessible, without requiring a tangle of JavaScript code or a JavaScript toolkit from another company.

In this chapter, you'll tour all the new features of HTML5 forms. You'll see which ones are supported, which ones aren't, and which workarounds can help you smooth over the differences. You'll also consider a feature that isn't technically part of the HTML5 forms standard but is all about interactivity—putting a rich HTML editor in an ordinary web page.

Understanding Forms

Odds are that you've worked with forms before. But if you're a bit sketchy on the details, the following recap will refresh your memory.

A *web form* is a collection of text boxes, lists, buttons, and other clickable widgets that a web surfer uses to supply some sort of information to a website. Forms are all over the Web—they allow you to sign up for email accounts, review products, and make bank transactions. The simplest possible form is the single text box that adorns search engines like Google (see Figure 4-1).

All basic web forms work in the same way. The user fills in some information and then clicks a button. At that point, the server collects all the data that the user has entered and sends it back to the web server. On the web server, some sort of application digests the information and takes the appropriate next step. The server-side program might consult a database (either to read or to store some information), before sending a new page back to the web browser.

The tricky part of this discussion is that there are hundreds of ways to build the server-side part of the equation (that's the application that processes the information that's submitted from the form). Some developers may use stripped-down scripts that let them manipulate the raw form data, while others may work with higher-level models that package the form details in neat programming objects. But either way, the task is basically the same—examine the form data, do something with it, and then send back a new page.

Note: This book doesn't make any assumptions about your choice of server-side programming tool. In fact, it doesn't really matter, because you still need to use the same set of form elements, and these elements are still bound by the same HTML5 rules.

UP TO SPEED

Bypassing Form Submission with JavaScript

It's worth noting that forms aren't the only way to send user-entered information to a web server (although they were, once upon a time). Today, crafty developers can use the XMLHttpRequest object (page 325) in JavaScript code to quietly communicate with a web server. For example, the Google search page uses this approach in two different ways—first, to get search suggestions, which it displays in a drop-down list; and second, to get a search results page as you type, if you've enabled the Google Instant feature (www.google.com/instant).

It might occur to you that JavaScript can completely bypass the form submission step, as it does in Google Instant. But while it's possible to offer this as a *feature*, it's not acceptable to include it as a *requirement*. That's because the JavaScript approach isn't bulletproof (for example, it may exhibit the occasional quirk on a slow connection) and

there's still a small fraction of people with no JavaScript support or with JavaScript turned off in their browsers.

Finally, it's worth noting that it's perfectly acceptable to have a page that never submits its form. You've probably seen pages that perform simple calculations (for example, a mortgage interest rate calculator). These forms don't need any help from the server, so they can perform their calculations entirely in JavaScript and display the result on the current page.

From the HTML5 point of view, it really doesn't matter whether you submit your form to a server, use the data in an ordinary JavaScript routine, or pass it back to the server through XMLHttpRequest. In all cases, you'll still build your form using the standard HTML forms controls.

Revamping a Traditional HTML Form

The best way to learn about HTML5 forms is to take a typical example from today and enhance it. Figure 4-2 shows the example you'll start out with.

Figure 4-2:
If you've traveled the Web, you've seen your share of forms like this one, which collects basic information from a web page visitor.

The markup is dishwasher-dull. If you've worked with forms before, you won't see anything new here. First, the entire form is wrapped in a `<form>` element:

```
<form id="zooKeeperForm" action="processApplication.cgi">
  <p><i>Please complete the form. Mandatory fields are marked with
    a </i><em>*</em></p>
  ...
```

The `<form>` element bundles together all the form widgets (also known as *controls* or *fields*). It also tells the browser where to post the page when it's submitted, by providing a URL in the action attribute. If you plan to do all the work in client-side JavaScript code, you can simply use a number sign (#) for the action attribute.

Note: HTML5 adds a mechanism for placing form controls outside of the form to which they belong. The trick is to use the new `form` attribute to refer to the form by its id value (as in `form="zooForm"`). However, browsers that don't support this feature will completely overlook your data when the form is submitted, which means this minor feature is still too risky to use in a real web page.

A well-designed form, like the zookeeper application, divides itself into logical chunks using the `<fieldset>` element. Each chunk gets a title, courtesy of the `<legend>` element. Here's the `<fieldset>` for the Contact Details section (which is dissected in Figure 4-3):

```
...
<fieldset>
  <legend>Contact Details</legend>
  <label for="name">Name <em>*</em></label>
  <input id="name"><br>
  <label for="telephone">Telephone</label>
  <input id="telephone"><br>
  <label for="email">Email <em>*</em></label>
  <input id="email"><br>
</fieldset>
...
```

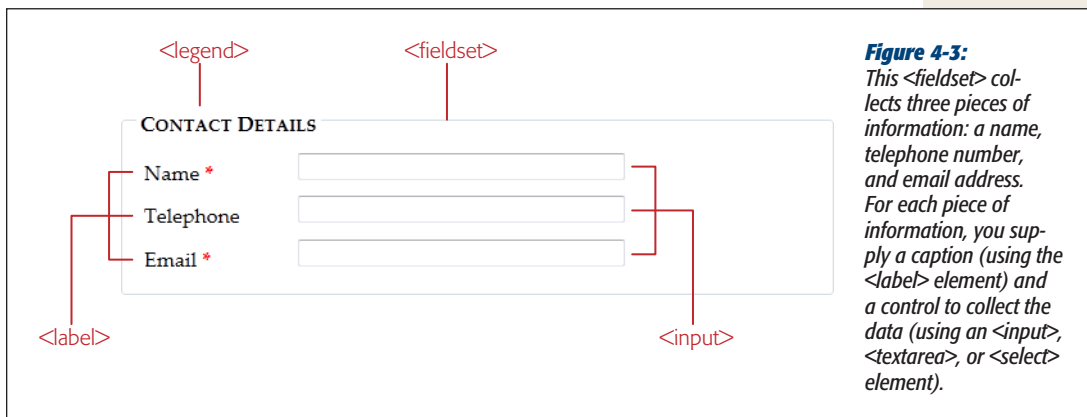

Figure 4-3: This `<fieldset>` collects three pieces of information: a name, telephone number, and email address. For each piece of information, you supply a caption (using the `<label>` element) and a control to collect the data (using an `<input>`, `<textarea>`, or `<select>` element).

As in all forms, the bulk of the work is handled by the all-purpose `<input>` element, which collects text and creates checkboxes, radio buttons, and list buttons. Along with `<input>`, the `<textarea>` element gives people a way to enter multiple lines of text, and the `<select>` element creates a list. If you need a refresher, Table 4-1 will fill you in.

Table 4-1. Form controls

Control	HTML element	Description
Single-line textbox	<code><input type="text"></code> <code><input type="password"></code>	Shows a text box where visitors can type in text. If you use the password type, the browser won't display the text. Instead, visitors see an asterisk (*) or a bullet (•) in place of each letter as they type in their password.
Multiline textbox	<code><textarea>...</textarea></code>	Shows a large text box that can fit multiple lines of text.
Checkbox	<code><input type="checkbox"></code>	Shows a checkbox that can be switched on or off.
Radio button	<code><input type="radio"></code>	Shows a radio button (a circle you can turn on or off). Usually, you have a group of radio buttons with the same value for the <i>name</i> attribute, in which case the visitor can select only one.
Button	<code><input type="submit"></code> <code><input type="image"></code> <code><input type="reset"></code> <code><input type="button"></code>	Shows the standard clickable button. A <i>submit</i> button always gathers up the form data and sends it to its destination. An <i>image</i> button does the same thing, but it lets you display a clickable picture instead of the standard text-on-a-button. A <i>reset</i> button clears the visitor's selections and text from all the input controls. A <i>button</i> button doesn't do anything unless you add some JavaScript code.
List	<code><select>...</select></code>	Shows a list where your visitor can select one or more items. You add an <code><option></code> element for each item in the list.

Here's the rest of the zookeeper form markup, with a few new details (a `<select>` list, checkboxes, and the button that submits the form):

```
...
<fieldset>
  <legend>Personal Information</legend>
  <label for="age"><em>*</em>Age</label>
  <input id="age"><br>
  <label for="gender">Gender</label>
  <select id="gender">
    <option value="female">Female</option>
    <option value="male">Male</option>
  </select><br>
  <label for="comments">When did you first know you wanted to be a
    zoo-keeper?</label>
  <textarea id="comments"></textarea>
</fieldset>

<fieldset>
  <legend>Pick Your Favorite Animals</legend>
```

```

<label for="zebra"><input id="zebra" type="checkbox"> Zebra</label>
<label for="cat"><input id="cat" type="checkbox"> Cat</label>
<label for="anaconda"><input id="anaconda" type="checkbox"> Anaconda
</label>
<label for="human"><input id="human" type="checkbox"> Human</label>
<label for="elephant"><input id="elephant" type="checkbox"> Elephant
</label>
<label for="wildebeest"><input id="wildebeest" type="checkbox">
  Wildebeest</label>
<label for="pigeon"><input id="pigeon" type="checkbox"> Pigeon</label>
<label for="crab"><input id="crab" type="checkbox"> Crab</label>
</fieldset>
<p><input type="submit" value="Submit Application"></p>
</form>

```

You can find the full example, along with the relatively simple style sheet that formats it, on the try-out site (www.prosetech.com/html5). Look for the Zookeeper-Form_Original.html file to play around with traditional, unenhanced version of the form, and ZookeeperForm_Revised.html to get all the HTML5 goodies.

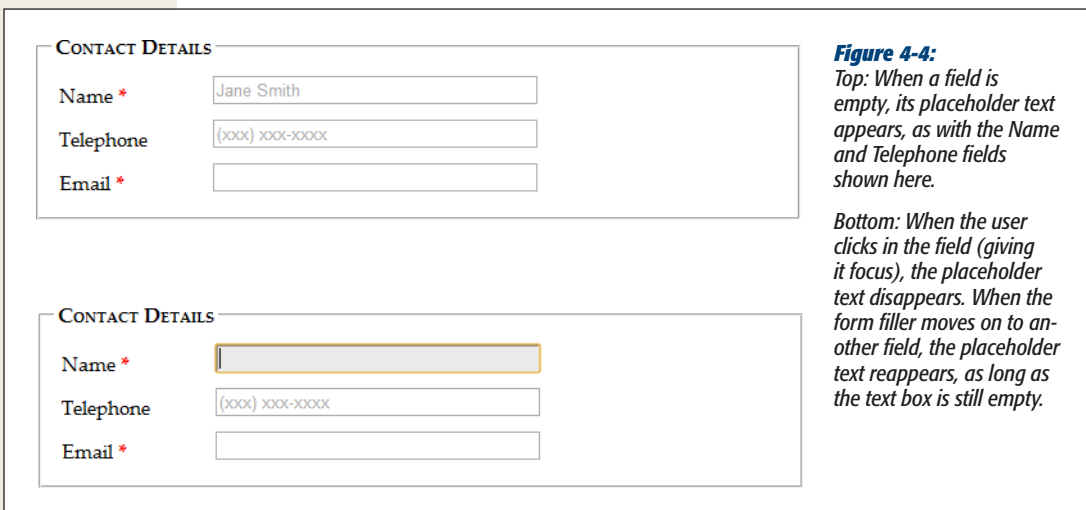

Note: One limit of HTML forms is that you can't change how the browser draws controls. For example, if you want to replace the standard dull gray checkbox with a big black-and-white box with a fat red checkmark image, you can't. (The alternative is to create a normal element that has checkbox-like behavior using JavaScript—in other words, it changes its appearance back and forth when someone clicks it.)

HTML5 keeps this no-customization limit in place, and extends it to the new controls you'll learn about in this chapter. That means forms won't suit people who need highly stylized widgets and complete control over the look of their pages.

Now that you've got a form to work with, it's time to start improving it with HTML5. In the following sections, you'll start small, with placeholder text and an autofocus field.

Adding Hints with Placeholders

Forms usually start out empty. But a column of blank text boxes can be a bit intimidating, especially if it's not absolutely clear what belongs inside each text box. That's why you commonly see some sort of sample text inside otherwise-empty text boxes. This placeholder text is also called a *watermark*, because it's often given a light gray color to distinguish it from real, typed-in content. Figure 4-4 shows a placeholder in action.

To create a placeholder, simply use the *placeholder* attribute:

```
<label for="name">Name <em>*</em></label>
<input id="name" placeholder="Jane Smith"><br>
<label for="telephone">Telephone</label>
<input id="telephone" placeholder="(xxx) xxx-xxxx"><br>
```

Browsers that don't support placeholder text just ignore the placeholder attribute; Internet Explorer is the main culprit. Fortunately, it's not a big deal, since placeholders are just nice form frills, not essential to your form's functioning. If it really bothers you, there are plenty of JavaScript patches that can bring IE up to speed, painlessly, at <http://tinyurl.com/polyfills>.

Right now, there's no standard, consistent way to change the appearance of placeholder text (for example, to italicize it or to change the text color). Eventually, browser makers will create the CSS styling hooks that you need—in fact, they're hashing out the details even as you read this. But for now, you'll either need to fiddle with browser-specific pseudoclasses (namely, *-webkit-input-placeholder* and *-moz-placeholder*) or leave it alone. (Page 389 explains pseudoclasses.)

However, you can use the better-supported *focus* pseudoclass to change the way a text box looks when it gets the focus. For example, you might want to assign a darker background color to make it stand out:

```
input:focus {
    background: #eaeaea;
}
```

UP TO SPEED

Writing Good Placeholders

You don't need placeholders for every text box. Instead, you should use them to clear up potential ambiguity. For example, no one needs an explanation about what goes in a First Name box, but the Name box in Figure 4-4 isn't quite as obvious. The placeholder text makes it clear that there's room for a first and last name.

Sometimes placeholders include a sample value—in other words, something you might actually type into the box. For example, Google's recipe search (<http://www.google.com/landing/recipes>) uses the text *chicken pasta* for a placeholder, making it obvious that you should enter part of a recipe name, not a list of ingredients or the name of the chef who cooked it up.

Other times, placeholders indicate the way a value should be formatted. The telephone box in Figure 4-4 is an example—it shows the value *(xxx) xxx-xxxx* to concisely indicate that telephone numbers should consist of a three-digit area code, followed by a sequence of three, then four digits. This placeholder doesn't necessarily mean that differently formatted input isn't allowed, but it does offer a suggestion that uncertain people can follow.

There are two things you shouldn't try with a placeholder. First, don't try to cram in a description of the field or instructions. For example, imagine you have a box for a credit card's security code. The text, "The three digits listed on the back of your card" is *not* a good placeholder. Instead, consider adding a text note under the input box, or using the title attribute to make a pop-up window appear when someone hovers over the field:

```
<label for="promoCode">Promotion Code</label>
<input id="promoCode" placeholder="QRB001"
      title="Your promotion code is three letters
            followed by three numbers">
```

Second, you shouldn't add special characters to your placeholder in an attempt to make it obvious that your placeholder is not real, typed-in text. For example, some websites use placeholders like *[John Smith]* instead of *John Smith*, with the square brackets there to emphasize that the placeholder is just an example. This convention can be confusing.

Focus: Starting in the Right Spot

After loading up your form, the first thing your visitors want to do is start typing. Unfortunately, they can't—at least not until they tab over to the first control, or click it with the mouse, thereby giving it *focus*.

You can make this happen with JavaScript, by calling the `focus()` method of the appropriate `<input>` element. But this involves an extra line of code and can sometimes cause annoying quirks. For example, it's sometimes possible for the user to click somewhere else and start typing before the `focus()` method gets called, at which point focus is rudely transferred back to the first control. But if the browser were able to control the focus, it could be a bit smarter, and transfer focus only if the user hasn't already dived into another control.

That's the idea behind HTML5's new *autofocus* attribute, which you can add to a single `<input>` or `<textarea>` element, like this:

```
<label for="name">Name <em>*</em></label>
<input id="name" placeholder="Jane Smith" autofocus><br>
```

The autofocus has similar support as the placeholder attribute, which means basically every browser recognizes it except Internet Explorer. Once again, it's easy enough to plug the hole. You can check for autofocus support using Modernizr (page 38) and then run your own autofocus code if needed. Or, you can use a ready-made JavaScript polyfill that adds autofocus support (<http://tinyurl.com/polyfills>). However, it hardly seems worth it for such a minor frill, unless you're also aiming to give IE support for other form features, like the validation system discussed next.

Validation: Stopping Errors

The fields in a form are there to gather information from web page visitors. But no matter how politely you ask, you might not get what you want. Impatient or confused visitors can skip over important sections, enter partial information, or just hit the wrong keys. The end result? They click Submit, and your website gets a whack-load of scrambled data.

What a respectable web page needs is *validation*—a way to catch mistakes when they happen (or even better, to prevent them from happening at all). For years, developers have done that by writing their own JavaScript routines or using professional JavaScript libraries. And, truthfully, these approaches work perfectly well. But seeing as validation is so common (just about everyone needs to do error-checking), and seeing as validation generally revolves around a few key themes (for example, spotting invalid email addresses or dates), and seeing as validation is boring (no one really wants to write the same code for every form, not to mention *test* it), there's clearly room for a better way.

The creators of HTML5 spotted this low-hanging fruit and invented a way for browsers to help out, by getting them to do the validation work instead of web developers. They devised a *client-side* validation system (see the box on page 117) that lets you embed common error-checking rules into any `<input>` field. Best of all, this system is easy—all you need to do is insert the right attribute.

How HTML5 Validation Works

The basic idea behind HTML5 form validation is that you indicate where validation should happen, but you don't actually *implement* the tedious details. It's a bit like being promoted into a management job, just without the pay raise.

For example, imagine you decide a certain field cannot be left blank—the form filler needs to supply some sort of information. In HTML5, you can make this demand by adding the *required* attribute:

```
<label for="name">Name <em>*</em></label>
<input id="name" placeholder="Jane Smith" autofocus required><br>
```

UP TO SPEED

Validating in Two Places

Throughout the years, crafty developers have attacked the validation problem in different ways. Today, the consensus is clear. To make a bulletproof form, you need two types of error-checking:

- **Client-side validation.** These are the checks that happen in the browser, *before* a form is submitted. The goal here is to make life easier for the people filling out the form. Instead of waiting for them to complete three dozen text boxes and click a submit button, you want to catch problems in the making. That way you can pop up a helpful error message right away and in the right spot, allowing the form filler to correct the mistake before submitting the form to the server.
- **Server-side validation.** These are the checks that happen *after* a form is sent back to the web server. At

this point, it's up to your server-side code to review the details and make sure everything is kosher before continuing. No matter what the browser does, server-side validation is essential. It's the only way to defend yourself from malicious people who are deliberately trying to tamper with form data. If your server-side validation detects a problem, you send back a page with an error message.

So client-side validation (of which HTML5 validation is an example) is there to make life easier for your web page visitors, while server-side validation ensures correctness. The key thing to understand is that you need both types of validation—unless you have an exceedingly simple form where mistakes aren't likely or aren't a big deal.

Initially, there's no visual detail to indicate that a field is required. For that reason, you might want to use some other visual clue, such as giving the text box a different border color or placing an asterisk next to the field (as in the zookeeper form).

Validation kicks in only when the form filler clicks a button to submit the form. If the browser implements HTML5 forms, then it will notice that a required field is blank, intercept the form submission attempt, and show a pop-up message that flags the invalid field (Figure 4-5).

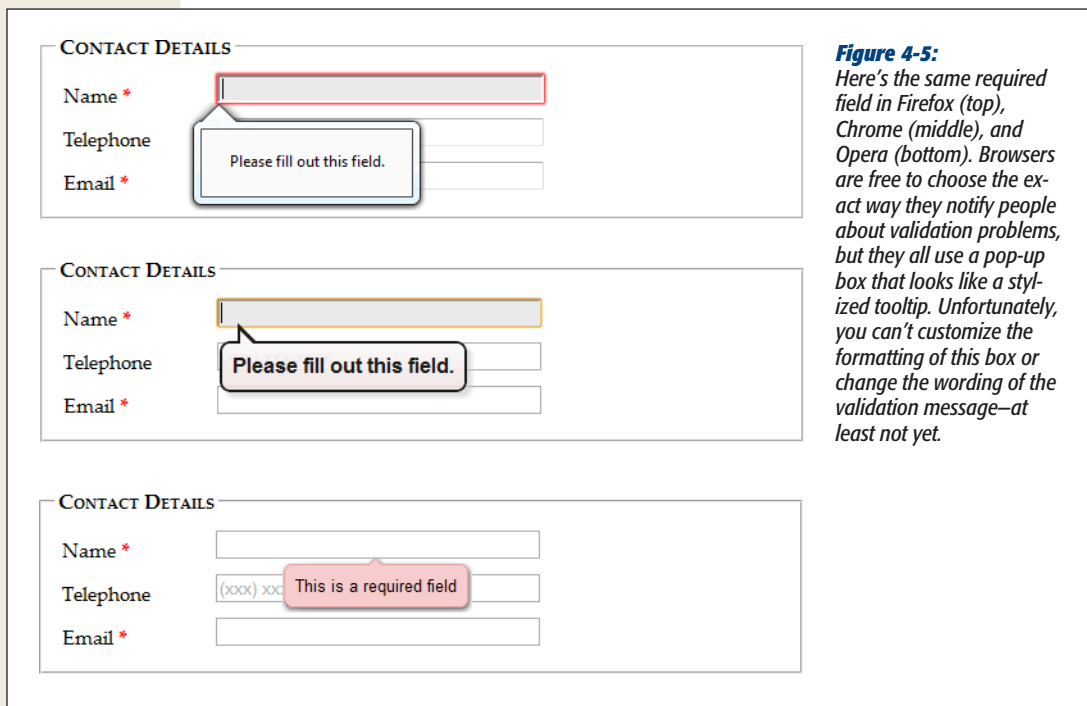

As you'll see in the following sections, different attributes let you apply different error-checking rules. You can apply more than one rule to the same input box, and you can apply the same rule to as many `<input>` elements as you want (and to the `<textarea>` element). All the validation conditions must be met before the form can be submitted.

This raises a good question: What happens if form data breaks more than one rule—for example, it has multiple required fields that aren't filled in?

Once again, nothing happens until the person filling out the form clicks the submit button. Then, the browser begins examining the fields from top to bottom. When it finds the first invalid value, it stops checking any further. It cancels the form submission and pops up an error message next to this value. (Additionally, if the offending text box isn't currently visible, the browser scrolls up just enough that it appears at the top of the page.) If the visitor corrects the problem and clicks the submit button again, the browser will stop and highlight the next invalid value.

Figure 4-5:

Here's the same required field in Firefox (top), Chrome (middle), and Opera (bottom). Browsers are free to choose the exact way they notify people about validation problems, but they all use a pop-up box that looks like a stylized tooltip. Unfortunately, you can't customize the formatting of this box or change the wording of the validation message—at least not yet.

Note: Web browsers hold off on validation until a submit button is clicked. This ensures that the validation system is efficient and restrained, so it works for everyone.

Some web developers prefer to alert people as soon as they leave an invalid field (by tabbing away or clicking somewhere else with the mouse). This sort of validation is handy in long forms, especially if there's a chance that someone may make a similar mistake in several different fields. Unfortunately, HTML5 doesn't have a way for you to dictate when the web browser does its validation, although it's possible that it might add one in the future. For now, if you want immediate validation messages, it's best to write the JavaScript yourself or to use a good JavaScript library.

Turning Validation Off

In some cases, you may need to disable the validation feature. For example, you might need to turn it off for testing to verify that your server-side code deals appropriately with invalid data. To turn validation off for an entire form, you add the `novalidate` attribute to the containing `<form>` element:

```
<form id="zooKeeperForm" action="processApplication.cgi" novalidate>
```

The other option is to provide a submit button that bypasses validation. This technique is sometimes useful in a web page. For example, you may want to enforce strict validation for the official submit button, but provide another button that does

something else (like storing half-completed data for later use). To allow this, add the *formnovalidate* attribute to the `<input>` element that represents your button:

```
<input type="submit" value="Save for Later" formnovalidate>
```

You've now seen how to use validation to catch missing information. Next, you'll learn to search for errors in different types of data.

Note: Planning to validate numbers? There's no validation rule that forces text to contain digits, but there is a new *number* data type, which you'll examine on page 129. Unfortunately, its support is still sketchy.

Validation Styling Hooks

Although you can't style validation messages, you can change the appearance of the input fields based on their validation *state*. For example, you can give invalid values a different background color, which will appear in the text box as soon as the browser detects the problem.

To use this technique, you simply need to add a few new pseudoclasses (page 389). Your options include:

- **required** and **optional**, which apply styles to fields based on whether they use the required attribute.
- **valid** and **invalid**, which apply styles to controls based on whether they contain mistakes. But remember that most browsers won't actually discover invalid values until the visitor tries to submit the form, so you won't see the invalid formatting right away.
- **in-range** and **out-of-range**, which apply formatting to controls that use the min and max attributes to limit numbers to a range (page 129).

For example, if you want to give required `<input>` fields a light yellow background, you could use a style rule with the *required* pseudoclass:

```
input:required {
  background-color: lightyellow;
}
```

Or, you might want to highlight only those fields that are required and currently hold invalid values by combining the *required* and *invalid* pseudoclasses like this:

```
input:required:invalid {
  background-color: lightyellow;
}
```

With this setting, blank fields are automatically highlighted, because they break the required-field rule.

You can use all sorts of other tricks, like combining the validation pseudoclasses with the *focus* pseudoclass, or using an offset background that includes an error icon to flag invalid values. Of course, a hefty disclaimer applies: You can use these pseudoclasses to improve your pages, but make sure your form still looks good without them, because support lags in older browsers.

Validating with Regular Expressions

The most powerful (and complex) type of validation that HTML5 supports is based on regular expressions. Seeing as JavaScript already supports regular expression, adding this feature to HTML forms makes perfect sense.

A *regular expression* is a pattern written using the regular expression language. Regular expressions are designed to match patterned text—for example, a regular expression can make sure that a postal code has the right sequence of letters and digits, or that an email address has an @ symbol and a domain extension that's at least two characters long. For example, consider this expression:

```
[A-Z]{3}-[0-9]{3}
```

The square brackets at the beginning define a range of allowed characters. In other words, [A-Z] allows any uppercase letter from A to Z. The curly brackets that follow multiply this effect, so {3} means you need three uppercase letters. The dash that follows doesn't have a special meaning, so it indicates that a dash must follow the three-letter sequence. Finally, [0-9] allows a digit from 0 to 9, and {3} requires three of them.

Regular expression matching is useful for searching (finding pattern matches in a long document) and validation (verifying that a value matches a pattern). HTML5 forms use regular expressions for validation.

Note: Regular expression geeks take note: You don't need the magic ^ and \$ characters to match the beginning or end of a value in a field. HTML5 assumes both details automatically, which means a regular expression must match the *entire* value in a field in order to be deemed valid.

These values are valid, because they match the pattern shown above:

```
QRB-001
TTT-952
LAA-000
```

But these values are not:

```
qrb-001
TTT-0952
LA5-000
```

Regular expressions quickly get much more complex than this example. Writing a regular expression can be quite a chore, which is why most developers simply search for a ready-made regular expression that validates the type of data they want to check. Or they get help.

Tip: To learn just enough about the regular expression language to make your own super-simple expressions, check out the concise tutorials at www.w3schools.com/js/js_obj_regexp.asp or <http://tinyurl.com/jsregex>. To find ready-made regular expressions that you can use with your forms, visit <http://regexlib.com>. And to become a regular expression guru, read *Mastering Regular Expressions, Third Edition* by Jeffrey Friedl (O'Reilly).

Once you have a regular expression, you can enforce it in any `<input>` or `<textarea>` element by adding the *pattern* attribute:

```
<label for="promoCode">Promotion Code</label>
<input id="promoCode" placeholder="QRB-001" title=
  "Your promotion code is three uppercase letters, a dash, then three numbers"
  pattern="[A-Z]{3}-[0-9]{3}">
```

Figure 4-6 shows what happens if you break the regular expression rule.

Tip: Browsers don't validate blank values. In this example, a blank promotion code passes muster. If this isn't what you want, then combine the pattern attribute with the required attribute.

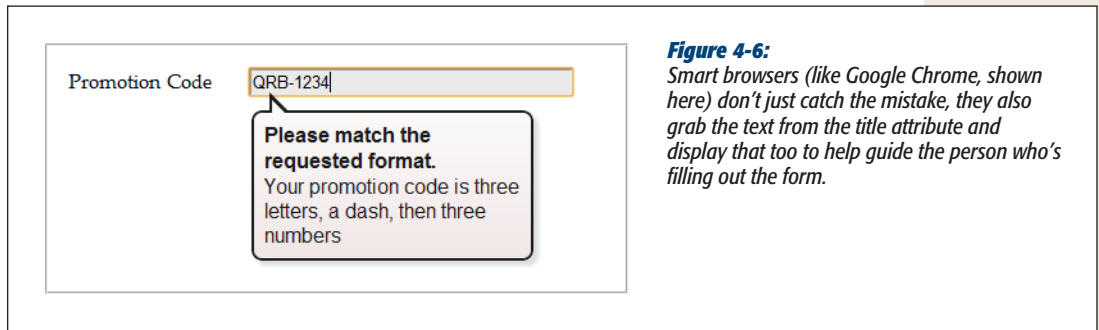

Figure 4-6:

Smart browsers (like Google Chrome, shown here) don't just catch the mistake, they also grab the text from the title attribute and display that too to help guide the person who's filling out the form.

Note: Regular expressions seem like a perfect match for email addresses (and they are). However, hold off on using them this way, because HTML5 already has a dedicated input type for email addresses that has the right regular expression baked in (page 128).

Custom Validation

The HTML5 specification also outlines a set of JavaScript properties that let you find out if fields are valid (or force the browser to validate them). The most useful of these is the `setCustomValidity()` method, which lets you write custom validation logic for specific fields and have it work with the HTML5 validation system.

Here's how it works. First, you need to check the appropriate field for errors. You do this by handling the `onInput` event, which is nothing new:

```
<label for="comments">When did you first know you wanted to be a
  zookeeper?</label>
<textarea id="comments" oninput="validateComments(this)" ></textarea>
```

In this example, the `onInput` event triggers a function named `validateComments()`. It's up to you to write this function, check the current value of the `<input>` element, and then call `setCustomValidity()`.

If the current value has problems, you need to supply an error message when you call `setCustomValidity()`. Or, if the current value checks out, you need to call `setCustomValidity()` with an empty string. This clears any error custom messages that you may set earlier.

Here's an example that forces the text in the comment box to be at least 20 characters long:

```
function validateComments(input) {
  if (input.value.length < 20) {
    input.setCustomValidity("You need to comment in more detail.");
  }
  else {
    // There's no error. Clear any error message.
    input.setCustomValidity("");
  }
}
```

Figure 4-7 shows what happens if someone breaks this rule and then tries to submit the form.

PERSONAL INFORMATION

Age* 6666666

Gender Female

When did you first know you wanted to be a zoo-keeper?* I had a dream.

You need to comment in more detail.

Figure 4-7: When you supply an error message with `setCustomValidity()`, the browser treats it the same as its own, built-in validation messages. Try to submit the form, and you'll see a pop-up warning with your message text.

Of course, you could solve this problem more neatly with a regular expression that requires long strings. But while regular expressions are great for validating some data types, custom validation logic can do *anything*, from complex algebra to contacting the web server.

Note: Remember, your web page visitors can see anything you put in JavaScript, so it's no place for secret algorithms. For example, you might know that in a valid promotional code, the digits always add up to 12. But you probably don't want to betray that detail in a custom validation routine, because it will help shifty people cook up fake codes. Instead, keep this sort of validation in the web server.

Browser Support for Validation

Browser makers added support for validation in pieces. That means some browser builds support some validation features while ignoring others. Table 4-2 indicates the minimum browser versions you need to use to get solid support for all the validation tricks you’ve learned so far.

Table 4-2. Browser support for validation

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	10*	4	10	5 (Windows only)	10	-	-

**Currently, this version is available in early beta builds only.*

Because HTML5 validation doesn’t replace the validation you do on your web server, you may see it as a frill, in which case you can accept this uneven support. Browsers that don’t implement validation, like IE 9, let people submit forms with invalid dates, but you can then catch these problems on the web server and return the same page, but with error details.

On the other hand, your website might include complex forms with lots of potential for confusion, and you might not be ready to accept a world of frustrated IE users. In this case, you have two basic choices: Fall back on your own validation system, or use a JavaScript library that adds the missing smarts. Your choice depends on the extent and complexity of your validation.

If all your form needs is a smattering of simple validation, it’s probably worth adding your own checks. Using Modernizr (page 38), you can check for a variety of HTML5 web forms features. For example, use the `Modernizr.input.pattern` property to check whether the current browser recognizes the `pattern` attribute:

```
if (!Modernizr.input.pattern) {
    // The current browser doesn't perform regular expression validation.
    // You can use the regular expression features in JavaScript instead.
    ...
}
```

Note: The `pattern` property is just one of the properties exposed by `Modernizr.input` object. Other properties that are useful for testing web form support include `placeholder`, `autofocus`, `required`, `max`, `min`, and `step`.

Of course, this example doesn’t tell you *when* to perform this check or *how* to react. If you want your validation to mimic the HTML5 validation system, it makes sense to perform your validation when the person viewing the form attempts to submit it. You do this by handling the form’s `onSubmit` event, and then returning either `true` (which means the form is valid and the browser can submit it) or `false` (which means the form has a problem and the browser should cancel the operation):

```
<form id="zooKeeperForm" action="processApplication.cgi"
    onsubmit="return validateForm()">
```

Here's an example of a very simple custom validation routine that enforces required fields:

```
function validateForm() {
  if (!Modernizr.input.required) {
    // The required attribute is not supported, so you need to check the
    // required fields yourself.

    // First, get an array that holds all the elements.
    var inputElements = document.getElementById("zooKeeperForm").elements;

    // Next, move through that array, checking each element.
    for(var i = 0; i < inputElements.length; i++) {

      // Check if this element is required.
      if (inputElements[i].hasAttribute("required")) {
        // If this element is required, check if it has a value.
        // If not, the form fails validation, and this function returns false.
        if (inputElements[i].value == "") return false;
      }
    }

    // If you reach this point, everything worked out and the browser
    // can submit the form.
    return true;
  }
}
```

Tip: This block of code relies on a number of basic JavaScript techniques, including element lookup, a loop, and conditional logic. To learn more about all these details, check out Appendix B.

If you have a complex form and you want to save some effort (while at the same time preparing for the future), you may prefer to use a JavaScript patch to solve all your problems. Technically, the approach is the same—your page will check for validation support and then perform validation manually if necessary. The difference is that the JavaScript library already has all the tedious code you need.

At <http://tinyurl.com/polyfills>, you can find a long, intimidating list of JavaScript libraries that all attempt to do more or less the same thing. One of the best ones is simply called `webforms2`, and is available from <https://github.com/westonruter/webforms2> (to get a copy, look for the easy-to-miss Download button).

The `webforms2` library implements all the attributes you've seen so far. To make it work, you download all the files to your website folder (or, more commonly, a sub-folder of your website folder), and add a single reference to the library in your web page:

```
<head>
  <title>...</title>
  <script src="webforms2.js"></script>
  ...
</head>
```

The `webforms2` library integrates nicely with another JavaScript patch, called `html5Widgets`, which adds support for the form features you'll learn about next, like the slider, date picker, and color chooser. To learn more about this all-in-one patch, visit www.useragentman.com/tests/html5Widgets. Both of these libraries offer good all-around web forms support, but there are inevitable gaps and minor bugs buried in the code. Only time will tell if these already-impressive libraries are properly maintained and gradually improved.

GEM IN THE ROUGH

A Few Rogue Input Attributes

HTML5 recognizes a few more attributes that can control browser behavior when editing forms, but aren't used for validation. Not all of these attributes apply to all browsers. Still, they make for good experimenting:

- **Spellcheck.** Some browsers try to help you avoid embarrassment by spell-checking the words you type in an input box. The obvious problem is that not all text is meant to be real words, and there are only so many red squiggles a web surfer can take before getting just a bit annoyed. Set `spellcheck` to `false` to recommend that the browser not spellcheck a field, or `true` to recommend that it does. (Browsers differ on their default spell-checking behavior, which is what you get if you don't set the `spellcheck` attribute at all.)
- **Autocomplete.** Some browsers try to save you time by offering you recently typed-in values when you enter information in a field. This behavior isn't always appropriate—as the HTML5 specification points out, some types of information may be sensitive (like nuclear attack codes) or may be relevant for only a short amount of time (like a one-time bank login code). In these cases, set `autocomplete` to `off` to recommend that the browser not offer autocomplete suggestions. You can also set `autocomplete` to `on` to recommend it for a particular field.
- **Autocorrect** and **autocapitalize.** Use these attributes to control automatic correction and capitalization features on some mobile devices—namely, the version of Safari that runs on iPads and iPhones.
- **Multiple.** Web designers have been adding the `multiple` attribute to the `<select>` element to create multiple-selection lists since time immemorial. But now you can add it to certain types of `<input>` elements, including ones that use the `file` type (for uploading files) and ones that use the `email` type (page 128). On a supporting browser, the user can then pick several files to upload at once, or stick multiple email addresses in one box.

New Types of Input

One of the quirks of HTML forms is that one ingredient—the vaguely named `<input>` element—is used to create a variety of controls, from checkboxes to text boxes to buttons. The `type` attribute is the master switch that determines what each `<input>` element really is.

If a browser runs into an `<input>` element with a type that it doesn't recognize, the browser treats it like an ordinary text box. That means these three elements get exactly the same treatment in every browser:

```
<input type="text">
<input type="super-strange-wonky-input-type">
<input>
```

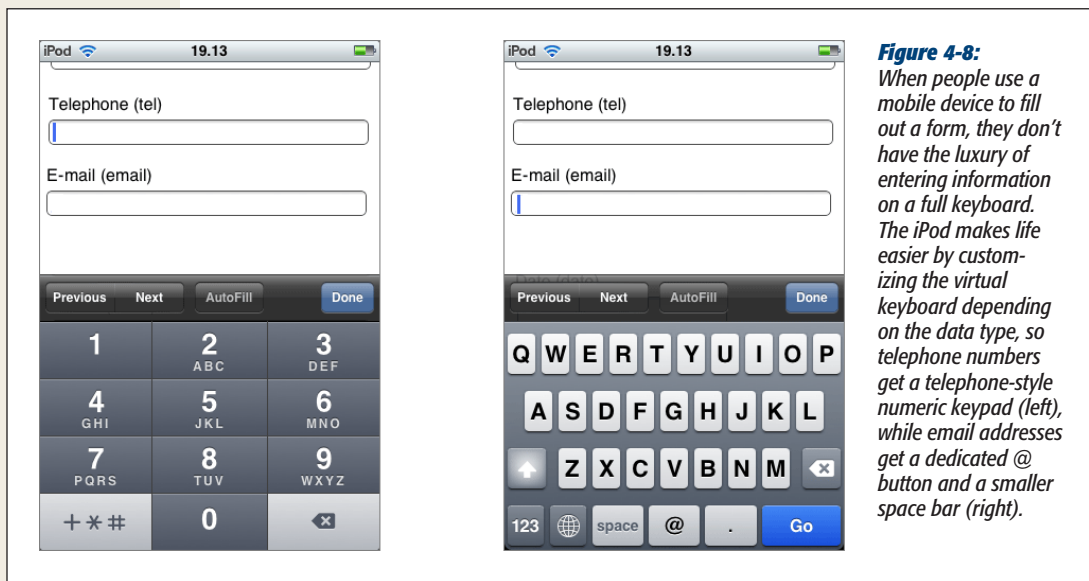

HTML5 uses this default to its benefit. It adds a few new data types to the `<input>` element, secure in the knowledge that browsers will treat them as ordinary text boxes if they don't recognize them. For example, if you need to create a text box that holds an email address, you can use the new input type *email*:

```
<label for="email">Email <em>*</em></label>
<input id="email" type="email"><br>
```

If you view this page in a browser that doesn't directly support the email input type (like Internet Explorer 9), you'll get an ordinary text box, which is perfectly acceptable. But browsers that support HTML5 forms are a bit smarter. Here's what they can do:

- **Offer editing conveniences.** For example, an intelligent browser might give you a way to get an email from your address book and pop it into an email field.
- **Restrict potential errors.** For example, browsers can ignore letters when you type in a number text box. Or, they can reject invalid dates (or just force you to pick one from a mini calendar, which is easier *and* safer).
- **Perform validation.** Browsers can perform more sophisticated checks when you click a submit button. For example, an intelligent browser will spot an obviously incorrect email address in an email box and refuse to continue.

The HTML5 specification doesn't give browser makers any guidance on the first point. Browsers are free to manage the display and editing of different data types in any way that makes sense, and different browser can add different little luxuries. For example, mobile browsers take advantage of this information to customize the virtual keyboard that they show, hiding keys that don't apply (see Figure 4-8).

The error-prevention and error-checking features are more important. At a bare minimum, a browser that supports HTML5 web forms must prevent a form from being submitted if it contains data that breaks the data type rules. So if the browser doesn't prevent errors (according to the second point in this list), it must validate them when the user submits the data (that's the third point).

Unfortunately, not all current browsers live up to this requirement. Some recognize the new data types and provide some sort of editing niceties but no validation. Many understand one data type but not another. Mobile browsers are particularly problematic—they provide some editing conveniences but currently have none of the validation.

Table 4-3 lists the new data types and the browsers that support them completely—meaning that they prevent forms from being submitted when the data type rules are broken.

Table 4-3. Browser compatibility for new input types

Data type	IE	Firefox	Chrome	Safari	Opera	Safari iOS**	Android
email	-	4	10	5 (Windows only)	10.6	-	-
url	-	4	10	5 (Windows only)	10.6	-	-
search*	n/a	n/a	n/a	n/a	n/a	n/a	n/a
tel*	n/a	n/a	n/a	n/a	n/a	n/a	n/a
number	-	-	10	5 (Windows only)	-	-	-
range	-	-	6	5	11	-	-
datetime, date, month, week, time	-	-	10	-	11	-	-
color	-	-	-	-	11	-	-

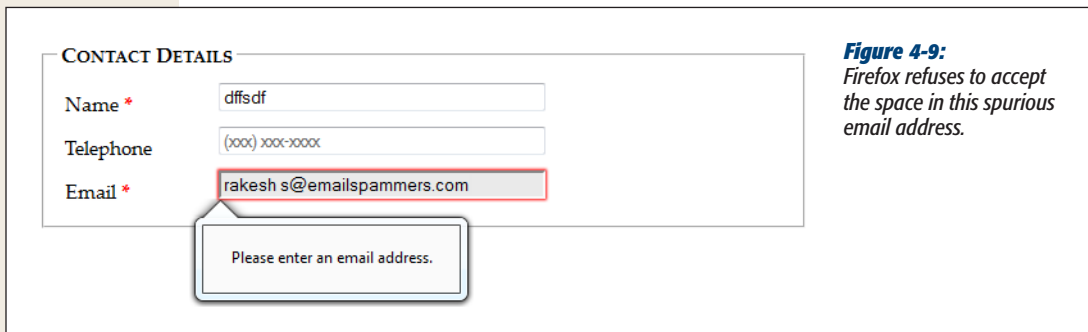

* The HTML5 standard does not require validation for this data type.

** Although the iOS browser doesn't provide validation, its virtual keyboard customization (see Figure 4-8) is a significant convenience, so it's still worth using specialized data types.

Tip: Incidentally, you can test for data type support in Modernizr using the properties of the Modernizr.inputtypes object. For example, Modernizr.inputtypes.range returns true if the browser supports the range data type.

Email Addresses

Email addresses use the *email* type. Generally, a valid email address is a string of characters (with certain symbols not allowed). An email address must contain the @ symbol and a period, and there needs to be at least one character between them and two characters after the period. These are, more or less, the rules that govern email addresses. However, writing the right validation logic or regular expression for email addresses is a surprisingly subtle task that has tripped up many a well-intentioned developer. Which is why it's great to find web browsers that support the email data type and perform validation automatically (see Figure 4-9).

Email attributes support the *multiple* attribute, which allows the field to hold multiple email addresses. However, these multiple email addresses still look like a single piece of text—you just separate each one with a comma.

Note: Remember, blank values bypass validation. If you want to force someone to enter a valid email address, you need the email data type combined with the required attribute (page 116).

URLs

URLs use the *url* type. What constitutes a valid URL is still a matter of hot debate. But most browsers use a relatively lax validation algorithm. It requires a URL prefix (which could be legitimate, like *http://*, or made up, like *bonk://*), and accepts spaces and most special characters other than the colon (:).

Some browsers also show a drop-down list of URL suggestions, which is typically taken from the browser's history of recently visited pages.

Search Boxes

Search boxes use the *search* type. A search box is generally meant to contain keywords that are then used to perform some sort of search. It could be a search of the

entire Web (as with Google, in Figure 4-1), a search of a single page, or a custom-built search routine that examines your own catalog of information. Either way, a search box looks and behaves almost exactly like a normal text box.

On some browsers, like Safari, search boxes are styled slightly differently, with rounded corners. Also, as soon as you start typing in a search box in Safari or Chrome, a small X icon appears on the right side that you can click to clear the box. Other than these very minor differences, search boxes *are* text boxes. The value is in the semantics. In other words, you use the search data type to make the purpose of the box clear to browsers and assistive software. They can then guide visitors to the right spot or offer other smart features—maybe, someday.

Telephone Numbers

Telephone numbers use the *tel* type. Telephone numbers come in a variety of patterns. Some use only numbers, while others incorporate spaces, dashes, plus signs, and parentheses. Perhaps it's because of these complications that the HTML5 standard doesn't ask browsers to perform any telephone number validation at all. However, it's hard to ignore the feeling that a *tel* field should at least reject letters (which it doesn't).

Right now, the only value in using the *tel* type is to get a customized virtual keyboard on mobile browsers, which focuses on numbers and leaves out letters.

Numbers

HTML5 defines two numeric data types. The *number* type is the one to use for ordinary numbers.

The number data type has obvious potential. Ordinary text boxes accept anything: numbers, letters, spaces, punctuation, and the symbols usually reserved for cartoon character swearing. For this reason, one of the most common validation tasks is to check that a given value is numeric and falls in the right range. But use the number data type, and the browser automatically ignores all non-numeric keystrokes. Here's an example:

```
<label for="age">Age<em>*</em></label>
<input id="age" type="number"><br>
```

Of course, there are plenty of numbers, and they aren't all appropriate for every kind of data. The markup shown above allows ages like 43,000 and -6. To fix this, you need to use the *min* and *max* attributes. Here's an example that limits ages to the reasonable range of 0 to 120:

```
<input id="age" type="number" min="0" max="120"><br>
```

Ordinarily, the number data type accepts only whole numbers, so a fractional age like 30.5 isn't accepted. (In fact, some browsers won't even let you type the decimal point.) However, you can change this too by setting the *step* attribute, which indicates the acceptable intervals for the number. For example, a step minimum value of

0 and a step of 0.1 means you can use values like 0, 0.1, 0.2, and 0.3. Try to submit a form with 0.15, however, and you'll get the familiar pop-up error message. The default step is 1.

```
<label for="weight">Weight (in pounds)</label>
<input id="weight" type="number" min="50" max="1000" step="0.1"
value="160"><br>
```

The step attribute also affects how the spin buttons work in the number box, as shown in Figure 4-10.

Figure 4-10:

Many browsers add spin buttons to number boxes. Every time you click the up arrow, the number increases by the step value (unless you reach the maximum allowed number). Similarly, when you click the down arrow, the number decreases by one step.

Sliders

The *range* type is HTML5's other numeric data type. Like the number type, it can represent whole numbers or fractional values. It also supports the same attributes for setting the range of allowed values (min and max). Here's an example:

```
<label for="weight">Weight (in pounds)</label>
<input id="weight" type="range" min="50" max="1000" value="160"><br>
```

The difference is the way the range type presents its information. Instead of asking you to type the value you want in a text box, intelligent browsers show a slider control (Figure 4-11).

Figure 4-11:

You've probably used range-like controls to set things like sound volume. They work well for information where there's a narrow range of values between a known minimum and a known maximum, and the specific numeric value isn't important (but the placement of that value relative to the minimum and maximum is).

To set a range type, you simply pull the tab to the position you want, somewhere between the minimum and maximum values at either end of the slider. Browsers that support the range type don't give any feedback about the specific value that's set. If you want that piece of information, you need to add a scrap of JavaScript that reacts when the slider changes (perhaps by handling the `onChange` event) and then

displays the value nearby. Of course, you'd also want to check if the current browser supports the range type (using a tool like Modernizr). If the browser doesn't support the range type, there's no need to take any extra steps, because the value will show up in an ordinary text box.

Dates and Times

HTML5 defines several date-related types. Browsers that understand the date types can provide handy drop-down calendars for people to pick from. Not only does this clear away confusion about the right way to format the date, it also prevents people from accidentally (or deliberately) picking a date that doesn't exist. And smart browsers can go even further—for example, adding integration with a personal calendar.

Right now, the date types are poorly supported, despite their obvious usefulness. Opera is the only browser that provides the drop-down calendars (see Figure 4-12). Chrome provides the bare minimum in support: It uses a text box with spin buttons, like the number type, and refuses bad dates.

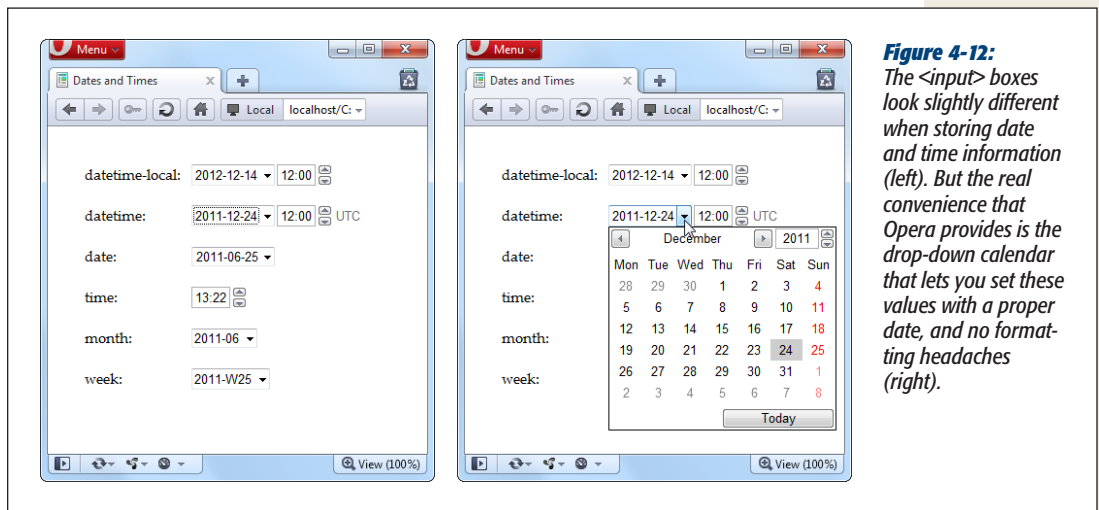

Figure 4-12: The `<input>` boxes look slightly different when storing date and time information (left). But the real convenience that Opera provides is the drop-down calendar that lets you set these values with a proper date, and no formatting headaches (right).

Tip: If you decide to use one of the date types, you may want to use a polyfill for browsers that don't understand it, like `html5Widgets` library described earlier (www.useragentman.com/tests/html5Widgets). That's because it's easy for people on non-supporting browsers to enter dates in the wrong format, and it's tedious for you to validate date data and provide the appropriate guidance. (That's also why custom JavaScript date controls already exist—and why they're all over the Web.)

Table 4-4 explains the six date formats.

Table 4-4. Date data types

Date type	Description	Example
date	A date in the format <i>YYYY-MM-DD</i> .	January 25, 2012, is: <i>2012-01-25</i>
time	A 24-hour time with an optional seconds portion, in the format <i>HH:mm:ss.ss</i> .	2:35 p.m. (and 50.2 seconds) is: <i>14:35</i> or <i>14:35:50.2</i>
datetimelocal	A date and a time, separated by a capital T (so the format is <i>YYYY-MM-DDTHH:mm:ss</i>).	January 25, 2012, 2:35 p.m.: <i>2012-01-15T14:35</i>
datetime	A date and a time, like the <i>datetime-local</i> data type, but with a time-zone offset. This uses the same format (<i>YYYY-MM-DDTHH:mm:ss-HH:mm</i>) as the <code><time></code> element you considered on page 83.	January 25, 2012, 2:35 p.m., in New York: <i>2012-01-15T14:35-05:00</i>
month	A year and month number, in the format <i>YYYY-MM</i> .	First month in 2012: <i>2012-01</i>
week	A year and week number, in the format <i>YYYY-Wwww</i> . Note that there can be 52 or 53 weeks, depending on the year.	Second week in 2012: <i>2012-W02</i>

Tip: Browsers that support the date types also support the `min` and `max` attributes with them. That means you can set maximum and minimum dates, as long as you use the right date format. So, to restrict a date field to dates in the year 2012, you would write: `<input type="date" min="2012-01-01" max="2012-12-31">`.

Colors

Colors use the *color* type. The color data type is an interesting, albeit little-used, frill that lets a web page visitor pick a color from a drop-down color picker, which looks like what you might see in a desktop paint program. Currently, Opera is the only browser to add one. In other browsers, you need to type a hexadecimal color code on your own (or use the `html5Widgets` library, from www.useragentman.com/tests/html5Widgets).

New Elements

So far, you've learned how HTML5 extends forms with new validation features, and how it gets smarter about data by adding more input types. These are the most practical and the most widely supported new features, but they aren't the end of the HTML5 forms story.

HTML5 also introduces a few entirely new elements to fill gaps and add features. Using these nifty new elements, you can add a drop-down list of suggestions, a progress bar, a toolbar, and more. The problem with new elements is that old browsers are guaranteed not to support them, and even new browsers are slow to wade in when the specification is still changing. As a result, these details include some of the *least* supported features covered in this chapter. You may want to see how they work, but you'll probably wait to use them, unless you're comfortable inching your way out even further into the world of browser quirks and incompatibilities.

Input Suggestions with <datalist>

The <datalist> element gives you a way to fuse a drop-down list of suggestions to an ordinary text box. It gives people filling out a form the convenience to pick an option from the list, or the freedom to type exactly what they want (see Figure 4-13).

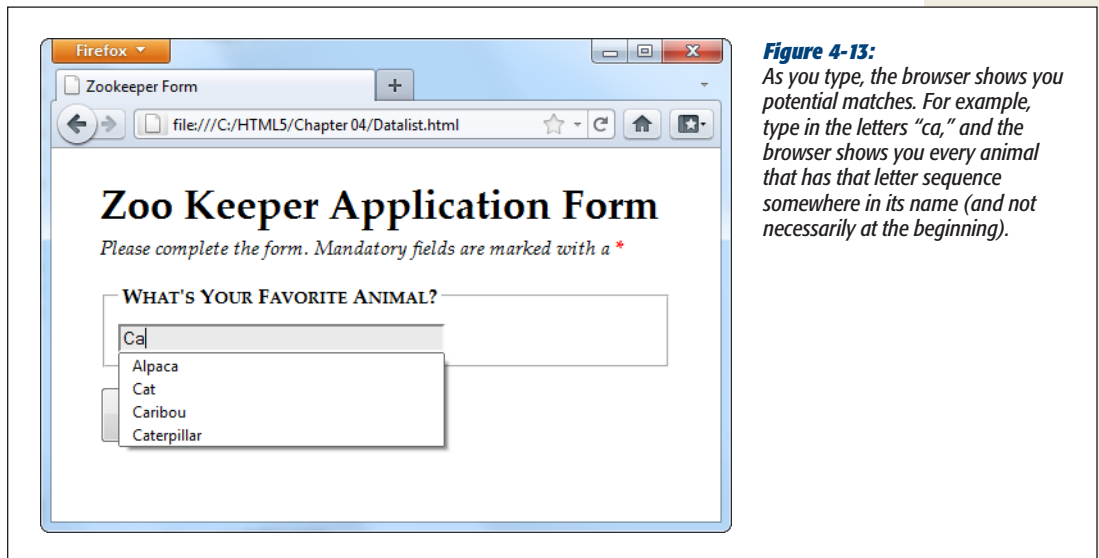

Figure 4-13: As you type, the browser shows you potential matches. For example, type in the letters “ca,” and the browser shows you every animal that has that letter sequence somewhere in its name (and not necessarily at the beginning).

To use a datalist, you must first start with a standard text box. For example, imagine you have an ordinary <input> element like this:

```
<legend>What's Your Favorite Animal?</legend>
<input id="favoriteAnimal">
```

To add a drop-down list of suggestions, you need to create a datalist. Technically, you can place that <datalist> element anywhere you want. That's because the datalist can't display itself—instead, it simply provides data that an input box will use. However, it makes logical sense to place the <datalist> element just after or just before the <input> element that uses it. Here's an example:

```
<datalist id="animalChoices">
  <option label="Alpaca" value="alpaca">
  <option label="Zebra" value="zebra">
```

```

<option label="Cat" value="cat">
<option label="Caribou" value="caribou">
<option label="Caterpillar" value="caterpillar">
<option label="Anaconda" value="anaconda">
<option label="Human" value="human">
<option label="Elephant" value="elephant">
<option label="Wildebeest" value="wildebeest">
<option label="Pigeon" value="pigeon">
<option label="Crab" value="crab">
</datalist>

```

The datalist uses `<option>` elements, just like the traditional `<select>` element. Each `<option>` element represents a separate suggestion that may be offered to the form filler. The label shows the text that appears in the text box, while the value tracks the text that will be sent back to the web server, if the user chooses that option. On its own, a datalist is invisible. To hook it up to a text box so it can start providing suggestions, you need to set the *list* attribute to match the ID of the corresponding datalist:

```
<input id="favoriteAnimal" list="animalChoices">
```

On browsers that supports the datalist—and right now, that’s only Opera 10 and Firefox 4 (or later)—visitors will see the result shown in Figure 4-13. Other browsers will ignore the list attribute and the datalist markup, rendering your suggestions useless.

However, there’s a clever fallback trick that makes other browsers behave properly. The trick is to put other content inside the datalist. This works because browsers that support the datalist pay attention to `<option>` elements only, and ignore all other content. Here’s a revised example that exploits this behavior. (The bold parts are the markup that datalist-supporting browsers will ignore.)

```

<legend>What's Your Favorite Animal?</legend>
<datalist id="animalChoices">
  <span class="Label">Pick an option:</span>
<select id="favoriteAnimalPreset">
  <option label="Alpaca" value="alpaca">
  <option label="Zebra" value="zebra">
  <option label="Cat" value="cat">
  <option label="Caribou" value="caribou">
  <option label="Caterpillar" value="caterpillar">
  <option label="Anaconda" value="anaconda">
  <option label="Human" value="human">
  <option label="Elephant" value="elephant">
  <option label="Wildebeest" value="wildebeest">
  <option label="Pigeon" value="pigeon">
  <option label="Crab" value="crab">
</select>
<br>
<span class="Label">Or type it in:</span>
</datalist>
<input list="animalChoices" name="list">

```

If you remove the bold markup, you end up with the same markup you had before. That means browsers that recognize the datalist still show the single input box and

the drop-down suggestion list, as shown in Figure 4-13. But on other browsers, the additional details wrap the datalist suggestion in a traditional select list, giving users the option of typing in what they want or picking it from a list (Figure 4-14).

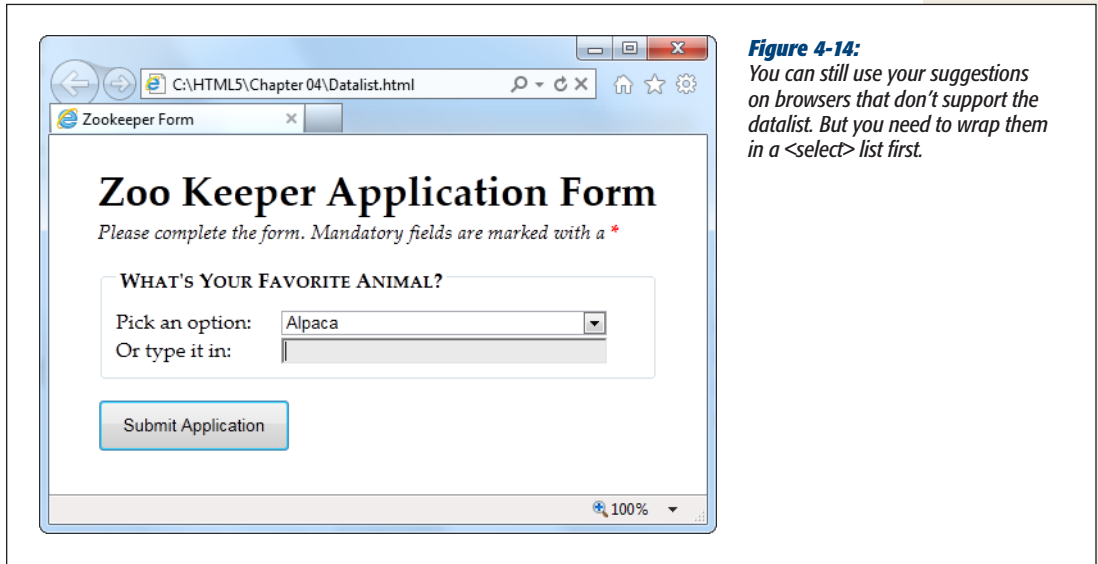

Figure 4-14:

You can still use your suggestions on browsers that don't support the datalist. But you need to wrap them in a `<select>` list first.

This effect isn't completely seamless. When you receive the form data on the web server, you need to check for data from the list (in this example, that's `favoriteAnimalPreset`) and from the text box (that's `favoriteAnimal`). But other than this minor wrinkle, you've got a solid way to add new conveniences without leaving anyone behind.

Note: When the datalist was first created, it had a feature that it let it fetch suggestions from somewhere else—for example, it could call a web server, which could then pull a list of suggestions out of a database. This feature might still be added in a future version of the HTML standard, but for now it's possible only if you write JavaScript code to handle the fetching, with the help of the XMLHttpRequest object (page 325).

Progress Bars and Meters

The `<progress>` and `<meter>` element are two new graphical widgets that look similar but serve different purposes (Figure 4-15).

The `<progress>` element indicates how far a task has progressed. It uses a gray background that's partially filled in with a pulsating green bar. The `<progress>` element resembles the progress bars you've probably seen before (for example, when the Windows operating system is copying files), although its exact appearance depends on the browser being used to view the page.

The `<meter>` element indicates a value within a known range. It looks similar to the `<progress>` element, but the green bar is a slightly different shade, and it doesn't pulse. Depending on the browser, the meter bar may change color when a value is classified as "too low" or "too high"—for example, in the latter case Chrome changes the bar from green to yellow. But the most important difference between `<progress>` and `<meter>` is the semantic meaning that the markup conveys.

Note: Technically, the new `<meter>` and `<progress>` elements don't need to be in a form. In fact, they aren't even real controls (because they don't collect input from the web page visitor). However, the official HTML5 standard lumps them all together, because in some respects the `<progress>` and `<meter>` elements *feel* like form widgets, probably because they display bits of data in a graphical way.

Currently, the `<progress>` and `<meter>` elements work in Chrome (version 9 or later), Opera (version 11 or later), and Safari (version 5.1 or later). Firefox and Internet Explorer don't support them yet.

Using the `<progress>` and `<meter>` elements is easy. First, consider the `<progress>` element. It takes a *value* attribute, which sets the percentage of progress (and thus the width of the green fill) as a fractional value from 0 to 1. For example, you could set the value to 0.25 to represent a task that's 25 percent complete:

```
<progress value="0.25"></progress>
```

Alternatively, you can use the *max* attribute to set an upper maximum and change the scale of the progress bar. For example, if *max* is 200, your value needs to fall between 0 and 200. If you set it to 50, you'd get the same 25 percent fill as in the previous example:

```
<progress value="50" max="200"></progress>
```

The scale is simply a matter of convenience. The web page viewer doesn't see the actual value in the progress bar.

Note: The `<progress>` element is simply a way to display a nicely shaded progress bar. It doesn't actually *do* anything. For example, if you're using the progress bar to show the progress of a background task (say, using web workers, as demonstrated on page 364), it's up to you to write the JavaScript code that grabs hold of the `<progress>` element and changes its value.

Browsers that don't recognize the `<progress>` element simply ignore it. To deal with this problem, you can put some fallback content inside the `<progress>` element, like this:

```
<progress value="0.25">25%</progress>
```

Just remember that the fallback content won't appear in browsers that *do* support the `<progress>` element.

There's one other progress bar option. You can show an *indeterminate* progress bar, which indicates that a task is under way, but you aren't sure how close it is to completion. (Think of an indeterminate progress bar as a fancy "in progress" message.) An indeterminate progress bar looks like an empty gray bar but has a periodic green flash travel across it, from left to right. To create one, just leave out the value attribute, like this:

```
<progress>Task in progress ...</progress>
```

The `<meter>` element has a similar model, but it indicates any sort of measurement. The `<meter>` element is sometimes described as a *gauge*. Often, the specific meter value you use will correspond to something in the real world (for example, an amount of money, a number of days, an amount of weight, and so on). To control how the `<meter>` element displays this information, you're able to set both a minimum and maximum value (using the *min* and *max* attributes):

```
Your suitcase weighs: <meter min="5" max="70" value="28">28 pounds</meter>
```

Once again, the content inside the `<meter>` element is shown only if the browser doesn't know how to display a meter bar. Of course, sometimes it's important to show the specific number that the `<meter>` element uses. In this case, you'll need to add it to the page yourself, and you don't need the fallback content. The following example uses this approach. It provides all the information up-front and adds an optional `<meter>` element on browsers that support it:

```
<p>Our goal is to raise $50,000 for SLF (Save the Lemmings Foundation).</p>
<p>So far we've raised $14,000. <meter max="50000" value="14000"></meter>
```

The `<meter>` element also has the smarts to indicate that certain values are too high or too low, while still displaying them properly. To do this, you use the *low* and *high* attributes. For example, a value that's above high (but still below max) is higher than it should be, but still allowed. Similarly, a value that's below low (but still above min) is lower than it should be:

```
Your suitcase weighs:
<meter min="5" max="100" high="70" value="79">79 pounds</meter>*
<p><small>* A surcharge applies to suitcases heavier than 70 pounds.
</small></p>
```

Browsers may or may not use this information. For example, Chrome shows a yellow bar for overly high values (like the one in the previous example). It doesn't do anything to indicate low values. Finally, you can flag a certain value as being an optimal value using the *optimum* attribute, but it won't change the way it shows up in today's browsers.

All in all, `<progress>` and `<scale>` are minor conveniences that will be useful once their browser support improves just a bit.

Toolbars and Menus with `<command>` and `<menu>`

Count this as the greatest feature that's not yet implemented. The idea is to have an element that represents actions the user can trigger (that's `<command>`) and another one to hold a group of them (that's `<menu>`). Depending on how you put it together and what styling tricks you use, the `<menu>` element could become anything from a toolbar docked to the side of the browser window to a pop-up menu that appears when you click somewhere on the page. But right now, no browser supports these elements, and so you'll have to wait to find out if they're really as cool as web developers hope.

An HTML Editor in a Web Page

As you learned in Chapter 1, HTML5 believes in paving cowpaths—in other words, taking the unstandardized features that developers use today, and making them part of the official HTML5 standard. One of the single best examples is its inclusion of two odd attributes, named `contentEditable` and `designMode`, which let you turn an ordinary browser into a basic HTML editor.

These two attributes are nothing new. In fact, they were originally added to Internet Explorer 5 in the dark ages of the Internet. At the time, most developers dismissed them as more Windows-only extensions to the Web. But as the years wore on, more browsers began to copy IE's practical but quirky approach to rich HTML editing. Today, every desktop browser supports these attributes, even though they have never been part of an official standard.

Using `contentEditable` to Edit an Element

The first tool you have for HTML editing is the `contentEditable` attribute. Add it to any element to make the content of that element editable:

```
<div id="editableElement" contentEditable>You can edit this text, if you'd  
like.</div>
```

You probably won't notice the difference at first. But if you load your page in a browser and click inside that `<div>`, a text-editing cursor (called a *caret*) will appear (Figure 4-16).

UP TO SPEED

When to Use HTML Editing

Before you try out rich HTML editing, it's worth asking what the feature is actually for. Despite its immediate cool factor, HTML editing is a specialized feature that won't appeal to everyone. It makes most sense if you need a quick-and-easy way for users to edit HTML content—for example, if you need to let them add blog posts, enter reviews, post classified ads, or compose messages to other users.

Even if you decide you need this sort of feature, the `contentEditable` and `designMode` attributes might not be your first choice. That's because they don't give you all the

niceties of a real web design tool, like markup-changing commands, the ability to view and edit the HTML source, spell-checking, and so on. Using HTML's rich editing feature, you *can* build a much fancier editor, with a bit of work. But if you really need rich editing functionality, you may be happier using someone else's ready-made editor, which you can then plug into your own pages. To review some of the most popular options, read the blog post at <http://ajaxian.com/archives/richtexteditors-compared>.

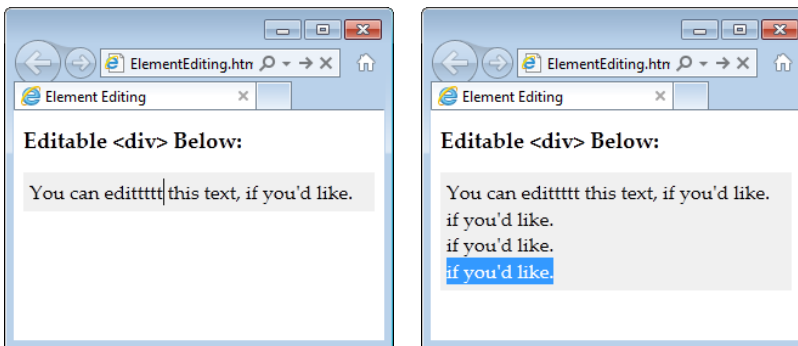

Figure 4-16: When you click in an editable region, you can move around using the arrow keys, delete text, and insert new content (left). You can also select text with the Shift key and then copy, cut, and paste it (right). It's a bit like typing in a word processor, only you won't be able to escape the confines of the `<div>` to get to the rest of the page.

In this example, the editable `<div>` contains nothing but text. However, you could just as easily put other elements inside. In fact, this `<div>` element could wrap your entire page, making the whole thing editable. Similarly, you could use `contentEditable` on multiple elements to make several sections of a page editable.

Tip: Some browsers support a few built-in commands. For example, you can get bold, italic, and underline formatting in IE using the shortcut keys `Ctrl+B`, `Ctrl+I`, and `Ctrl+U`. Similarly, you can reverse your last action in Firefox by pressing `Ctrl+Z`, and you can use all of these shortcuts in Chrome. To learn more about these editing commands, and how you can create a custom toolbar that triggers them, see Opera's two-part article series at <http://tinyurl.com/htmlEdit1> and <http://tinyurl.com/htmlEdit2>.)

Usually, you won't set `contentEditable` in your markup. Instead, you'll turn it on using a bit of JavaScript, and you'll turn it off when you want to finish editing. Here are two functions that do exactly that:

```
function startEdit() {
    // Make the element editable.
    var element = document.getElementById("editableElement");
    element.contentEditable = true;
}

function stopEdit() {
    // Return the element to normal.
    var element = document.getElementById("editableElement");
    element.contentEditable = false;

    // Show the markup in a message box.
    alert("Your edited content: " + element.innerHTML);
}
```

And here are two buttons that use them:

```
<button onclick="startEdit()">Start Editing</button>
<button onclick="stopEdit()">Stop Editing</button>
```

Just make sure you don't place the buttons in the editable region of your page, because when a page is being edited, its elements stop firing events and won't trigger your code.

Figure 4-17 shows the result after the element has been edited and some formatting has been applied (courtesy of the Ctrl+B shortcut command).

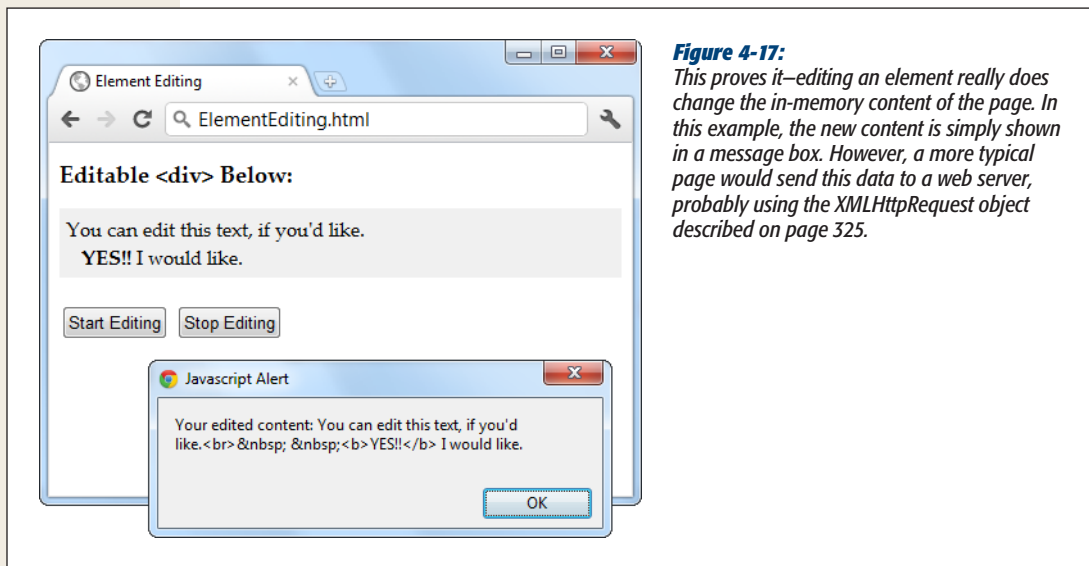

Figure 4-17:

This proves it—editing an element really does change the in-memory content of the page. In this example, the new content is simply shown in a message box. However, a more typical page would send this data to a web server, probably using the XMLHttpRequest object described on page 325.

Note: There are subtle differences in the way rich HTML editing works in different browsers. For example, pressing Ctrl+B in Chrome adds a element, while pressing it in IE adds the element. Similar variations occur when you hit the Enter key to add a new line or Backspace to delete a tag. One of the reasons that it makes sense for HTML5 to standardize the rich HTML editing feature is the ability to enforce better consistency.

Using designMode to Edit a Page

The designMode property is similar to contentEditable, except it allows you to edit an entire web page. This may seem like a bit of a problem—after all, if the whole page is editable, how will the user click buttons and control the editing process? The solution is to put the editable document inside an <iframe> element, which then acts as a super-powered editing box (Figure 4-18).

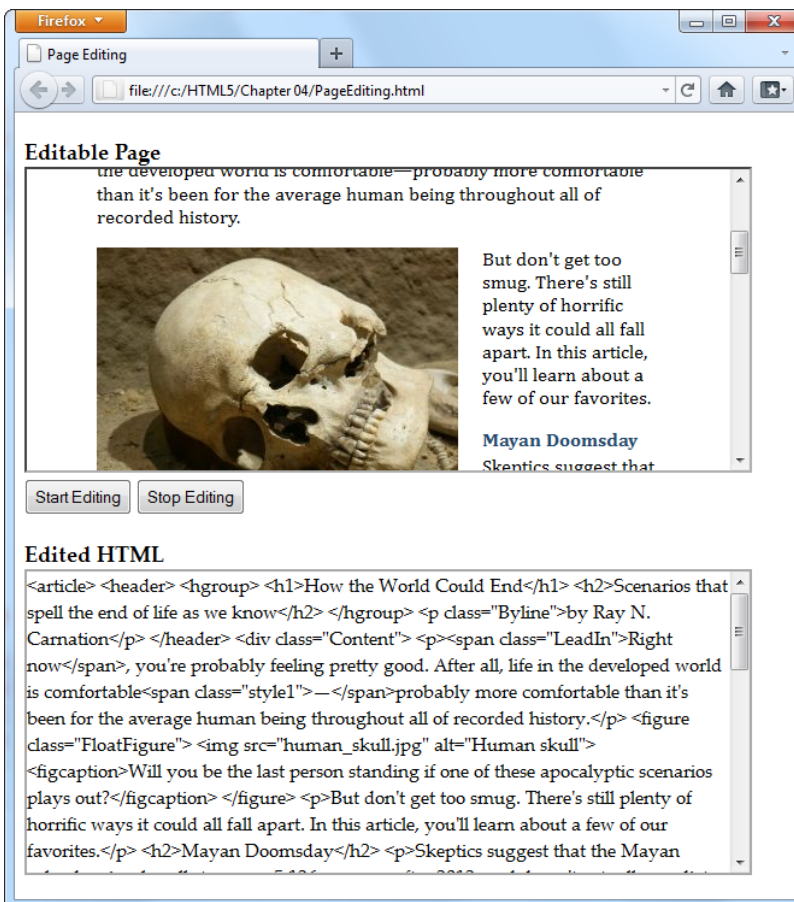

Figure 4-18:

This page contains two boxes. The first is an <iframe> that shows the apocalypse page example from Chapter 2. The second is an ordinary <div> that shows the HTML markup of the page, after it's been edited. The two buttons at the top of the page control the show, switching the <iframe> into design mode when the user is ready to work.

The markup in this page is refreshingly simple. Here are the complete contents of the `<body>` element in the page:

```
<h1>Editable Page</h1>
<iframe id="pageEditor" src="ApocalypsePage_Revised.html"></iframe>
<div>
  <button onclick="startEdit()">Start Editing</button>
  <button onclick="stopEdit()">Stop Editing</button>
</div>

<h1>Edited HTML</h1>
<div id="editedHTML"></div>
```

As you can see, this example relies on the `startEdit()` and `stopEdit()` methods, much like the previous example. However, the code is tweaked so that it sets the `designMode` attribute rather than the `contentEditable` attribute:

```
function startEdit() {
  // Turn on design mode in the <iframe>.
  var editor = document.getElementById("pageEditor");
  editor.contentWindow.document.designMode = "on";
}

function stopEdit() {
  // Turn off design mode in the <iframe>.
  var editor = document.getElementById("pageEditor");
  editor.contentWindow.document.designMode = "off";

  // Display the edited HTML (just to prove it's there).
  var htmlDisplay = document.getElementById("editedHTML");
  htmlDisplay.textContent = editor.contentWindow.document.body.innerHTML;
}
```

This example gives you a better idea of the scope of the rich editing feature. For example, click on a picture and you'll see how the browser lets you manipulate it. You can resize it, drag it to a new place, or delete it completely with a single click of the Delete button. You'll have similar power over form controls, if they're in the page you're editing.

Of course, there's still a significant gap you'll need to cross if you want to turn this example into something practical. First, you'll probably want to add better editing controls. Once again, the helpful folks at Opera have your back if you're ready to make a deeper exploration into the command model, which is beyond the scope of this chapter (see <http://tinyurl.com/htmlEdit1> and <http://tinyurl.com/htmlEdit2>). Second, you'll need to do something useful with your edited markup, like sending it to your web server via XMLHttpRequest (page 325).

There's one more caveat to note. If you run this example locally from your hard drive, it won't work in all browsers. (Internet Explorer and Chrome run into security restrictions, while Firefox sails ahead without a problem.) To avoid the problem, you can run it from the try-out site at www.prosetech.com/html5.

Audio and Video

There was a time when the Internet was primarily a way to share academic research. Then, things changed and in a blink the Web became a news and commerce powerhouse. A few more blinks, and here we are today, with an Internet that uses state-of-the-art networking technology to funnel jaw-dropping amounts of slapstick video and piano-playing kittens around the planet.

It's hard to exaggerate the magnitude of this shift. What was just a “wouldn't it be cool” dream in early 2005 is now YouTube, the world's third-most-popular website. 3- and 4-minute videos have taken over the Web (and, in the process, at least part of our lives). And network colossus Cisco reports that the trend isn't slowing down, estimating that a staggering *90 percent* of all Internet traffic will be video by 2013.

Amazingly, this monumental change happened despite the fact that HTML and web browsers have no built-in support for video or even audio. Instead, they rely on plug-ins like Flash, which work well for most people, most of the time. But there are clear blind spots—like the one Apple created when it released the iPad with no Flash support.

HTML5 addresses the gap by adding the `<audio>` and `<video>` elements that HTML has been missing all these years. Finally, rich media gets consistent, standardized support that doesn't require a plug-in. But the story isn't all rosy. The major browser companies are locked into an audio and video format war that's way dirtier than Blu-ray versus HD-DVD. The sad consequence is that there's no single audio and video format that works on every browser, and you'll need to encode and then re-encode your media files to get them working in HTML5. In this chapter, you'll learn how.

But first, it's time to step back, take a look at the big picture, and see where video left off before HTML5 hit the scene.

Understanding Video Today

Without HTML5, you have a couple of ways to add video to a web page. Most simply, you can shoehorn it into a page with the `<embed>` element. The browser then creates a video window that uses Windows Media Player, Apple QuickTime, or some other video player, and places it on the page.

The key problem with this technique is that it puts you in a desolate no-man's-land of browser support. You have no way to control playback, you may not be able to buffer the video to prevent long playback delays, and you have no way of knowing whether your video file will be playable at all on different browsers or operating systems.

The second approach is to use a browser plug-in—like Microsoft's relative newcomer, Silverlight, or the more typical Adobe Flash. Up until recently, Flash had the problem of browser support solved cold. After all, Flash video works everywhere the Flash plug-in is installed, and currently that's on more than 99 percent of Internet-connected computers. Flash also gives you nearly unlimited control over the way playback works. For example, you can use someone else's prebuilt Flash video player for convenience, or you can design your own and customize every last glowy button.

But the Flash approach isn't perfect. To get Flash video into a web page, you need to throw down some seriously ugly markup that uses the `<object>` and `<embed>` elements. You need to encode your video files appropriately, and you may also need to buy the high-priced Flash developer software and learn to use it—and the learning curve can be steep. But the worst problem is Apple's new wave of mobile devices: the iPhone and the iPad. They refuse to tolerate Flash at all, slapping blank boxes over the web page regions that use it.

Note: Plug-ins also have a reputation for occasional unreliability. That's because of the way they work. For example, when you visit a page that uses Flash, the browser lets the Flash plug-in take control of a rectangular box somewhere on the web page. Most of the time, this hands-off approach works well, but minor bugs or unusual system configurations can lead to unexpected interactions and glitches, like suddenly garbled video or pages that suck up huge amounts of computer memory and slow your web surfing down to a crawl.

Still, if you watch video on the Web today (and you aren't using an iPhone or iPad), odds are that it's wrapped in a Flash mini-application. If you're not sure, try right-clicking the video player. If the menu that pops up includes a command like "About Flash Player 10," then you know you're dealing with the ubiquitous Flash plug-in. And even when you move to HTML5, you'll probably still need a Flash-powered fallback for browsers that aren't quite there yet, like Internet Explorer 8.

Note: In 2010, YouTube rolled out a trial HTML5 video player. To try it out, visit www.youtube.com/html5. Everywhere else, YouTube sticks exclusively with Flash.

Introducing HTML5 Audio and Video

A simple idea underpins HTML5's audio and video support. Just as you can add images to a web page with the `` element, you should be able to insert sound with an `<audio>` element and video with a `<video>` element. Logically enough, HTML5 adds both.

UP TO SPEED

Turn Back Now If...

Unfortunately, some things are beyond HTML5's new audio and video capabilities. If you want to perform any of these tricks, you'll need to scramble back to Flash (at least for now):

- **Licensed content.** HTML5 video files don't use any sort of copy protection system. In fact, folks can download HTML5 videos as easily as downloading pictures—with a simple right-click of the mouse.
- **Video or audio recording.** HTML5 has no way to stream audio or video from your computer to another computer. So if you want to build a web chat program that uses the microphones and webcams of your visitors, stick with Flash. The creators of HTML5 are experimenting with a `<device>` element that might serve the same purpose, but for now there's no HTML-only solution, in any browser.
- **Adaptive video streaming.** Advanced, video-heavy websites like YouTube need fine-grained control over video streaming and buffering. They need to provide videos in different resolutions, stream live events, and
- adjust the video quality to fit the bandwidth of the visitor's Internet connection. Until HTML5 can provide these features, video sharing sites may add HTML5 support, but they won't completely switch from Flash.
- **Low-latency, high-performance audio.** Some applications need audio to start with no delay or they need to play multiple audio clips in perfect unison. Examples include a virtual synthesizer, music visualizer, or a real-time game with plenty of overlapping sound effects. And while browser makers are hard at work improving HTML5's audio performance, it still can't live up to these demands.
- **Dynamically created or edited audio.** What if you could not just play recorded audio, but also analyze audio information, modify it, or generate it in real time? New standards, like the Firefox-sponsored Audio Data API (http://wiki.mozilla.org/Audio_Data_API), are competing to add on these sorts of features to HTML5 audio, but they aren't here yet.

Making Some Noise with `<audio>`

Here's an example of the `<audio>` element at its absolute simplest:

```
<p>Hear us rock out with our new song,  
<cite>Death to Rubber Duckies</cite>:</p>  
<audio src="rubberduckies.mp3" controls></audio>
```

The `src` attribute provides the file name of the audio file you want to play. The `controls` attribute tells the browser to include a basic set of playback controls. Each browser has a slightly different version of these controls, but they always serve the same purpose—to let the user start and stop playback, jump to a new position, and change the volume (Figure 5-1).

Note: The `<audio>` and `<video>` elements must have both a start and an end tag. You can't use empty element syntax, like `<audio />`.

Figure 5-1:
Here's what playback controls look like on three browsers: Internet Explorer (top), Google Chrome (middle), and Firefox (bottom). However, to create a page with audio that actually works in all three browsers requires a bit of audio-format juggling, as you'll learn on page 149.

Hear us rock out with our new song, *Death to Rubber Duckies*:

Hear us rock out with our new song, *Death to Rubber Duckies*:

Hear us rock out with our new song, *Death to Rubber Duckies*:

The `<audio>` element supports three more attributes: `preload`, `autoplay`, and `loop`. The `preload` attribute tells the browser how it should download the audio. You can use `auto` to tell the browser to start downloading the whole file, so it's available when the user clicks the play button. Of course, this download process unfolds in the background, so your web page visitor can scroll around and read the page without waiting for the download to finish.

The `preload` attribute also supports two more values. You can use `metadata` to tell the browser to grab the first small chunk of data from the file, which is enough to determine some basic details (like the total length of the audio). Or, you can use `none`, which tells the browser to hold off completely. You might use one of these options to save bandwidth, for example, if you have a page stuffed full of `<audio>` elements and you don't expect the visitor to play more than a few of them.

```
<audio src="rubberduckies.mp3" controls preload="metadata"></audio>
```

When you use the *none* or *metadata* values, the browser downloads the audio file as soon as someone clicks the play button. Happily, browsers can play one chunk of audio while downloading the next, without a hiccup, unless you're working over a slow network connection.

If you don't set the *preload* attribute, browsers can do what they want, and different browsers make different assumptions. Most browsers assume *auto* as the default value, but Firefox uses *metadata*. Furthermore, it's important to note that the *preload* attribute isn't a rigid rule, but a recommendation you're giving to the browser—one that may be ignored depending on other factors. (And some slightly older browser builds don't play attention to the *preload* attribute at all.)

Note: If you have a page stuffed with `<audio>` elements, the browser creates a separate strip of playback controls for each one. The web page visitor can listen to one audio file at a time, or start them all playing at once.

Next up is the *autoplay* attribute, which tells the browser to start playback immediately once the page has finished loading:

```
<audio src="rubberduckies.mp3" controls autoplay></audio>
```

Without *autoplay*, it's up to the person viewing the page to click the play button.

You can also use the `<audio>` element to play background music unobtrusively, or even to provide the sound effects for a browser-based game. To get background music, remove the *controls* attribute and add the *autoplay* attribute (or use JavaScript-powered playback, as described on page 160). But use this approach with caution, and remember that your page still needs some sort of audio shutoff switch.

Warning: No one wants to face a page that blares music or sound effects but lacks a way to shut the sound off. If you decide to use the `<audio>` element without the *controls* attribute, you *must*, at a bare minimum, add a mute button that uses JavaScript to silence the audio.

Finally, the *loop* attribute tells the browser to start over at the beginning when the audio ends:

```
<audio src="rubberduckies.mp3" controls loop></audio>
```

In most browsers, playback is fluid enough that you can use this technique to create a seamless, looping soundtrack. The trick is to choose a loopable piece of audio that ends where it begins. You can find hundreds of free examples at www.flashkit.com/loops. (These loops were originally designed for Flash but can also be downloaded in MP3 and WAV versions.)

If the `<audio>` element seems too good to be true, well, it is. On page 149, you'll consider the format headaches that make HTML5 developers miserable. But first, it's worth taking a look at the `<audio>` element's close companion: the `<video>` element.

Getting the Big Picture with <video>

The <video> element pairs nicely with the <audio> element. It has the same src, controls, preload, autoplay, and loop attributes. Here's a straightforward example:

```
<p>A butterfly from my vacation in Switzerland!</p>
<video src="butterfly.mp4" controls></video>
```

Once again, the *controls* attribute gets the browser to generate a set of handy play-back controls (Figure 5-2). In most browsers, these controls disappear when you click somewhere else on the page, and return when you hover over the movie.

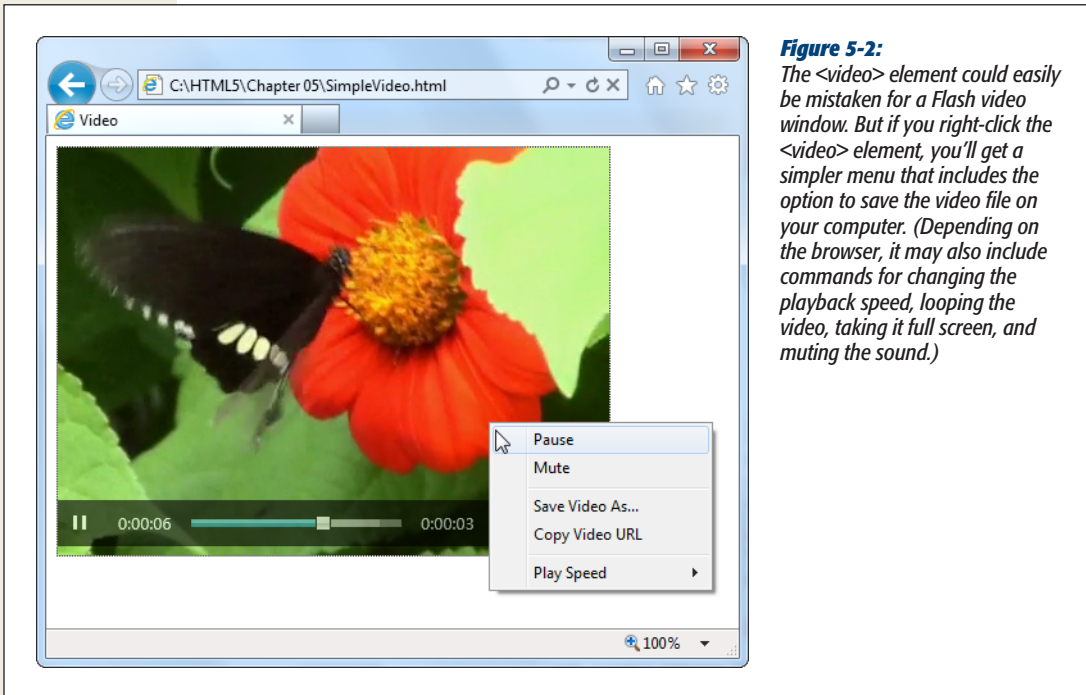

Figure 5-2:

The <video> element could easily be mistaken for a Flash video window. But if you right-click the <video> element, you'll get a simpler menu that includes the option to save the video file on your computer. (Depending on the browser, it may also include commands for changing the playback speed, looping the video, taking it full screen, and muting the sound.)

The <video> element also adds three more attributes: height, width, and poster.

The *height* and *width* attributes set the size of the video window (in pixels). Here's an example that creates a video box that measures 400 × 300 pixels:

```
<video src="butterfly.mp4" controls width="400" height="300"></video>
```

This should match the natural size of the video itself, but you might choose to indicate these details explicitly so your layout doesn't get messed up before the video loads (or if the video fails to load altogether).

Finally, the *poster* attribute lets you supply an image that should be used in place of the video. Browsers use this picture in three situations: if the first frame of the video hasn't been downloaded yet, if you've set the preload attribute to none, or if the selected video file wasn't found.

```
<video src="butterfly.mp4" controls poster="swiss_alps.jpg"></video>
```

Although you’ve now learned everything there is to know about audio and video markup, there’s a lot more you can do with some well-placed JavaScript. But before you can get any fancier with the `<audio>` and `<video>` elements, you need to face the headaches of audio and video codec support.

Note: The HTML5 standard specifies two more attributes that apply to the `<audio>` and `<video>` elements. You can add the *muted* attribute to shut off the sound initially (the viewer can switch it on using the playback controls). You can use the *mediagroup* attribute to link multiple media files together, so their playback is synchronized (which is particularly useful if the audio track for your video is in a separate audio file). However, browsers don’t currently support either attribute.

Format Wars and Fallbacks

The examples you’ve just considered use two popular standards: MP3 audio and H.264 video. They’re enough to keep Internet Explorer 9 and Safari happy, but other browsers have their own ideas (Figure 5-3).

Figure 5-3:

Try to play an MP3 file in Firefox (top) or a Theora video in IE (bottom), and here’s all the joy you’ll get.

When confronted with the HTML5 format wars, web developers have a few angry questions. Like, is HTML5 audio and video hopelessly broken? And who can we blame first? But the issue isn’t as clear-cut as it seems. Different browser makers have defensible reasons for preferring different video standards. Small companies (like Mozilla, the creators of Firefox) aren’t willing to pay stiff licensing costs for popular standards like MP3 audio and H.264 video. And it’s hard to blame them—after all, they are giving away their work for free.

Bigger companies, like Microsoft and Apple, have their own reasonable-sounding excuses for shunning unlicensed standards. They complain that these standards won't perform as well (they currently lack hardware acceleration) and aren't as widespread (unlike H.264, which is used in camcorders, Blu-ray players, and a host of other devices). But the biggest problem may be that no one is really sure that these unlicensed standards don't have obscure ties to someone else's intellectual property. If they do, and if big companies like Microsoft and Apple start using them, they open themselves up to pricey patent lawsuits that could drag on for years.

FREQUENTLY ASKED QUESTIONS

H.264 Licensing

I'm using H.264 for my videos. Do I have to pay licensing costs?

If you're using an H.264 decoder in your product (for example, you're creating a browser that can play H.264-encoded video), you definitely need to pay. But if you're a video provider, it's less clear cut.

First, the good news. If you're using H.264 to make free videos, you won't be asked to pay anything, ever. If you're creating videos that have a commercial purpose but aren't actually being sold (say, you're shooting a commercial or promoting yourself in an interview), you're also in the clear.

If you're *selling* H.264-encoded video content on your website, you may be on the hook to pay license fees to

MPEG-LA, either now or in the future. Right now, the key detail is the number of subscribers. If you have fewer than 100,000, there's no licensing cost, but if you have 100,000 to 250,000, you're expected to cough up \$25,000 a year. This probably won't seem like much bank for a video-selling company of that size, and it may pale in comparison to other considerations, like the cost of professional encoding tools. However, these numbers could change when the licensing terms are revised in 2016. Big companies looking to make lots of money in web video might prefer to use an open, unlicensed video standard like Theora or WebM.

For the full licensing legalese on H.264, visit www.mpegla.com/main/programs/AVC/Pages/Intro.aspx.

Meet the Formats

The official HTML5 standard doesn't require support for any specific video or audio format. (Early versions did, but the recommendation was dropped after intense lobbying.) As a result, browser makers are free to choose the formats *they* want to support, despite the fact that they're congenitally unable to agree with one another. Table 5-1 shows the standards that they're using right now.

Table 5-1. Some of the standards that HTML5 browsers may support

Format	Description	Common file extension	MIME type
MP3	The world's most popular audio format. However, licensing costs make it impractical for small players like Firefox and Opera.	.mp3	audio/mp3
Ogg Vorbis	A free, open standard that offers high-quality, compressed audio comparable to MP3.	.ogg	audio/ogg
WAV	The original format for raw digital audio. Doesn't use compression, so files are staggeringly big and unsuitable for most web uses.	.wav	audio/wav
H.264	The industry standard for video encoding, particularly when dealing with high-definition video. Used by consumer devices (like Blu-ray players and camcorders), web sharing websites (like YouTube and Vimeo), and web plug-ins (like Flash and Silverlight).	.mp4	video/mp4
Ogg Theora	A free, open standard for video by the creators of the Vorbis audio standard. Byte for byte, the quality and performance doesn't match H.264, although it's still good enough to satisfy most people.	.ogv	video/ogg
WebM	The newest video format, created when Google purchased VP8 and transformed it into a free standard. Critics argue that the quality isn't up to the level of H.264 video—yet—and that it may have unexpected links to other people's patents, which could lead to a storm of lawsuits in the future. Still, WebM is the best bet for a future of open video.	.webm	video/webm

Table 5-1 also lists the recommended file extensions your media files should use. To realize why this is important, you need to understand that there are actually three standards at play in a video file. First, and most obviously, is the *video codec*, which compresses the video into a stream of data (examples include H.264, Theora, and WebM). Second is the *audio codec*, which compresses one or more tracks of audio using a related standard. (For example, H.264 generally uses MP3, while Theora uses Vorbis.) Third is the *container format*, which packages everything together with some descriptive information and, optionally, other frills like still images and subtitles. Often, the file extension refers to the container format, so .mp4 signifies an MPEG-4 container, .ogv signifies an Ogg container, and so on.

Here's the tricky part: Most container formats support a range of different video and audio standards. For example, the popular Matroska container (.mkv) can hold video that's encoded with H.264 or Theora. For reasons of not making your head explode, Table 5-1 puts each video format with the container format that's most common and has the most reliable web support.

Table 5-1 also indicates the proper MIME type, which must be configured on your web server. If you use the wrong MIME type, browsers may stubbornly refuse to play a perfectly good media file. (If you're a little fuzzy on exactly what MIME types do and how to configure them, see the box on page 153.)

Browser Support for Media Formats

All the audio and video formats in the world aren't much use until you know how they're supported. Table 5-2 describes the support for different audio formats on different browsers. Table 5-3 shows the same information for video formats.

Table 5-2. Browser support for HTML5 audio formats

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
MP3	9	-	5	3.1	-	3	-
Ogg Vorbis	-	3.6	5	-	10.5	-	-
WAV	-	3.6	8	3.1	10.5	-	-

Table 5-3. Browser support for HTML5 video formats

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
H.264 Video	9	-	*	3.1	-	4**	2.3
Ogg Theora	-	3.5	5	-	10.5	-	-
WebM	***	4	6	-	10.6	-	2.3

* Chrome currently supports this standard but has pledged to remove it in future versions to better promote WebM.

** iOS 3.x supports video, but there are a few subtle video bugs hiding in the Safari browser. For example, if you set the poster attribute (page 148) the video becomes unplayable.

*** IE will support the WebM format, if computer users install the codec on their own.

Mobile browsers pose particular support headaches. First of all, there are quirks. Some features, like autoplay and looping, may not be supported, and some devices may perform playback in a dedicated player (rather than right in the web page window). More significantly, mobile devices usually need video encoded with a reduced size and lower quality.

Tip: As a general rule of thumb, if you want a video to be playable on a mobile device, you should encode it using the H.264 Baseline Profile (rather than High Profile). For iPhone and Android phones, use a size of 640 × 480 or smaller (and stick to 480 × 360 if you want to play it on a BlackBerry). Many encoding programs (see the box on page 156) have presets that let you prepare mobile-optimized video.

UP TO SPEED

Understanding MIME Types

A *MIME type* (sometimes called a *content type*) is a piece of information that identifies the type of content in a web resource. For example, the MIME type of a web page is *text/html*.

Before a web server sends a resource to a browser, it sends the MIME type. For example, if a browser asks for the page *SuperVideoPlayerPage.html*, the web server sends the *text/html* MIME type, a few other pieces of information, and the actual file content. When the browser receives the MIME type, it knows what to do with the content that comes next. It doesn't need to try to make a guess based on a file name extension or some other sort of hackery.

For common file types—for example, HTML pages and images—you don't need to worry about MIME types, because every web server already handles them properly. But some web servers might not be configured with the MIME types for audio and video. That's a problem, because browsers will be thrown off course if the web server sends a media file with the wrong MIME type. Usually, they won't play the file at all.

To avoid this problem, make sure your web server is set up with the MIME types listed in Table 5-1, and use the corresponding file extensions for your audio and video files. (It's no use configuring the MIME type and then using the wrong file extension, because the web server needs to be able to pair the two together. For example, if you configure *.mp4* files to use the MIME type *video/mp4*, but then you give your video file the extension *.mpFour*, the web server won't have a clue what you're trying to do.)

Configuring MIME types is an easy job, but the exact steps depend on your web hosting company (or your web server software, if you're hosting your site yourself). If your web hosting company uses the popular cPanel interface, then look for an icon named MIME Types, and click it. You'll then see a page like the one shown in Figure 5-4. And if you're in any doubt, contact your web hosting company for help.

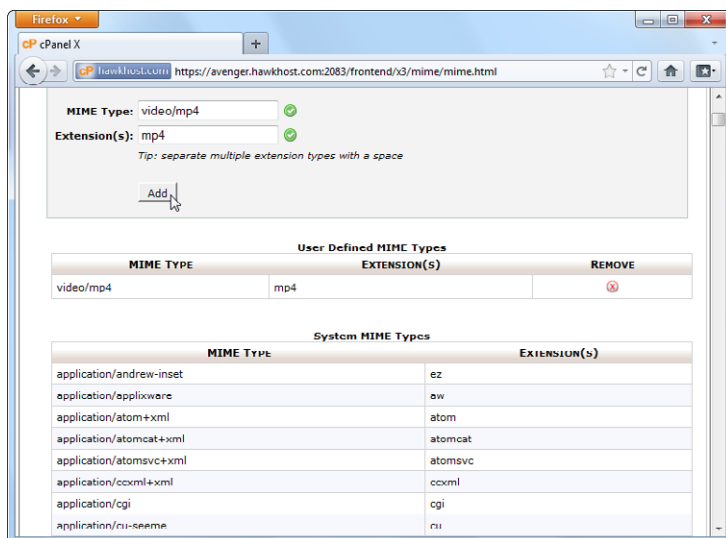

Figure 5-4:
Here a new MIME type is being added to support H.264 video files. In many cases, you won't need to take this step, because your website will already be configured correctly.

Multiple Formats: How to Please Every Browser

Faced with these format differences, what's an honest web developer to do? The sad truth is that no single audio or video format can work on all browsers. If you want to support all browsers—and you should—you need to prepare your media in multiple formats. You'll probably also need a Flash fallback for visitors who are using HTML5-ignorant browsers like IE 8.

Fortunately, the `<audio>` and `<video>` elements support a fallback system that works quite well, and pioneering webheads have already ironed out most of the quirks. Less happily, the format wars mean that you'll need to encode your content at least twice—a process that wastes time, CPU power, and disk space.

Before you get started, you need to choose a strategy for supporting non-HTML5 browsers. Basically, web developers have two good choices:

- **Use Flash with an HTML5 fallback.** This gives everybody Flash, except for those who don't have it installed. This strategy makes sense if you're already showing video content on your website with a mature Flash video player, but you want to reach out to iPad and iPhone users.
- **Use HTML5 with a Flash fallback.** This gives everybody HTML5 video (or audio), except for people with older browsers, who get Flash. If you go this route, you can also decide to support fewer formats, in which case people who have HTML5 browsers but don't support your chosen format will also get the Flash fallback. This approach is the way of the future, assuming you can live with the current limits of HTML5 video and audio (see page 145).

In the following sections, you'll put the second approach to work. That way, you ensure that browsers get a pure HTML5 solution, whenever it's possible.

The `<source>` Element

The first step to support multiple formats is to remove the `src` attribute from the `<video>` or `<audio>` element, and replace it with a list of nested `<source>` elements inside. Here's an example with the `<audio>` element:

```
<audio controls>
  <source src="rubberduckies.mp3" type="audio/mp3">
  <source src="rubberduckies.ogg" type="audio/ogg">
</audio>
```

Here, the same `<audio>` element holds two `<source>` elements, each of which points to a separate audio file. The browser then chooses the first file it finds that has a format it supports. Firefox and Opera will grab *rubberduckies.ogg*. Internet Explorer, Safari, and Chrome will stick with *rubberduckies.mp3*.

In theory, a browser can determine whether or not it supports a file by downloading a chunk of it. But a better approach is to use the *type* attribute to supply the correct MIME type (see page 153). That way, the browser will attempt to download only a file it believes it can play. (To figure out the correct MIME type, consult Table 5-1.)

The same technique works for the `<video>` element. Here's an example that supplies the same video file twice, once encoded with H.264 and once with Theora:

```
<video controls width="700" height="400">
  <source src="beach.mp4" type="video/mp4">
  <source src="beach.ogv" type="video/ogg">
</video>
```

In this example, there's one new detail to note. When using multiple video formats, the H.264-encoded file should always come first. Otherwise, it won't work for old iPads running iOS 3.x. (The problem has since been fixed in iOS 4, but there's no disadvantage to keeping H.264 in the top spot.)

Note: Just because a browser believes it supports a specific type of audio or video doesn't necessarily mean it can play it. For example, you may have used an insanely high bitrate, or a strange codec in a recognized container format. You can deal with issues like these by supplying type *and* codec information through the type attribute, but it'll make a mess of your markup. The HTML5 spec has all the gruesome details at <http://tinyurl.com/3aq5nk3>.

So how many video formats should you use? To cover absolutely all your bases, you need H.264, Theora, and a Flash fallback (which is covered in the next section). For better quality, you can replace Theora with WebM. This won't work for slightly older versions of Firefox and Opera, but these versions aren't terribly common anyway. Or, you can get encoder-crazy, and include H.264, Theora, and WebM versions of your work (in that order). You put WebM before Theora so browsers that support both use the better-quality video.

If you're really ambitious, you may opt to create a single video page that's meant for both desktop browsers and mobile devices. In this case, you not only need to worry about the H.264 and Theora video formats, but you also need to think about creating low-bandwidth versions of your video files that are suitable for devices that have less hardware power and use slower Internet connections. To make sure mobile devices get the lighter-weight video files while desktop browsers get the higher-quality ones, you need to use *media queries*, as explained on page 263.

The Flash Fallback

Every web browser since the dawn of time deals with unrecognized tags in the same way—it ignores them. For example, if Internet Explorer 8 comes across the opening tag for the `<video>` element, it barrels merrily on, without bothering to check the `src` attribute. However, browsers don't ignore the *content* inside unrecognized element, which is a crucial difference. It means if you have markup like this:

```
<video controls width="400" height="300">
  <source src="discoParty.mp4" type="video/mp4">
  <source src="discoParty.ogv" type="video/ogg">
  <p>We like disco dancing.</p>
</video>
```

Browsers that don't understand HTML5 will act as though they saw this:

```
<p>We like disco dancing.</p>
```

This fallback content provides a seamless way to deal with older browsers.

UP TO SPEED

Encoding Your Media

Now you know what combination of formats to use, but you don't necessarily know how to transform your media files into those formats. Don't despair, as there are plenty of tools. Some work on entire batches of files at once, some have a reputation for professional-grade quality (and a price tag to match), and some do their work on powerful web servers so you don't have to wait. The trick is picking through all the options to get the encoder that works for you.

Here are some of your options:

- **Audio editors.** If you're looking to edit WAV files and save them in the MP3 or Vorbis formats, a basic audio editor can help out. Audacity (<http://audacity.sourceforge.net>) is a free editor for Mac and Windows that fits the bill, although you'll need to install the LAME MP3 encoder to get MP3 support (<http://lame.buanzo.com.ar>). Goldwave (www.goldwave.com) is a similarly capable audio editor that's free to try, but sold for a nominal fee.
- **Miro Video Converter.** This free, open-source program runs on Windows and Mac OS X. It can take virtually any video file, and convert it to WebM, Theora, or H.264. It also has presets that match the screen sizes and supported formats for mobile devices, like iPads, iPhones, or Android phones. The only downside is that you can't tweak more advanced options to control how the encoding is done. To try it out, go to www.mirovideoconverter.com.
- **Firefogg.** This Firefox plug-in (available at <http://firefogg.org>) can create Theora or WebM video files, while giving you a few more options than Miro. It also runs right inside your web browser (although it does all its work locally, without involving a web server).
- **HandBrake.** This open-source, multi-platform program (available at <http://handbrake.fr>) converts a wide range of video formats into H.264 (and a couple of other modern formats).
- **Zencoder.** Here's an example of a professional media encoding service that you can integrate with your website. Zencoder (<http://zencoder.com>) pulls video files off your web server, encodes them in all the formats and bitrates you need, gives them the names you want, and places them in the spot they belong. A big player (say, a video sharing site), would pay Zencoder a sizeable monthly fee.

Note: Browsers that support HTML5 audio ignore the fallback section, even if they can't play the media file. For example, consider what happens if Firefox finds a <video> element that uses an H.264 video file but doesn't support Theora. In this situation, Firefox shows a displayed video player window with an X icon (as in Figure 5-3), but it still won't show the fallback content.

So now that you know how to add fallback content, you need to decide what your fallback content should include. One example of bad fallback content is a text message (as in, “Your browser does not support HTML5 video, so please upgrade.”). Website visitors consider this sort of comment tremendously impolite, and they’re likely never to return when they see it.

The proper thing to include for fallback content is another working video window—in other words, whatever you’d use in an ordinary, non-HTML5 page. One possibility is a YouTube video window. If you use this approach, you need to meet YouTube’s rules (make sure your video is less than 15 minutes and doesn’t contain offensive or copyrighted content). You can then upload your video to YouTube in the best format you have on hand, and YouTube will re-encode the video into the formats it supports. To get started, head to http://upload.youtube.com/my_videos_upload.

Another possibility is to use a Flash video player. (Or, if you’re playing audio, a Flash audio player.) Happily, the world has plenty of Flash video players. Many of them are free, at least for noncommercial uses. And best of all, most support H.264, a format you’re probably already using for HTML5 video.

Here’s an example that inserts the popular Flowplayer (<http://flowplayer.org>) into an HTML5 `<video>` element:

```
<video controls width="700" height="400">
  <source src="beach.mp4" type="video/mp4">
  <source src="beach.ogv" type="video/ogg">

  <object id="flowplayer" width="700" height="400"
    data="flowplayer-3.2.7.swf"
    type="application/x-shockwave-flash">
    <param name="movie" value="flowplayer-3.2.7.swf">
    <param name="flashvars" value='config={"clip":"beach.mp4"}'>
  </object>
</video>
```

Here, the bold part is a parameter that the browser passes to the Flowplayer, with the file name of the video file. As you can see, even though this example has three possible outcomes (HTML5 video with H.264, HTML5 video with Theora, or Flash video with H.264), it needs only two video files, which saves on the encoding work. Figure 5-5 shows the result in action.

Tip: Although it’s convenient to reuse your H.264 file with Flash, this approach isn’t perfect. Flash didn’t add support for H.264 until Flash 9.0.115.0. Browsers with older versions of the Flash plug-in won’t be able to play a H.264-encoded video file unless they upgrade. You *could* use the Flash Video Format (.flv), which is guaranteed to work for all versions of Flash, but that requires yet another round of re-encoding.

Figure 5-5:

One video, served three ways: in IE 9 (top), in Firefox (middle), and in IE 7, with Flash (bottom).

Of course, some people won't have Flash or a browser that supports HTML5. As you'll see, you can offer them another fallback, such as a link to download the video file and open it in an external program. You place that content after the Flash content, but still inside the `<object>` element, like this:

```
<video controls width="700" height="400">
  <source src="beach.mp4" type="video/mp4">
  <source src="beach.ogv" type="video/ogg">

  <object id="flowplayer" width="700" height="400"
    data="http://releases.flowplayer.org/swf/flowplayer-3.2.7.swf"
    type="application/x-shockwave-flash">
    <param name="movie" value="beach.mp4">

    
    <p>Your browser does not support HTML5 video or Flash.</p>
    <p>You can download the video in <a href="beach.mp4">MP4 H.264</a>
    or <a href="beach.ogv">Ogg Theora</a> format.</p>
  </object>
</video>
```

If you want a Flash player with an HTML fallback (instead of an HTML video player with a Flash fallback), you simply need to invert this example. Start with the `<object>` element, and nestle the `<video>` element inside, just before the closing `</object>` tag. Place the fallback content just after the last `<source>` element, like this:

```
<object id="flowplayer" width="700" height="400"
  data="http://releases.flowplayer.org/swf/flowplayer-3.2.7.swf"
  type="application/x-shockwave-flash">
  <param name="movie" value="butterfly.mp4">

  <video controls width="700" height="400">
    <source src="beach.mp4" type="video/mp4">
    <source src="beach.ogv" type="video/ogg">

    
    <p>Your browser does not support HTML5 video or Flash.</p>
    <p>You can download the video in <a href="beach.mp4">MP4 H.264</a>
    or <a href="beach.ogv">Ogg Theora</a> format.</p>
  </video>
</object>
```

Usually, you'll only use this approach if you need to take an existing Flash-based website and extend it to support Apple devices like the iPad. Incidentally, there's at least one JavaScript player that has a baked-in HTML5 fallback. It's the JW Player, which you can get at www.longtailvideo.com/players/jw-flv-player.

Controlling Your Player with JavaScript

So far, you've covered some heavy ground. You've learned how to take the new `<audio>` and `<video>` elements and turn them into a reasonably supported solution that works on *more* web pages than today's Flash-based players. Not bad for a bleeding-edge technology.

That's about the most you can do with the `<audio>` and `<video>` elements if you stick to markup only. But both elements have an extensive JavaScript object model, which lets you control playback with code. In fact, you can even adjust some details—like playback speed—that aren't available in the browser's standard audio and video players.

In the following sections, you'll explore the JavaScript support by considering two practical examples. First, you'll add sound effects to a game. Next, you'll create a custom video player. And finally, you'll consider the solutions that other people have developed using this potent mix of HTML5 and JavaScript, including supercharged, skinnable players and accessible captioning.

Adding Sound Effects

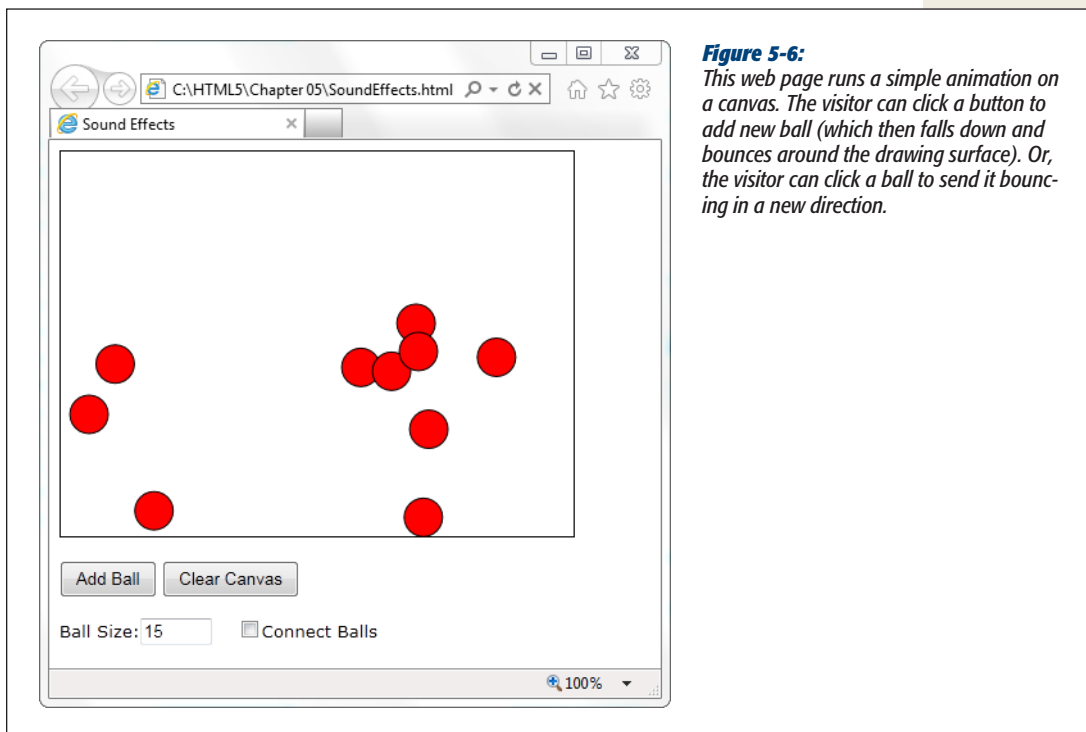

The `<audio>` element doesn't just let web visitors play songs and voice recordings. It's also a useful tool for playing sound effects, whenever you need them. This makes it particularly useful if you need to add music and sound effects to a game.

Figure 5-6 shows a very simple example, with an interactive ball-dropping animation. You'll see the code that makes this example work when you consider the `<canvas>` element in Chapter 6. But for now, the only important detail is how you can add a suitable sonic backdrop.

This example combines a background music track with sound effects. The background music track is the easiest part. To create it, you start by adding an invisible `<audio>` element to your page, like this:

```
<audio id="backgroundMusic" loop>
  <source src="TheOwlNamedOrion.mp3" type="audio/mp3">
  <source src="TheOwlNamedOrion.ogg" type="audio/ogg">
</audio>
```

This audio player doesn't include the `autoplay` or `controls` attributes, so initially it's silent and invisible. It does use the `loop` attribute, so once it starts playing it will repeat the music track endlessly. To control playback, you need to use two methods of the audio (or video) object: `play()` and `pause()`. Confusingly, there's no `stop` method—for that, you need to pause the video and then reset the `currentTime` property to 0, which represents the beginning of the file.

**Figure 5-6:**

This web page runs a simple animation on a canvas. The visitor can click a button to add new ball (which then falls down and bounces around the drawing surface). Or, the visitor can click a ball to send it bouncing in a new direction.

With this in mind, it's quite easy to start playback on the background audio when the first ball is created:

```
var audioElement = document.getElementById("backgroundMusic");
audioElement.play();
```

And just as easy to stop playback when the canvas is cleared:

```
var audioElement = document.getElementById("backgroundMusic");
audioElement.pause();
audioElement.currentTime = 0;
```

As you learned earlier, there's no limit on the amount of audio you can play at once. So while the background audio is playing its tune, you can concentrate on the more interesting challenge of adding sound effects.

In this example, a “boing” sound effect is played every time a ball ricochets against the ground or a wall. To keep things interesting, several slightly different boing sounds are used. This is a stand-in for a more realistic game, which would probably incorporate a dozen or more sounds.

There are several ways to implement this design, but not all of them are practical. The first option is to add a single new `<audio>` element to play sound effects. Then, every time a collision happens, you can load a different audio file into that element

(by setting the `src` property) and play it. This approach hits two obstacles. First, a single `<audio>` element can play only a single sound at once, so if more than one ball hits the ground in quick succession, you need to either ignore the second, overlapping sound, or interrupt the first sound to start the second one. The other problem is that setting the `src` property forces the browser to request the audio file. And while some browsers will do this quickly (if the audio file is already in the cache), Internet Explorer doesn't. The result is laggy audio—in other words, a boing that happens half a second after the actual collision.

A better approach is to use a group of `<audio>` elements, one for each sound. Here's an example:

```
<audio id="audio1">
  <source src="boing1.mp3" type="audio/mp3">
  <source src="boing1.wav" type="audio/wav">
</audio>
<audio id="audio2">
  <source src="boing2.mp3" type="audio/mp3">
  <source src="boing2.wav" type="audio/wav">
</audio>
<audio id="audio3">
  <source src="boing3.mp3" type="audio/mp3">
  <source src="boing3.wav" type="audio/wav">
</audio>
```

Note: Even though these three `<audio>` elements use different audio files, that isn't a requirement. For example, if you wanted to have the same boing sound effect but allow overlapping audio, you'd still use three audio players.

Whenever a collision happens, the JavaScript code calls a custom function named `boing()`. That method grabs the next `<audio>` element in the sequence, and plays it.

Here's the code that makes it happen:

```
// Keep track of the number of <audio> elements.
var audioElementCount = 3;

// Keep track of the <audio> element that's next in line for playback.
var audioElementIndex = 1;

function boing() {
  // Get the <audio> element that's next in the rotation.
  var audioElementName = "audio" + audioElementIndex;
  var audio = document.getElementById(audioElementName);

  // Play the sound effect.
  audio.currentTime = 0;
  audio.play();

  // Move the counter to the next <audio> element.
  if (audioElementIndex == audioElementCount) {
    audioElementIndex = 1;
  }
}
```

```

    }
    else {
        audioElementIndex += 1;
    }
}

```

Tip: To get an idea of the noise this page causes with its background music and sound effects, visit the try-out site at www.prosetech.com/html5.

This example works well, but what if you want to have a much larger range of audio effects? The easiest choice is to create a hidden `<audio>` element for each one. If that's impractical, you can dynamically set the `src` property of an existing `<audio>` element. Or, you can create a new `<audio>` element on the fly, like this:

```

var audio = document.createElement("audio");
audio.src = "newsound.mp3";

```

or use this shortcut:

```

var audio = new Audio("newsound.mp3");

```

However, there are two potential problems with both approaches. First, you need to set the source well before you play the audio. Otherwise, playback will be noticeably delayed, particularly on Internet Explorer. Second, you need to know what the supported audio formats are, so you can set the right file type. This requires using the clunky `canPlayType()` method. You pass in an audio or video MIME type, and `canPlayType()` tells you if the browser can play that format—sort of. It actually returns a blank string if it can't, the word “probably” if it thinks it can, and the word “maybe” if it hopes it might, but just can't make any promises. This rather embarrassing situation exists because supported container formats can use unsupported codecs, and supported codes can still use unsupported encoding settings.

Most developers settle on code like this, which attempts playback if `canPlayType()` gives any answer other than a blank string:

```

if (audio.canPlayType("audio/ogg")) {
    audio.src = "newsound.ogg";
}
else if (audio.canPlayType("audio/mp3")) {
    audio.src = "newsound.mp3";
}

```

Creating a Custom Video Player

One of the most common reasons to delve into JavaScript programming with the `<audio>` and `<video>` elements is to build your own player. The basic idea is pure simplicity—remove the *controls* attribute, so that all you have is a video window, and add your own widgets underneath. Finally, add the JavaScript code that makes these new controls work. Figure 5-7 shows an example.

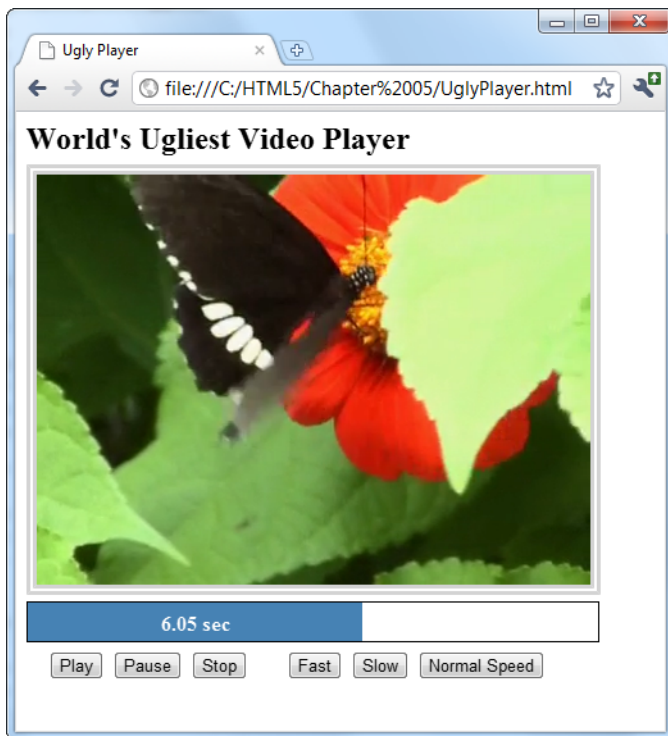

Figure 5-7:

Making a custom HTML5 video player is easy (making it pretty is not). This example includes the standard playback buttons, a playback progress bar, and a few extra buttons that show off what JavaScript can do with the `<video>` element.

Every video player needs a basic complement of playback buttons. Figure 5-7 uses plain-Jane buttons:

```
<button onclick="play()">Play</button>
<button onclick="pause()">Pause</button>
<button onclick="stop()">Stop</button>
```

These buttons trigger the following super-simple functions:

```
function play() {
    video.play();
}

function pause() {
    video.pause();
}

function stop() {
    video.pause();
    video.currentTime = 0;
}
```

The other three playback buttons are more exotic. They adjust the `playbackRate` property to change the speed. For example, a `playbackRate` of 2 plays video at twice the normal speed, but with pitch correction so the audio sounds normal, just accelerated. This is a great feature for getting through a slow training video in a hurry. Similarly, a `playbackRate` of 0.5 plays video at half normal speed, and a `playbackRate` of -1 should play video at normal speed, backward, but browsers have trouble smoothly implementing this behavior.

```
function speedUp() {
    video.play();
    video.playbackRate = 2;
}

function slowDown() {
    video.play();
    video.playbackRate = 0.5;
}

function normalSpeed() {
    video.play();
    video.playbackRate = 1;
}
```

Creating the playback progress bar is a bit more interesting. From a markup point of view, it's built out of two `<div>` elements, one inside the other:

```
<div id="durationBar">
  <div id="positionBar"><span id="displayStatus">Idle.</span></div>
</div>
```

Tip: The playback progress bar is an example where the `<progress>` element (page 135) would make perfect sense. However, the `<progress>` element still has limited support—far less than the HTML5 video feature—so this example builds something that looks similar using two `<div>` elements.

The outer `<div>` element (named `durationBar`) draws the solid black border, which stretches over the entire bar and represents the full duration of the video. The inner `<div>` element (named `positionBar`) indicates the current playback position, by filling in a portion of the black bar in blue. Finally, a `` element inside the inner `<div>` holds the status text, which shows the current position (in seconds) during playback.

Here are the style sheet rules that size and paint the two bars:

```
#durationBar {
    border: solid 1px black;
    width: 100%;
    margin-bottom: 5px;
}

#positionBar {
    height: 30px;
    color: white;
    font-weight: bold;
    background: steelblue;
    text-align: center;
}
```

When video playback is under way, the `<video>` element triggers the `onTimeUpdate` event continuously. You can react to this event to update the playback bar:

```
<video id="videoPlayer" ontimeupdate="progressUpdate()">
  <source src="butterfly.mp4" type="video/mp4">
  <source src="butterfly.ogv" type="video/ogg">
</video>
```

Here, the code gets the current positing in the video (from the `currentTime` property), divides that into the total time (from the `duration` property), and turns that into a percentage that sizes the `positionBar` `<div>` element:

```
function progressUpdate() {
  // Resizing the blue positionBar, from 0 to 100%.
  var positionBar = document.getElementById("positionBar");
  positionBar.style.width = (video.currentTime / video.duration * 100) + "%";

  // Display the number of seconds, using two decimal places.
  displayStatus.innerHTML = (Math.round(video.currentTime*100)/100) + " sec";
}
```

Tip: To get fancier, you could superimpose a download progress bar that shows how much current content has been downloaded and buffered so far. Browsers already add this feature to their built-in players. To add it to your own player, you need to handle the `onProgress` event and work with the `seekable` property. For more information about the many properties, methods, and events provided by the `<video>` element, check out Microsoft's decent reference at <http://msdn.microsoft.com/library/ff975073.aspx>.

JavaScript Media Players

If you're truly independent-minded, you can create your own audio or video player from scratch. But it's not a small project, especially if you want nifty features, like an interactive playlist. And if you don't have a small art department to back you up, there's a distinct possibility that your final product will look just a little bit ugly.

Happily, there's a better option for web authors in search of the perfect HTML5 player. Instead of building one yourself, you can pick up a free, JavaScript-customized media player from the Web. Two solid choices are VideoJS (<http://videojs.com>) and, for jQuery fans, jPlayer (www.jplayer.org). Both of these players are lightweight, easy to use, and *skinnable*, which means you can switch from one style to another by plugging in a different style sheet (Figure 5-8).

Most JavaScript media players (including VideoJS and jPlayer) have built-in Flash fallbacks, which saves you from needing to find a separate Flash player. And jPlayer includes its own handy playlist feature, which lets you queue up a whole list of audio and video files (Figure 5-9).

Figure 5-8:
The VideoJS player includes ready-to-use skins that mimic the look of popular video websites, including YouTube, Vimeo, and Hulu. Here's how the playback controls change.

Figure 5-9:
Using jPlayer's playlist feature, you can offer a series of audio or video files. The user can then play them all in sequence or click to play a specific one. The example playlist here has three videos.

To use VideoJS, you start by downloading the JavaScript files from the VideoJS website. Then, you add the JavaScript reference and style sheet reference shown here:

```
<!DOCTYPE html>
<html>
<head>
  <meta charset="utf-8">
  <title>...</title>

  <script src="video.js"></script>
  <link rel="stylesheet" href="video-js.css">
</head>
...
```

Then, you use the exact same `<video>` element you'd normally use, with the multiple source elements and Flash fallback. (The VideoJS player sample code has the Flowplayer already slotted in for the Flash fallback, but you can remove it and use a different Flash player instead.) In fact, the only difference between a normal HTML5 video page and one that uses VideoJS is the fact that you must use a special `<div>` element to wrap the video player, as shown here:

```
<div class="video-js-box">
  <video class="video-js" width="640" height="264" controls ...>
  ...
</video>
</div>
```

It's nice to see that even when extending HTML5, life can stay pretty simple.

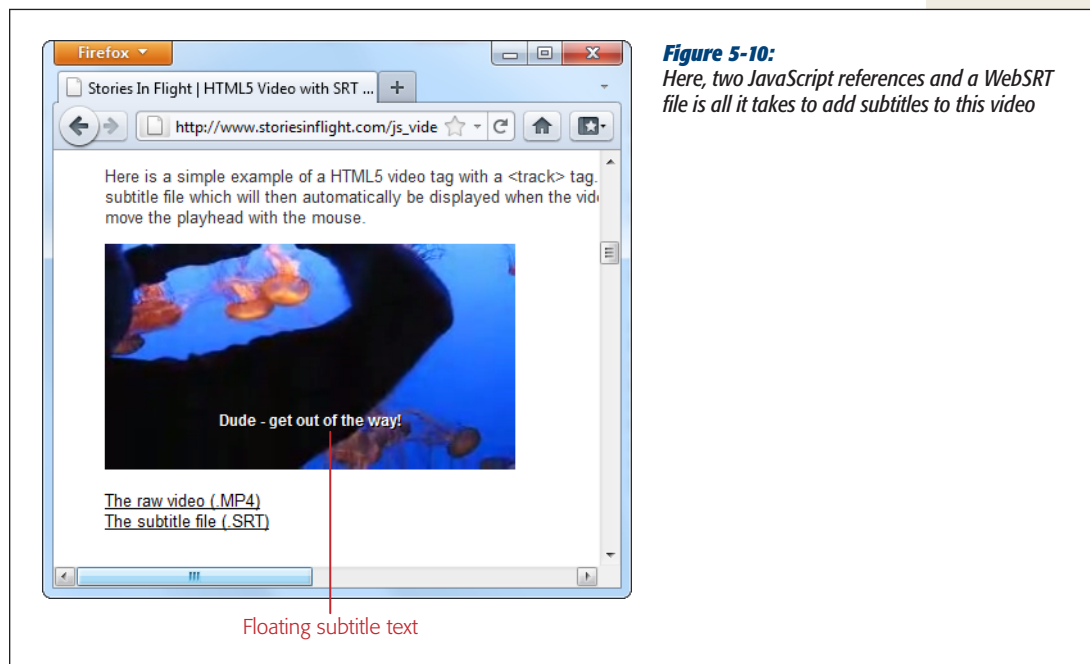

Captions and Accessibility

As you've seen in previous chapters, the creators of HTML5 were often thinking about web accessibility—in other words, how people with disabilities can use rich web pages easily and efficiently.

Adding accessibility information to images is easy enough. You simply need to bolt on some suitably descriptive text with the `alt` attribute. But what's the equivalent to alt text for a video stream? The consensus is to use *subtitles*, text captions that pop up at the right point during playback. Subtitles can be similar to television closed-captioning, by simply transcribing dialogue, or they can be descriptive and supplementary information of their own. The point is that they give people an avenue to follow the video even if they have hearing difficulties (or if they just don't want to switch on their computer speakers to play the *Iron Man 3* movie trailer for the entire office).

Unfortunately, despite the fact that subtitles stand out as the perfect solution, no one has agreed on exactly how to implement them yet. HTML5 has proposed a `<track>` element that will point out a linked subtitle file, perhaps using the WebSRT format, or perhaps using the new and still-evolving WebVTT format. Someday soon, browsers will read this element and provide controls that let users switch subtitles on or off. Search engines will retrieve subtitle files and index their content. But right now, the final details aren't settled, and no official moves have been made.

What developers *have* done is created their own subtitle workarounds with JavaScript. Usually, these involve floating a `` element over a video window and filling it with subtitle text when playback reaches the appropriate points. For example, www.storiesinflight.com/js_videosub has the VideoSub JavaScript library, which extracts text from a WebSRT subtitle file and displays it in a video window (see Figure 5-10). VideoSub checks for browser subtitle support and does its work only if the browser can't. (Currently, this is all the time, because no browser claims to support subtitles.) There's even a complete JavaScript-powered player, called the LeanBack Player, which has subtitle support built in (http://dev.mennerich.name/showroom/html5_video). Unfortunately, it's too soon to tell which is the best way to approach subtitles—the way that will work with the least amount of work on the next generation of web browsers. So if you really need subtitles right now, you need to stick with JavaScript and get ready to revise your pages as HTML evolves.

Basic Drawing with the Canvas

As you learned in Chapter 1, one of HTML5's goals is to make it easier to put *rich applications* inside otherwise ordinary web pages. In this case, the word “rich” doesn't have anything to do with your bank account. Instead, a rich application is one that's decked out with slick graphics, interactive features, and showy frills like animation.

The most important new tool for rich applications is the *canvas*, a drawing surface where you can let your inner Picasso loose. Compared with every other HTML element, the canvas is unique because it *requires* JavaScript. There's no way to draw shapes or paint pictures without it. That means the canvas is essentially a programming tool—one that takes you far beyond the original document-based idea of the Web.

At first, using the canvas can feel like stuffing your page with a crude version of Windows Paint. But dig deeper, and you'll discover that the canvas is the key to a range of graphically advanced applications, including some you've probably already thought about (like games, mapping tools, and dynamic charts) and others that you might not have imagined (like musical lightshows and physics simulators). In the not-so-distant past, these applications were extremely difficult without the help of a browser plug-in like Flash. Today, with the canvas, they're all suddenly possible, provided you're willing to put in a fair bit of work.

In this chapter, you'll learn how to create a canvas and fill it up with lines, curves, and simple shapes. Then you'll put your skills to use by building a simple painting program. And, perhaps most importantly, you'll learn how you can get canvas-equipped pages to work on old browsers that don't support HTML5 (page 196).

Note: For some developers, the canvas will be indispensable. For others, it will just be an interesting diversion. (And for some, it may be interesting but still way too much work compared with a mature programming platform like Flash.) But one thing is certain: This straightforward drawing surface is destined to be much more than a toy for bored programmers.

Getting Started with the Canvas

The `<canvas>` element is the place where all your drawing takes place. From a mark-up point of view, it's as simple as can be. You supply three attributes: `id`, `width`, and `height`:

```
<canvas id="drawingCanvas" width="500" height="300"></canvas>
```

The `id` attribute gives the canvas a unique name, which you'll need when your script code goes searching for it. The `width` and `height` attributes set the size of your canvas, in pixels.

Note: You should always set the size of your canvas through the `width` and `height` attributes, not the `width` and `height` style sheet properties. To learn about the possible problem that can occur if you use style sheet sizing, see the box on page 201.

Ordinarily, the canvas shows up as a blank, borderless rectangle (which is to say it doesn't show up at all). To make it stand out on the page, you can apply a background color or a border with a style sheet rule like this:

```
canvas {  
  border: 1px dashed black;  
}
```

Figure 6-1 shows this starting point.

To work with a canvas, you need to fire off a bit of JavaScript that takes two steps. First, your script must use the `document.getElementById()` method to grab hold of the canvas object:

```
var canvas = document.getElementById("drawingCanvas");
```

This is no surprise, as you use the `getElementById()` method anytime you need to find an element on the current page.

Note: If you aren't familiar with JavaScript, you won't get far with the canvas. To brush up with the absolute bare-minimum essentials, read Appendix B. Or, if you need to hone your programming skills and take time to get more comfortable with the JavaScript language, check out *JavaScript & jQuery: The Missing Manual*.

Next, your code must use the canvas object's `getContext()` method to retrieve a two-dimensional *drawing context*:

```
var context = canvas.getContext("2d");
```

**Figure 6-1:**

Every canvas begins as an empty rectangle somewhere on a web page. To put even a single line inside, you need to write some JavaScript code.

You can think of the context as a supercharged drawing tool that handles all your canvas tasks, like painting rectangles, writing text, pasting an image, and so on. It's a sort of one-stop shop for canvas drawing operations.

Note: The fact that the context is explicitly called *two-dimensional* (and referred to as “2d” in the code) raises an obvious question—namely, is there a three-dimensional drawing context? The answer is not yet, but the creators of HTML5 have clearly left space for one in the future.

You can grab the context object and start drawing at any point: for example, when the page first loads, when the visitor clicks a button, and so on. When you're just starting out with the canvas, you probably want to create a practice page that gets to work straightaway. Here's a template for a page that does just that:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Canvas Test</title>

  <style>
  canvas {
    border: 1px dashed black;
  }
  </style>

  <script>
```

```
window.onload = function() {  
    var canvas = document.getElementById("drawingCanvas");  
    var context = canvas.getContext("2d");  
  
    // (Put your fabulous drawing code here.)  
};  
</script>  
</head>  
  
<body>  
    <canvas id="drawingCanvas" width="500" height="300"></canvas>  
</body>  
</html>
```

The `<style>` section of this page makes the canvas stand out with a border. The `<script>` section handles the `window.onload` event, which occurs once the browser has completely loaded the page. The code then gets the canvas, creates a drawing context, and gets ready to draw. You can use this example as the starting point for your own canvas experiments.

Note: Of course, when you're using the canvas in a real page on your website, you'll want to declutter a bit by snipping out the JavaScript code and putting it in an external script file (page 401). But for now, this template gives you single-page convenience. If you want to type the examples in on your own, you can get this markup from the `CanvasTemplate.html` file on the try-out site (www.prosetech.com/html5).

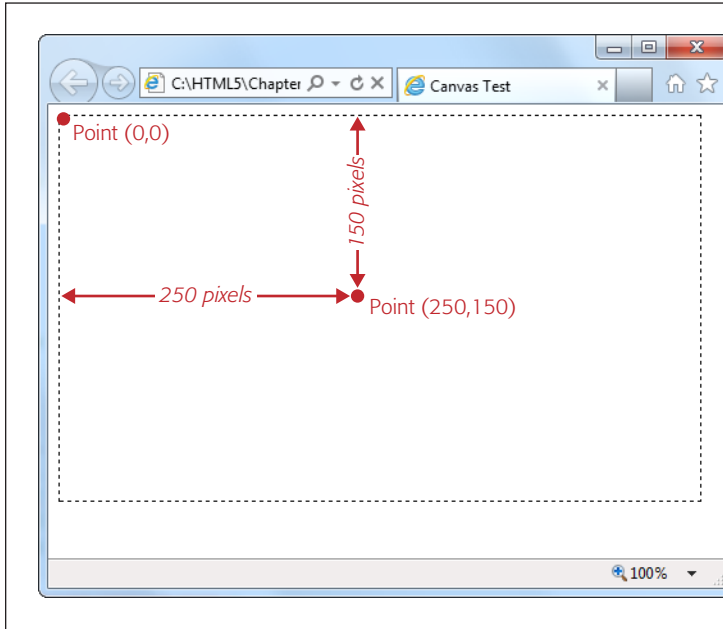

Straight Lines

Now you're just about ready to start drawing. But before you add anything on a canvas, you need to understand its coordinate system. Figure 6-2 shows you how it works.

The simplest thing you can draw on a canvas is a solid line. Doing that takes three actions with the drawing context. First, you use the `moveTo()` method to move to the point where you want the line to start. Second, you use the `lineTo()` method to travel from the current point to the end of the line. Third, you call the `stroke()` method to make the line actually appear:

```
context.moveTo(10,10);  
context.lineTo(400,40);  
context.stroke();
```

Or think of it this way: First you lift up your pen and put it where you want (using `moveTo`), then you drag the pen across the canvas (using `lineTo`), then you make the line appear (using `stroke`). This result is a thin (1-pixel) black line from point (10,10) to point (400,40).

**Figure 6-2:**

As with every other HTML element, the canvas designates its top-left corner as the point (0,0). As you move right, the x-value increases, and as you move down, the y-value increases. If a canvas is 500 × 300 pixels, the bottom-right corner is point (500, 300).

Happily, you can get a little fancier with your lines. At any point before you call the `stroke()` method that winks your line into existence, you can set three drawing context properties: `lineWidth`, `strokeStyle`, and `lineCap`. These properties affect everything you draw, until you change them.

You use `lineWidth` to set the width of your lines, in pixels. Here's a thick, 10-pixel line:

```
context.lineWidth = 10;
```

You use `strokeStyle` to set the color of your lines. You can use an HTML color name, an HTML color code, or the `rgb()` function from CSS, which lets you assemble a color out of red, green, and blue components. (This is useful because most drawing and painting programs use the same system.) No matter which approach you use, you need to wrap the whole value in quotation marks, as shown here:

```
// Set the color (brick red) using an HTML color code:
context.strokeStyle = "#cd2828";
```

```
// Set the color (brick red) using the rgb() function:
context.strokeStyle = "rgb(205,40,40)";
```

Note: This property is named `strokeStyle` rather than `strokeColor` because you aren't limited to plain colors. As you'll see later on, you can use color blends called gradients (page 208) and image-based patterns (page 207).

Finally, use *lineCap* to decide how you want to cap off the ends of your lines. The default is to make a squared-off edge with *butt*, but you can also use *round* (to round off the edge) or *square* (which looks the same as butt, but extends the line an amount equal to half its thickness on each end).

And here's the complete script code you need to draw three horizontal lines, with different line caps (Figure 6-3). To try this code out, pop it into any JavaScript function you want. To make it run right away, put it in the function that handles the `window.onload` event, as shown on page 174:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Set the line width and color (for all the lines).
context.lineWidth = 20;
context.strokeStyle = "rgb(205,40,40)";

// Draw the first line, with the standard butt ending.
context.moveTo(10,50);
context.lineTo(400,50);
context.lineCap = "butt";
context.stroke();

// Draw the second line, with a round cap.
context.beginPath();
context.moveTo(10,120);
context.lineTo(400,120);
context.lineCap = "round";
context.stroke();

// Draw the third line, with a square cap.
context.beginPath();
context.moveTo(10,190);
context.lineTo(400,190);
context.lineCap = "square";
context.stroke();
```

This example introduces one new feature: the `beginPath()` method of the drawing context. When you call `beginPath()`, you start a new, separate segment of your drawing. Without this step, every time you call `stroke()`, the canvas will attempt to draw everything over again. (This is a particular problem if you're changing other context properties. In this case, you'd end up drawing over your existing content with the same shapes but a new color, thickness, or line cap.)

Note: While you do need to begin new segments by calling `beginPath()`, you don't need to do anything special to end a segment. Instead, the current segment is automatically considered "finished" the moment you create a new segment.

**Figure 6-3:**

The top line uses the standard butt ending, while the lines below have added caps (round or square), which extend the line by an amount equal to half the line's thickness.

Paths and Shapes

In the previous example, you separated different lines by starting a new path for each one. This method lets you give each line a different color (and a different width and cap style). Paths are also important because they allow you to fill custom shapes. For example, imagine you create a red-outlined triangle using this code:

```
context.moveTo(250,50);
context.lineTo(50,250);
context.lineTo(450,250);
context.lineTo(250,50);

context.lineWidth = 10;
context.strokeStyle = "red";
context.stroke();
```

But if you want to *fill* that triangle, the `stroke()` method won't help you. Instead, you need to close the path by calling `closePath()`, pick a fill color by setting the `fillStyle` property, and then call the `fill()` method to make it happen:

```
context.closePath();
context.fillStyle = "blue";
context.fill();
```

It's worth tweaking a couple of things in this example. First, when closing a path, you don't need to draw the final line segment, because calling `closePath()` automatically draws a line between the last drawn point and the starting point. Second, it's best to fill your shape first, and *then* draw its outline. Otherwise, your outline may be partially overwritten by the fill.

Here's the complete triangle-drawing code:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

context.moveTo(250,50);
context.lineTo(50,250);
context.lineTo(450,250);
context.closePath();

// Paint the inside.
context.fillStyle = "blue";
context.fill();

// Draw the outline.
context.lineWidth = 10;
context.strokeStyle = "red";
context.stroke();
```

Notice that you don't need to use `beginPath()` in this example, because the canvas starts you off with a new path automatically. You need to call `beginPath()` only when you need a *new* path—for example, when changing line settings or drawing a new shape. Figure 6-4 shows the result.

Note: When drawing connecting line segments (like the three sides of this triangle), you can set the drawing context's *lineJoin* property to round or bevel the edges (by using the values *round* or *bevel*—the default is *mitre*).

Most of the time, when you want a complex shape, you'll need to assemble a path for it, one line at a time. But there's one shape that's important enough to get special treatment: the rectangle. You can fill a rectangular region in one step using the `fillRect()` method. You supply the coordinate for the top-left corner, the width, and the height.

For example, to place a 100 × 200 pixel rectangle starting at point (0,10), use this code:

```
fillRect(0,10,100,200);
```

The `fillRect()` method gets the color to use from the `fillStyle` property, just like the `fill()` method.

Similarly, you can use `strokeRect()` to draw the outline of a rectangle in one step:

```
strokeRect(0,10,100,200);
```

The `strokeRect()` method uses the current `lineWidth` and `strokeStyle` properties to determine the thickness and color of the outline, just as the `stroke()` method does.

**Figure 6-4:**

To create a closed shape like this triangle, use `moveTo()` to get to the starting point, `lineTo()` to draw each line segment, and `closePath()` to complete the shape. You can then fill it with `fill()` and outline it with `stroke()`.

Curved Lines

If you want something more impressive than lines and rectangles (and who doesn't?), you'll need to understand four methods that can really throw you for a curve: `arc()`, `arcTo()`, `bezierCurveTo()`, and `quadraticCurveTo()`. All of these methods draw curved lines in different ways, and they all require at least a smattering of math (and some need a whole lot more).

The `arc()` method is the simplest of the bunch. It draws a portion of a circle's outline. To draw an arc, you first need to visualize an imaginary circle, and then decide which part of the edge you need (see Figure 6-5). You'll then have all the data you need to pass to the `arc()` method.

Once you've sorted out all the details you need, you can call the `arc()` method:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Create variables to store each detail about the arc.
var centerX = 150;
var centerY = 300;
var radius = 100;
var startingAngle = 1.25 * Math.PI;
var endingAngle = 1.75 * Math.PI;

// Use this information to draw the arc.
context.arc(centerX, centerY, radius, startingAngle, endingAngle);
context.stroke();
```

**Figure 6-5:**

An arc seems simple enough, but you need several pieces of information to describe it completely. First, you need to pin down the imaginary circle. That requires the coordinates of the center point (#1) and the radius that indicates how big the circle is (#2). Next, you need to describe the length of the arc, which requires the angle where the arc starts (#3) and the angle where it ends (#4). You must supply angles in radian coordinates, which are expressed as fractions of the constant pi. (So 1 pi is halfway around the circle, and 2 pi is all the way around, as indicated here.)

Or, call `closePath()` before you call `stroke()` to add a straight line between the two ends of the arc. This creates a closed semi-circle.

Incidentally, a circle is simply an arc that stretches all the way around the circle. You can draw it like this:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

var centerX = 150;
var centerY = 300;
var radius = 100;
var startingAngle = 0;
var endingAngle = 2 * Math.PI;

context.arc(centerX, centerY, radius, startingAngle, endingAngle);
context.stroke();
```

Note: The `arc()` method doesn't let you draw an ellipse (a flattened circle). To get that, you need to do more work—either use some of the more sophisticated curve methods described next, or use a transform (page 182) to stretch out an ordinary circle as you draw it.

The three other curve methods—`arcTo()`, `bezierCurveTo()`, and `quadraticCurveTo()`—are a bit more intimidating to the geometrically challenged. They involve a concept called *control points*—points that aren't included in the curve, but influence the way it's drawn. The most famous example is the Bézier curve, which is used in virtually every computer illustration program ever created. It's popular because it creates a curve that looks smooth no matter how small or big you draw it. Figure 6-6 shows how control points shape a Bézier curve.

Figure 6-6:

A Bézier curve has two control points. The start of the curve runs parallel to the first control point. The end of the curve runs parallel to the second control point. In between, the line curves. The amount of curvature is influenced by the distance to the control point—the farther away the point is, the stronger its “pull.” It’s sort of like gravity, but in reverse.

And here's the code that creates the curve from Figure 6-6:

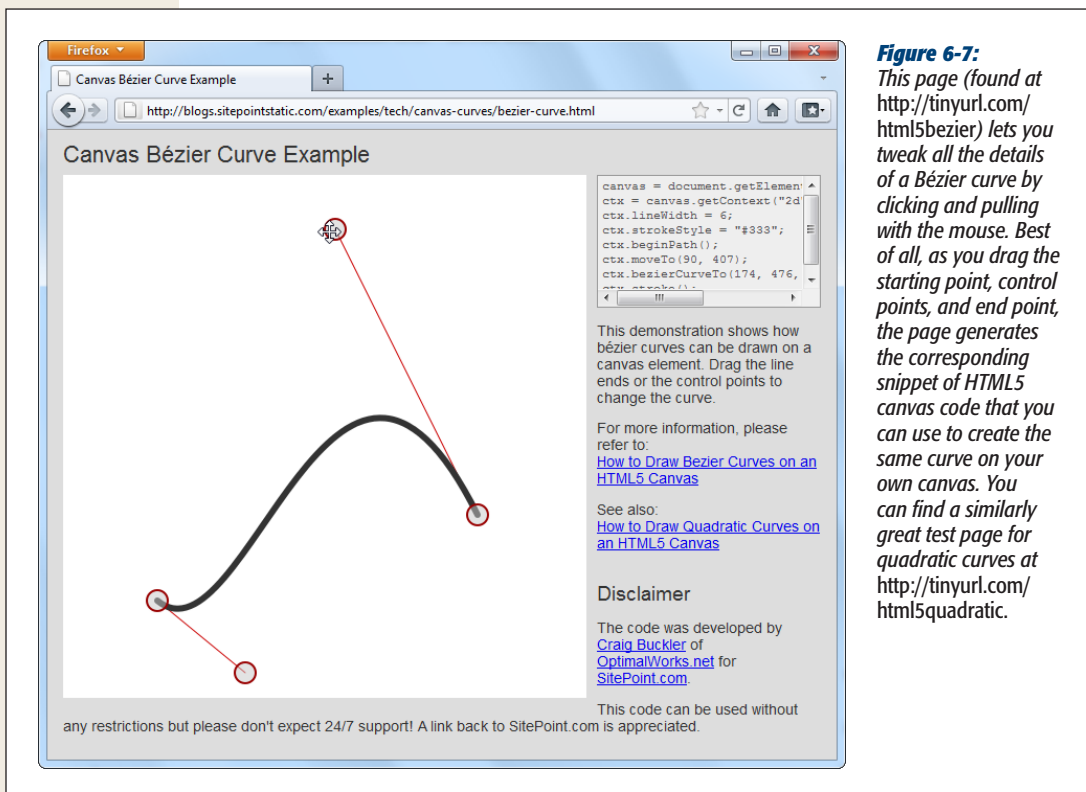

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Put the pen where the curve starts.
context.moveTo(62, 242);

// Create variables for the two control points and the end point of the curve.
var control1_x = 187;
var control1_y = 32;
var control2_x = 429;
var control2_y = 480;
var endPointX = 365;
var endPointY = 133;

// Draw the curve.
context.bezierCurveTo(control1_x, control1_y, control2_x, control2_y,
    endPointX, endPointY);
context.stroke();
```

The outline of a complex, organic shape often involves a series of arcs and curves glued together. Once you're finished, you can call `closePath()` to fill or outline the entire shape. The best way to learn about curves is to play with one on your own. You can find a perfect test page at <http://tinyurl.com/html5bezier> (Figure 6-7).

Transforms

A transform is a drawing technique that lets you shift the canvas's coordinate system. For example, imagine you want to draw the same square in three places. You could call `fillRect()` three times, with three different points:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Draw a 30x30 square, at three places.
context.rect(0, 0, 30, 30);
context.rect(50, 50, 30, 30);
context.rect(100, 100, 30, 30);

context.stroke();
```

FREQUENTLY ASKED QUESTIONS

Canvas Drawing for Math-Phobes

How do I get all the shapes with none of the headaches?

If you're hoping to use the canvas to create eye-catching graphics, but you don't want to pick up a degree in geometry, you might be a bit frustrated. Fortunately, there are several approaches that can help you draw what you want without worrying about the mathematical underpinnings:

- **Use a drawing library.** Why draw everything the hard way when you can use someone else's drawing library to draw circles, triangles, ellipses, and polygons in a single step? The idea is simple—you call a higher-level method (say, `fillEllipse()`, with the appropriate coordinates), and the JavaScript library translates that to the correct canvas operations. Two good examples are CanvasPlus (<http://code.google.com/p/canvasplus>) and Artisan JS (<http://artisanjs.com>). However, these libraries (and more) are still evolving rapidly. It's too soon to say which ones will have real staying power, and which ones are worth adopting for professional work.
- **Draw bitmap images.** Instead of painstakingly drawing each shape you need, you can copy ready-made graphics to your canvas. For example, if you have an image of a circle with a file name *circle.png*, you can insert that into your canvas using the code on page 200. However, this technique won't give you the same flexibility to manipulate your image (for example, to stretch it, rearrange it, remove part of it, and so on).
- **Use an export tool.** If you have a complex graphic and you need to manipulate it on the canvas or make it interactive, drawing a fixed bitmap isn't good enough. But a conversion tool that can examine your graphic and generate the right canvas-creation code just might solve your problem. One intriguing example is the Ai->Canvas plug-in for Adobe Illustrator (<http://visitmix.com/labs/ai2canvas>), which converts Adobe Illustrator artwork to an HTML page with JavaScript code that painstakingly recreates the picture on a canvas.

Or you could call `fillRect()` three times, with the *same* point, but shift the coordinate system each time so the square actually ends up in three different spots, like so:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Draw a square at (0,0).
context.rect(0, 0, 30, 30);

// Shift the coordinate system down 50 pixels and right 50 pixels.
context.translate(50, 50);
context.rect(0, 0, 30, 30);

// Shift the coordinate system down a bit more. Transforms are cumulative,
// so now the (0,0) point will actually be at (100,100).
context.translate(50, 50);
context.rect(0, 0, 30, 30);

context.stroke();
```

Both versions of this code have the same effect: They draw three squares, in the same three spots.

At first glance, transform may just seem like a way to make a somewhat complicated drawing task even more complicated. But transforms can work magic in some tricky situations. For example, suppose you have a function that draws a series of complex shapes that, put together, create a picture of a bird. Now, say you want to animate that bird, so it appears to fly around the canvas. (You'll see a basic example of animation on the canvas on page 222.)

Without transforms, you'd need to adjust every coordinate in your drawing code each time you drew the bird. But with transforms, you can leave your drawing code untouched and simply tweak the coordinate system over and over again.

Transforms come in several different flavors. In the previous example, a *translate* transform was used to move the center point of the coordinate system—that's the (0,0) point that's usually placed in the top-left corner of the canvas. Along with the translate transform, there's also a *scale* transform (which lets you draw things bigger or smaller), a *rotate* transform (which lets you turn the coordinate system around), and a *matrix* transform (which lets you stretch and warp the coordinate system in virtually any way—provided you understand the complex matrix math that underpins the visual effect you want).

Transforms are cumulative. The following example moves the (0,0) point to (100,100) with a translate transform and then rotates the coordinate system around that point several times. Each time, it draws a new square, creating the pattern shown in Figure 6-8:

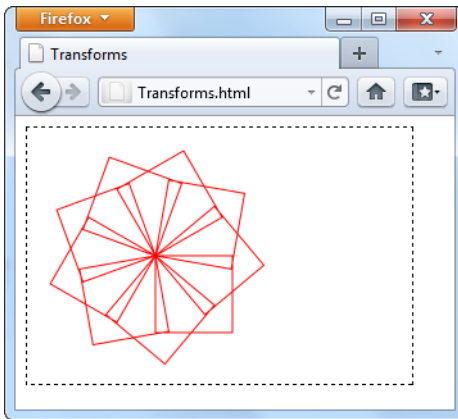

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Move the (0,0) point. This is important, because
// the rotate transform turns around this point.
context.translate(100, 100);

// Draw 10 squares.
var copies = 10;
for (var i=1; i<copies; i++) {
    // Before drawing the square, rotate the coordinate system.
    // A complete rotation is 2*Math.PI. This code does a fraction of this
    // for each square, so that it has rotated around completely by the time
    // it's drawn the last one.
    context.rotate(2 * Math.PI * 1/(copies-1));

    // Draw the square.
    context.rect(0, 0, 60, 60);
}
context.stroke();
```

Tip: You can use the drawing context's `save()` method to save the current state of the coordinate system. Later on, you can use the `restore()` method to return to your previous saved state. You might want to call `save()` before you've applied any transforms, so you can call `restore()` to get the coordinate system back to normal. And in long, complex drawing tasks, you might save the state many times. This list of saved states acts like the web page history in a browser. Each time you call `restore()`, the coordinate system reverts to the immediately preceding state.

**Figure 6-8:**

By drawing a series of rotated squares, you can create spirograph-like patterns.

Transforms are somewhat beyond the scope of this chapter. If you want to explore them in more detail, Mozilla (the company that created Firefox) has some helpful documentation and examples at <http://tinyurl.com/b742o4>.

Transparency

So far, you've been dealing with solid colors. However, the canvas also lets you use partial transparency to layer one shape over another. There are two ways to use transparency with the canvas. The first approach is to set a color (through the `fillStyle` or `strokeStyle` properties) with the `rgba()` function, instead of the more common `rgb()` function. The `rgba()` function takes four arguments—the numbers for the red, green, and blue color components (from 0 to 255), and an additional number for the alpha value (from 0 to 1), which sets the color's opacity. An alpha value of 1 is completely solid, while an alpha value of 0 is completely invisible. Set a value in between—for example, 0.5—and you get a partially transparent color that any content underneath shows through.

Note: What content is underneath and what content is on top depends solely on the order of your drawing operations. For example, if you draw a circle first, and then a square at the same location, the square will be superimposed on top of the circle.

Here's an example that draws a circle and a triangle. The both use the same fill color, except the triangle sets the alpha value to 0.5, making it 50 percent opaque:

```
var canvas = document.getElementById("drawingCanvas");
var context = canvas.getContext("2d");

// Set the fill and outline colors.
```

```

context.fillStyle = "rgb(100,150,185)";
context.lineWidth = 10;
context.strokeStyle = "red";

// Draw a circle.
context.arc(110, 120, 100, 0, 2*Math.PI);
context.fill();
context.stroke();

// Remember to call beginPath() before adding a new shape.
// Otherwise, the outlines of both shapes will
// be merged together in an unpredictable way.
context.beginPath();

// Give the triangle a transparent fill.
context.fillStyle = "rgba(100,150,185,0.5)";

// Now draw the triangle.
context.moveTo(215,50);
context.lineTo(15,250);
context.lineTo(315,250);
context.closePath();
context.fill();
context.stroke();

```

Figure 6-9 shows the result.

Figure 6-9:

Left: Two solid shapes, one on top of the other.

Right: One solid shape, with a semitransparent shape on top. Semitransparent shapes look lighter (because they let the white background through), and they allow you to see whatever content you've drawn underneath. Notice that in this example, the semitransparent shape uses a fully opaque color for its border.

The other way to use transparency is to set the drawing context's `globalAlpha` property, like this:

```

context.globalAlpha = 0.5;

// Now this color automatically gets an alpha value of 0.5:
context.fillStyle = "rgb(100,150,185)";

```

Do that, and everything you draw from that point on (until you change `globalAlpha` again) will use the same alpha value and get the same degree of transparency. This includes both stroke colors and fill colors.

So which approach is better? If you need just a single transparent color, use `rgba()`. If you need to paint a variety of shapes with different colors, and they all need the same level of transparency, use `globalAlpha`. The `globalAlpha` property is also useful if you want to paint semitransparent images on your canvas, as you'll learn to do on page 200.

POWER USERS' CLINIC

Composite Operations

So far, this chapter has assumed that when you put one shape on top of another, the second shape paints over the first, obscuring it. The canvas works this way most of the time. However, the canvas also has the ability to use more complex *composite operations*.

A composite operation is a rule that tells the canvas how to display two images that overlap. The default composite operation is *source-over*, which tells the canvas that the second shape should be painted over the top of the first. But other options are possible, like *xor*, which tells the canvas to show nothing at all in the area where the shapes overlap. Figure 6-10 shows an overview of the different composite operations.

To change the current composite operation that the canvas uses, simply set the drawing context's `globalCompositeOperation` property, like this:

```
context.globalCompositeOperation = "xor";
```

Used cleverly, a composite operation can provide shortcuts for certain drawing tasks. Unfortunately, different browsers don't yet agree on how to display them. As a result, some composite operations show different results on different browsers. For a description of the problem and a comparison of the differences, see the blog post at <http://tinyurl.com/68b2nmz>.

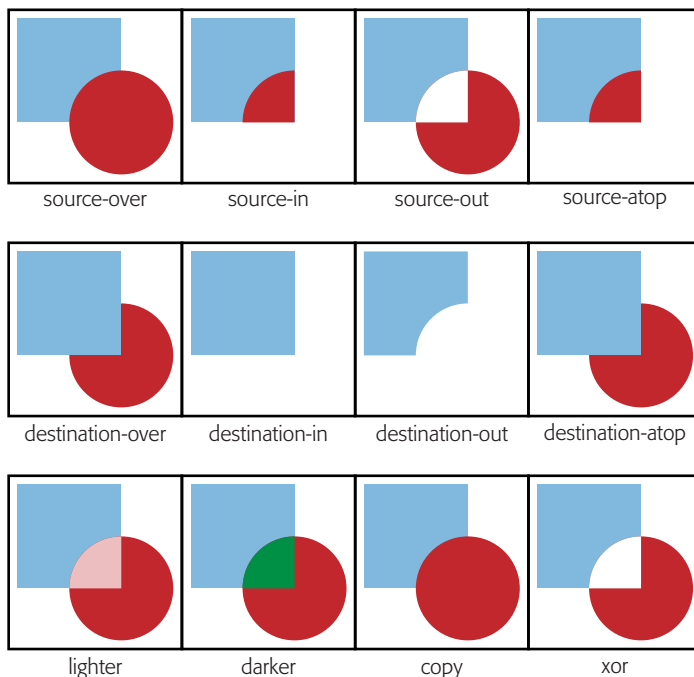

Figure 6-10:

Here are 12 possible composite operations and their effects, in the eyes of Firefox. Internet Explorer 9 and Opera treat the copy operation differently, while Chrome and Safari differ on the source-in, source-out, destination-in, and destination-atop operations.

Building a Basic Paint Program

The canvas still has a fair bit more in store for you. But you've covered enough ground to build your first practical canvas-powered program. It's the simple painting program shown in Figure 6-11.

The JavaScript that makes this example work is longer than the examples you've seen so far, but still surprisingly straightforward. You'll consider it piece by piece, in the following sections.

Tip: If you're curious about the style sheet rules that create the blue toolbars above and below the canvas, you want to see the whole example in one piece, or you just want to paint something in your browser, then you can use the Paint.html file on the try-out site (www.prosetech.com/html5).

Figure 6-11:

To express yourself with this paint program, just pick a pen color, pick a pen thickness, and scribble away with the mouse.

Preparing to Draw

First, when the page loads, the code grabs the canvas object and attaches functions that will handle several JavaScript events for different mouse actions: `onMouseDown`, `onMouseUp`, `onMouseOut`, and `onMouseMove`. (As you'll see, these events control the drawing process.) At the same time, the page also stores the canvas in a handy global variable (named `canvas`), and the drawing context in another global variable (named `context`). This way, these objects will be easily available to the rest of the code:

```
var canvas;
var context;

window.onload = function() {
  // Get the canvas and the drawing context.
  canvas = document.getElementById("drawingCanvas");
  context = canvas.getContext("2d");

  // Attach the events that you need for drawing.
  canvas.onmousedown = startDrawing;
  canvas.onmouseup = stopDrawing;
  canvas.onmouseout = stopDrawing;
  canvas.onmousemove = draw;
};
```

To get started with the paint program, the person using the page chooses the pen color and pen thickness from the two toolbars at the top of the window. These toolbars are simple `<div>` elements styled to look like nice steel-blue boxes, with a handful of clickable `` elements in them. For example, here's the toolbar with the three color choices:

```
<div class="Toolbar">
  - Pen Color -<br>
  
  
  
</div>
```

The important part of this markup is the `` element's `onclick` attribute. Whenever the web page visitor clicks a picture, the `` element calls the `changeColor()` function. The `changeColor()` function accepts two pieces of information—the new color, which is set to match the icon, and a reference to the `` element that was clicked. Here's the code:

```
// Keep track of the previous clicked <img> element for color.
var previousColorElement;

function changeColor(color, imgElement) {
  // Change the current drawing color.
  context.strokeStyle = color;
```

```
// Give the newly clicked <img> element a new style.
imgElement.className = "Selected";

// Return the previously clicked <img> element to its normal state.
if (previousColorElement != null) previousColorElement.className = "";
previousColorElement = imgElement;
}
```

The `changeColor()` code takes care of two basic tasks. First, it sets the drawing context's `strokeStyle` property to match the new color. This takes a single line of code. Second, it changes the style of the clicked `` element, giving it a solid border, so that it's clear which color is currently active. This requires a bit more work, because the code needs to keep track of the previously selected color, so it can remove the solid border around that `` element.

The `changeThickness()` function performs an almost identical task, only it alters the `lineWidth` property to have the appropriate thickness:

```
// Keep track of the previously clicked <img> element for thickness.
var previousThicknessElement;

function changeThickness(thickness, imgElement) {
  // Change the current drawing thickness.
  context.lineWidth = thickness;

  // Give the newly clicked <img> element a new style.
  imgElement.className = "Selected";

  // Return the previously clicked <img> element to its normal state.
  if (previousThicknessElement != null) {
    previousThicknessElement.className = "";
  }
  previousThicknessElement = imgElement;
}
```

This code gets all the drawing setup out of the way, but this example still isn't ready to run. The next (and final) step is to add the code that performs the actual drawing.

Drawing on the Canvas

Drawing begins when the user clicks down on the canvas with the mouse button. The paint program uses a global variable named *isDrawing* to keep track of when drawing is taking place, so the rest of the code knows whether it should be writing on the drawing context.

As you saw earlier, the `onMouseDown` event is linked to the `startDrawing()` function. It sets the `isDrawing` variable, creates a new path, and then moves to the starting position to get ready to draw something:

```
var isDrawing = false;

function startDrawing(e) {
  // Start drawing.
  isDrawing = true;
```

```
// Create a new path (with the current stroke color and stroke thickness).
context.beginPath();

// Put the pen down where the mouse is positioned.
context.moveTo(e.pageX - canvas.offsetLeft, e.pageY - canvas.offsetTop);
}
```

In order for the paint program to work properly, it needs to start drawing at the current position—that’s where the mouse is hovering when the user clicks down. However, getting the right coordinates for this point is a bit tricky.

The `onMouseDown` event provides coordinates (through the `pageX` and the `pageY` properties shown in this example), but these coordinates are relative to the whole page. To calculate the corresponding coordinate on the canvas, you need to subtract the distance between the top-left corner of the browser window and the top-left corner of the canvas.

The actual drawing happens while the user is moving the mouse. Every time the user moves the mouse, even just a single pixel, the `onMouseMove` event fires and the code in the `draw()` function runs. If `isDrawing` is set to `true`, then the code calculates the current canvas coordinate—where the mouse is *right now*—and then calls `lineTo()` to add a tiny line segment to the new position and `stroke()` to draw it:

```
function draw(e) {
  if (isDrawing == true) {
    // Find the new position of the mouse.
    var x = e.pageX - canvas.offsetLeft;
    var y = e.pageY - canvas.offsetTop;

    // Draw a line to the new position.
    context.lineTo(x, y);
    context.stroke();
  }
}
```

If the user keeps moving the mouse, the `draw()` function keeps getting called, and another short piece of line keeps getting added. This line is so short—probably just a pixel or two—that it doesn’t even look like a straight line when you start scribbling.

Finally, when the user releases the mouse button, or moves the cursor off to the side, away from the canvas, the `onMouseUp` or `onMouseOut` events fire. Both of these trigger the `stopDrawing()` function, which tells the application to stop drawing:

```
function stopDrawing() {
  isDrawing = false;
}
```

So far, this code covers almost all there is to the simple paint program. The only missing details are the two buttons under the canvas, which offer to clear or save the current work. Click clear, and the `clearCanvas()` function blanks out the entire surface, using the drawing context’s `clearRect()` method:

```
function clearCanvas() {
  context.clearRect(0, 0, canvas.width, canvas.height);
}
```

The save option is slightly more interesting, and you’ll consider it next.

Saving the Picture in the Canvas

When it comes to saving the picture in a canvas, there are countless options. First, you need to decide how you're going to get the data. The canvas gives you three basic options:

- **Use a data URL.** This converts the canvas to an image file, and then converts that image data to a sequence of characters, formatted as a URL. This gives you a nice, portable way to pass the image data around (for example, you can hand it to an `` element or send it off to the web server). The paint program uses this approach.
- **Use the `getImageData()` method.** This grabs the raw pixel data, which you can then manipulate as you please. You'll learn to use `getImageData()` on page 234.
- **Store a list of "steps."** For example, you can store an array that lists every line you drew on the canvas. Then, you can save that data, and use it to recreate the image later. This approach takes less storage space, and it gives you more flexibility to work with or edit the image later on. Unfortunately, it works only if you keep track of all the steps you're taking, using a technique like the one you'll see in the circle-drawing example (page 217).

If that seems a bit intimidating, well, you're not done quite yet. Once you decide what you want to save, you still need to decide *where* to save it. Here are some options for that:

- **In an image file.** For example, you can let the web surfer save a PNG or JPEG on the computer. That's the approach you'll see next.
- **In the local storage system.** You'll learn how that works in Chapter 9.
- **On the web server.** Once you transfer the data, the web server could store it in a file or a database, and make it available the next time the web page user visits.

To make the save feature work in the paint program, the code uses a feature called data URLs. Getting a URL for the current data, you simply use the canvas's `toDataURL()` method:

```
var url = canvas.toDataURL();
```

When you call `toDataURL()` without supplying any arguments, you get a PNG-formatted picture. Alternatively, you can supply an image type to request that format instead:

```
var url = canvas.toDataURL("image/jpeg");
```

But if the browser is unable to honor your format request, it will still send you a PNG file, converted to a long string of letters.

At this point, you're probably wondering what a data URL looks like. Technically, it's a long string of base-64 encoded characters that starts with the text `data:image/png;base64`. It looks like gobbledygook, but that's OK, because it's supposed to be readable by computer programs (like browsers). Here's a data URL for the current canvas picture:

```
data:image/png;base64,iVBORw0KGgoAAAANSUhEUgAAAFQAAAEsCAYAAAA1u0HIAAAAXNSR
oIArs4c6QAAAAARnQU1BAACxjwv8YQUAACqRSURBVHhe7Z1bkB1Hecdn5uxFFzA2FW0nsEEGiiew
nZgKsrWlrZXMRU9JgZQKhoSHVK...gAAEIQAACEIBAiAT+HxAYpeqDfKieAAAAAE1FTkSuQmCC
```

This example leaves out a huge amount of the content in the middle (where the ellipsis is) to save space. If it was all left in, this data URL would fill five typed pages in this book.

Note: Base-64 encoding is a system that converts image data to a long string of characters, numbers, and a small set of special characters. It avoids punctuation and all the bizarre extended characters, so the resulting text is safe to stick in a web page (for example, to set the *value* of a hidden input field or the *src* attribute in an `` element).

So, it's easy to convert a canvas to image data in the form of a data URL. But once you have that data URL, what can you do with it? One option is to send it to the web server for long-term storage. You can see an example of a web page that does that, using a sprinkling of PHP script on the server, at <http://tinyurl.com/5uud9ob>.

If you want to keep your data on the client, your options are a bit more limited. Some browsers will let you navigate directly to a data URL. That means you can use code like the following to navigate to the image:

```
window.location = canvas.toDataURL();
```

A more reliable technique is to hand the data URL over to an `` element. Here's what the paint program does (Figure 6-12):

```
function saveCanvas() {
    // Find the <img> element.
    var imageCopy = document.getElementById("savedImageCopy");

    // Show the canvas data in the image.
    imageCopy.src = canvas.toDataURL();

    // Unhide the <div> that holds the <img>, so the picture is now visible.
    var imageContainer = document.getElementById("savedCopyContainer");
    imageContainer.style.display = "block";
}
```

This code doesn't exactly "save" the image data, because the image hasn't yet been stored permanently, in a file. However, it takes just one more step to save the data once it's in an image. The web page visitor simply needs to right-click the image and choose the Save command. This isn't quite as convenient as a file download or the Save dialog box, but it's the only client-side option that works reliably in all browsers.

Note: Firefox has the built-in ability to save canvas content. Just right-click any canvas (not the image copy) and choose Save Image As. Other browsers, like Chrome and Internet Explorer, don't offer this option.

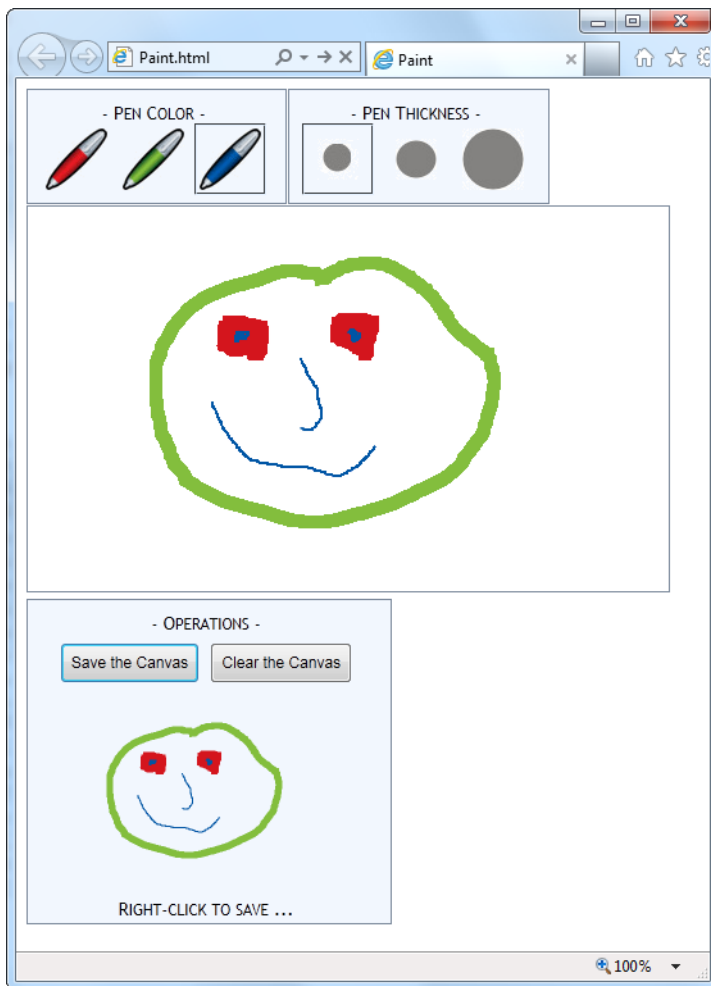

Figure 6-12:

Here, the data URL is used to transmit information to an `` element. The `` element has been given a smaller size, to distinguish it from the main canvas. If you want to save this image as a respectable .png file, simply right-click the image and choose “Save picture as,” just as you would with any other picture in a web page.

Note: The data URL feature is one of several canvas features that may fail to work if you’re running a test page from your computer hard drive. To avoid problems, upload your work to a live web server for testing.

GEM IN THE ROUGH

Canvas Paint Programs on the Web

A paint program is one of the first examples that comes to mind when people start exercising their canvas-programming muscles. It's thus no surprise that you can Google up many more paint program examples on the Web, including some ridiculously advanced versions. Here are a few examples:

- <http://canvaspaint.org>. A Bizarro-world attempt to recreate the classic, Windows XP version of Microsoft Paint, but in a browser. It's complete, with slightly dated menus and public-domain code that's free for the taking.
- www.jswidget.com/index-ipaint.html. A more advanced painting program that's similar to modern versions of Windows Paint. When the author finishes this experiment, he plans to move to building an Adobe Photoshop clone, but in a browser.
- <http://mugtug.com/sketchpad>. An amazingly tricked-out painting and drawing program, with support for advanced illustration features like shape manipulation, marquee selection, and spirograph drawing. Currently, it doesn't work on any version of Internet Explorer.

Browser Compatibility for the Canvas

You've come a long way with the canvas already. Now it's time to step back and answer the question that hangs over every new HTML5 feature: When is it safe to use it?

Fortunately, the canvas is one of the better-supported parts of HTML5. The latest version of every mainstream browser supports it, as shown in Table 6-1. Of course, the more up-to-date the browser, the better—later builds of these browsers improve the drawing speed of the canvas and remove occasional glitches.

Table 6-1. Browser support for the canvas

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	9	3.5	3	4	10	1	1

You're not likely to run into an older version of any of these browsers, except for Internet Explorer. And that's the clear issue that today's canvas users will be thinking about: How can you put the canvas in your pages without locking out old but still popular browsers like IE 8 and IE 7?

As with many HTML5 features, you have two compatibility choices. Your first option is to detect when canvas support is missing and try to fall back on a different approach. Your second option is to fill the gap with another tool that can simulate the HTML5 canvas, so your pages will work—as written—on old browsers. In the case of the canvas, the second approach is the surprise winner, as you'll learn in the next section.

Polyfilling the Canvas

There are several solid workarounds that grant canvas-like abilities to aging copies of IE. The first is the ExplorerCanvas library (also called *excanvas*), by Google engineer and JavaScript genius Erik Arvidsson. It simulates the HTML5 canvas in Internet Explorer 7 or 8, using nothing but JavaScript and a now out-of-date technology called VML (Vector Markup Language).

Note: VML is a specification for creating line art and other illustrations using markup in an HTML document. It's now been replaced by a similar, but better supported, standard called SVG (Scalable Vector Graphics), which browsers are just beginning to support. Today, VML still lingers in a few Microsoft products, like Microsoft Office and Internet Explorer. This makes it a reasonable substitute for the canvas, albeit with some limitations.

You can download the latest version of ExplorerCanvas from <http://code.google.com/p/explorercanvas>. To use it, copy the *excanvas.js* file to the same folder as your web page, and add a script reference like this to your web page:

```
<head>
  <title>...</title>
  <!--[if lt IE 9]>
    <script src="excanvas.js"></script>
  <![endif]-->
  ...
</head>
```

Notice that this reference is conditional. Versions of Internet Explorer that are *earlier* than IE 9 will use it, but IE 9 and non-IE browsers will ignore the script altogether.

From this point, you can use the `<canvas>` without any serious headaches. For example, this change is all you need to get the basic paint program (shown on page 188) working in old versions of IE.

Note: If you plan to draw text on your canvas (a feature discussed on page 203), you'll also need the help of a second JavaScript library, called Canvas-text, which works in conjunction with ExplorerCanvas. You can download it from <http://code.google.com/p/canvas-text>.

Of course, the ExplorerCanvas isn't perfect. If you use advanced features, you'll probably run into something that doesn't look right. The main features that aren't supported in ExplorerCanvas (at the time of this writing, anyway) include radial gradients, shadows, clipping regions, raw pixel processing, and data URLs.

If you have really ambitious plans—for example, you're planning to create complex animations or a side-scrolling game—you might find that ExplorerCanvas isn't fast enough to keep up. In this situation, you can consider switching to a different poly-fill that uses a high-performance browser plug-in like Silverlight or Flash. You can

review all your options on GitHub's polyfill page at <http://tinyurl.com/polyfills>. Or, go straight to one of the best: the free FlashCanvas library at <http://code.google.com/p/flashcanvas>. Like ExplorerCanvas, you can plug it into your page using a single line of JavaScript. But unlike ExplorerCanvas, it uses the Flash plug-in, without a trace of VML.

FlashCanvas also has a grown-up professional version called FlashCanvas Pro. It has even better canvas support—in fact, it ranks about as well as most major browsers in canvas compatibility tests. You can buy FlashCanvas Pro for a small fee (currently \$31) at <http://flashcanvas.net/purchase>. You can compare the canvas support of ExplorerCanvas, FlashCanvas, and FlashCanvas Pro at <http://flashcanvas.net/docs/canvas-api>.

Note: When you combine a canvas-powered page with a library like FlashCanvas, you get truly impressive support on virtually every browser known to humankind. Not only do you get support for slightly older versions of IE through Flash, but you also get support for Flash-free mobile devices like the iPad and iPhone through HTML5.

The Canvas Fallback and Feature Detection

The most popular way to extend the reach of pages that use the canvas is with ExplorerCanvas and FlashCanvas. However, they aren't the only options.

The `<canvas>` element supports fallback content, just like the `<audio>` and `<video>` elements you explored in the last chapter. For example, you could apply this sort of markup to use the canvas (if it's supported) or to display an image (if it isn't):

```
<canvas id="logoCreator" width="500" height="300">
  <p>The canvas isn't supported on your computer, so you can't use our
  dynamic logo creator.</p>
  
</canvas>
```

This technique is rarely much help. Most of time, you'll use the canvas to draw dynamic graphics or create some sort of interactive graphical application, and a fixed graphic just can't compensate. One alternative is to place a Flash application inside the `<canvas>` element. This approach is especially good if you already have a Flash version of your work but you're moving to the canvas for future development. It lets you offer a working Flash-based solution to old versions of IE, while letting everyone else use the plug-in-free canvas.

If you're using Modernizr (page 38), you can test for canvas support in your JavaScript code. Just test the `Modernizr.canvas` property, and check the `Modernizr.cavastext` property to look for the canvas's text-drawing feature (which was a later addition to the canvas drawing model). If you don't detect canvas support in the current browser, then you can use any workaround you'd like.

FREQUENTLY ASKED QUESTION

Canvas Accessibility

Is it possible to make the canvas more accessible?

One of the key themes of HTML5, the semantic elements, and the past few chapters is *accessibility*—designing a page that provides information to assistive software, so it can help disabled people use your website. After all this emphasis, it may come as a shock that one of HTML5’s premier new features has no semantics or accessibility model *at all*.

The creators of HTML5 are working to patch the hole. However, no one’s quite certain of the best solution. One proposal is to create a separate document model for assistive devices, which would then mirror the canvas content. The problem here is that it’s up to the author to keep this “shadow” model in sync with the visuals, and lazy or over-worked developers are likely to pass on this responsibility if it’s in any way complicated.

A second proposal is to extend image maps (an existing HTML feature that divides pictures into clickable regions) so they act as a layer over the top of the canvas. Because an image map is essentially a group of links, it could hold important information for assistive software to read and report to the user.

Currently, there’s no point in thinking too much about either of these ideas, because they’re both still being debated. In the meantime, it makes sense to use the canvas for a variety of graphical tasks, like arcade games (most of which can’t practically be made accessible) and data visualization (as long as you have the data available in text form elsewhere on the page). However, the canvas isn’t a good choice for an all-purpose page design element. So if you’re planning to use the canvas to create a fancy heading or a menu for your website, hold off for now.

Deeper into the Canvas

The canvas is a huge, sprawling feature. In the previous chapter, you learned how to draw line art and even create a respectable drawing program in a few dozen lines of JavaScript. But the canvas has more up its sleeve than that. Not only can it show dynamic pictures and host paint programs, but it can also play animations, process images with pixel-perfect control, and run interactive games. In this chapter, you'll learn the practical beginnings for all these tasks.

First, you'll start by looking at drawing context methods that let you paint different types of content on a canvas, including images and text. Next, you'll learn how to add some graphical pizzazz with shadows, patterned fills, and gradients. Finally, you'll learn practical techniques to make your canvas interactive and to host live animations. Best of all, you can build all of these examples with nothing more than ordinary JavaScript and raw ambition.

Note: For the first half of this chapter, you'll focus on small snippets of drawing code. You can incorporate this code into your own pages, but you'll need to first add a `<canvas>` element to your page and create a drawing context, as you learned on page 172. In the second half of this chapter, you'll look at much more ambitious examples. Although you'll see most (or all) of the canvas-drawing code that these examples use, you won't get every page detail. To try out the examples for yourself, visit the try-out site at www.prosetech.com/html5.

Other Things You Can Draw on the Canvas

Using the canvas, you can painstakingly recreate any drawing you want, from a bunch of lines and triangles to a carefully shaded portrait. But as the complexity of your drawing increases, so does the code. It's extremely unlikely that you'd write by hand all the code you need to create a finely detailed picture.

Fortunately, you have other options. The drawing context isn't limited to lines and curves—it also has methods that let you slap down pre-existing images, text, patterns, and even video frames. In the following sections, you'll learn how to use these methods to get more content on your canvas.

Drawing Images

You've probably seen web pages that build maps out of satellite images, which they download and stitch together. That's an example of how you can take images you already have and combine them to get the final image that you want.

The canvas supports ordinary image data through the drawing context's logically named `drawImage()` method. To put an image in your canvas, you call `drawImage()` and pass in an image object and your coordinates, like this:

```
context.drawImage(img, 10, 10);
```

But before you can call `drawImage()`, you need the image object. HTML5 gives you three ways to get it. First, you can build it yourself out of raw pixels, one pixel at a time, using `createImageData()`. This approach is tedious and slow (although you'll learn more about per-pixel manipulation on page 234).

Your second option is to use an `` element that's already on your page. For example, if you have this markup:

```

```

You can copy that picture onto the canvas with this code:

```
var img = document.getElementById("arrow_left");
context.drawImage(img, 10, 10);
```

The third way that you can get an image for use with `drawImage()` is by creating an image object and loading an image picture from a separate file. The disadvantage to this approach is that you can't use your image with `drawImage()` until that picture has been completely downloaded. To prevent problems, you need to wait until the image's `onLoad` event occurs before you do anything with the image.

To understand this pattern, it helps to look at an example. Imagine you have an image named *maze.png* that you want to display on a canvas. Conceptually, you want to take this series of steps:

```
// Create the image object.
var img = new Image();

// Load the image file.
img.src = "maze.png";
```

```
// Draw the image. (This could fail, because the picture
// might not be downloaded yet.)
context.drawImage(img, 0, 0);
```

TROUBLESHOOTING MOMENT

My Pictures are Squashed!

If you attempt to draw a picture and find that it's inexplicably stretched, squashed, or otherwise distorted, the most likely culprit is a style sheet rule.

The proper way to size the canvas is to use its height and width attributes in your HTML markup. You might think you could remove these in your markup, leaving a tag like this:

```
<canvas></canvas>
```

And replace them with a style sheet rule that targets your canvas, like this one:

```
canvas {
  height: 300px;
  width: 500px;
}
```

But this doesn't work. The problem is that the CSS height and width properties aren't the same as the canvas height and width properties. If you make this mistake, what actually happens is that the canvas gets its default size (300 × 150 pixels). Then, the CSS size properties stretch or squash the canvas to fit, causing it to resize its contents accordingly. As a result, when you put an image on the canvas, it's squashed too, which is decidedly unappealing.

To avoid this problem, always specify the canvas size using its height and width attributes. And if you need a way to change the size of the canvas based on something else, use a bit of JavaScript code to change the <canvas> element's height and width when needed.

The problem here is that setting the src attribute starts an image download, but your code carries on without waiting for it to finish. The proper way to arrange this code is like this:

```
// Create the image object.
var img = new Image();

// Attach a function to the onload event.
// This tells the browser what to do after the image is loaded.
img.onload = function() {
  context.drawImage(img, 0, 0);
};

// Load the image file.
img.src = "maze.png";
```

This may seem counterintuitive, since the order in which the code is listed doesn't match the order in which it will be *executed*. In this example, the context.drawImage() call happens last, shortly after the img.src property is set.

Images have a wide range of uses. You can use them to add embellishments to your line drawings, or as a shortcut to avoid drawing by hand. In a game, you can use images for different objects and characters, positioned appropriately on the canvas. And fancy paint programs use them instead of basic line segments so the user can draw “textured” lines. You'll see some practical examples that use image drawing in this chapter.

Slicing, Dicing, and Resizing an Image

The `drawImage()` function accepts a few optional arguments that let you alter the way your image is painted on the canvas. First, if you want to resize the image, you can tack on the width and height you want, like this:

```
context.drawImage(img, 10, 10, 30, 30);
```

This function makes a 30×30 pixel box for the image, with the top-left corner at point (10,10). Assuming the image is naturally 60×60 pixels, this operation squashes it by half in both dimensions, leaving it just a quarter as big as it would ordinarily be.

If you want to crop a piece out of the picture, you can supply the four extra arguments to `drawImage()` at the beginning of the argument list. These four points define the position and size of the rectangle you want to cut out of the picture, as shown here:

```
context.drawImage(img, source_x, source_y,  
                 source_width, source_height, x, y, width, height);
```

The last four arguments are the same as in the previous example—they define the position and size that the cropped picture should have on the canvas.

For example, imagine you have a 200×200 pixel image, and you want to paint just the top half. To do that, you create a box that starts at point (0,0) and has a width of 200 and a height of 100. You can then draw it on the canvas at point (75,25), using this code:

```
context.drawImage(img, 0, 0, 200, 100, 75, 25, 200, 100);
```

Figure 7-1 shows exactly what's happening in this example.

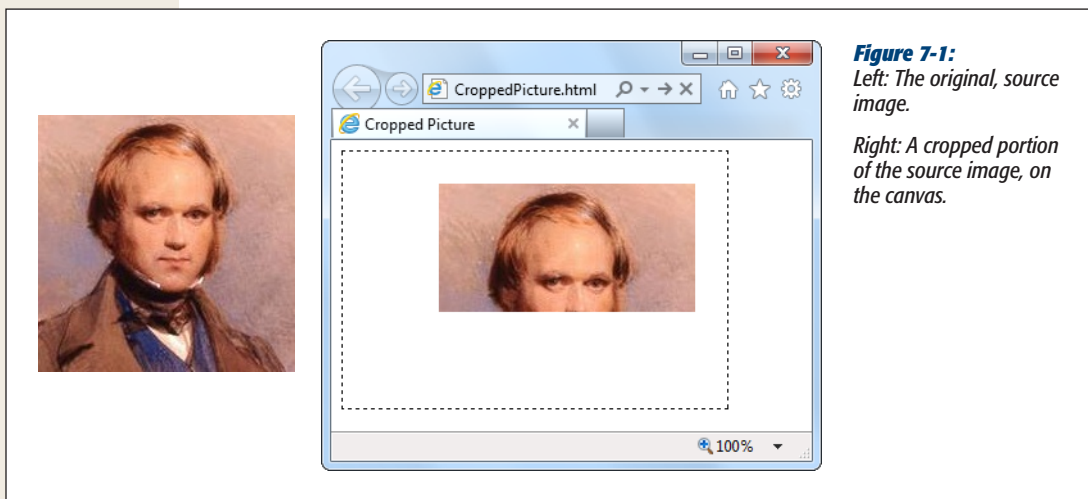

Figure 7-1:
Left: The original, source image.

Right: A cropped portion of the source image, on the canvas.

If you want to do more—for example, skew or rotate an image before you draw it, the `drawImage()` method can't keep up. However, you can use transforms to alter the way you draw anything and everything, as explained on page 182.

GEM IN THE ROUGH

Drawing a Video Frame

The first parameter of the `drawImage()` method is the image you want to draw. As you've seen, this can be an `Image` object you've just created, or an `` element that's elsewhere on the page.

But that's not the whole story. HTML5 actually allows two more substitutions. Instead of an image, you can throw in a complete `<canvas>` element (not the one you're drawing on). Or, you can use a currently playing `<video>` element, with no extra work:

```
var video =  
  document.getElementById("videoPlayer");  
context.drawImage(video, 0, 0,  
  video.clientWidth, video.clientWidth);
```

When this code runs, it grabs a single frame of video—the frame that's being played at the very instant this code runs. It then paints that picture onto the canvas.

This ability opens the door to a number of interesting effects. For example, you can use a timer to grab new video frames while playback is under way, and keep painting them on a canvas. If you do this fast enough, the copied sequence of images on the canvas will look like another video player.

To get more exotic, you can change something about the copied video frame before you paint it. For example, you could scale it larger or smaller, or dip into the raw pixels and apply a Photoshop-style effect. For an example, read the article at <http://html5doctor.com/video-canvas-magic>. It shows how you can play a video in grayscale simply by taking regular snapshots of the real video and converting each pixel in each frame to a color-free shade of gray.

Drawing Text

Text is another thing that you wouldn't want to assemble yourself out of lines and curves. And the HTML5 canvas doesn't expect you to. Instead, it includes two drawing context methods that can do the job.

First, before you draw any text, you need to set the drawing context's font property. You use a string that uses the same syntax as the all-in-one CSS font property. At a bare minimum, you must supply the font size, in pixels, and the font name, like this:

```
context.font = "20px Arial";
```

You can supply a list of font names, if you're not sure that your font is supported:

```
context.font = "20px Verdana,sans-serif";
```

And optionally, you can add italics or bold at the beginning of the string, like this:

```
context.font = "bold 20px Arial";
```

You can also use a fancy embedded font, courtesy of CSS3. All you need to do is register the font name first, using a style sheet (as described on page 244).

Once the font is in place, you can use the `fillText()` method to draw your text. Here's an example that puts the top-left corner of the text at the point (10,10):

```
context.textBaseline = "top";  
context.fillStyle = "black";  
context.fillText("I'm stuck in a canvas. Someone let me out!", 10, 10);
```

You can put the text wherever you want, but you're limited to a single line. If you want to draw multiple lines of text, you need to call `fillText()` multiple times.

Tip: If you want to divide a solid paragraph over multiple lines, you can create your own *word wrapping algorithm*. The basic idea is this: Split your sentence into words, and see how many words fit in each line using the drawing context's `measureText()` method. It's tedious to do, but the sample code at <http://tinyurl.com/6ec7hld> can get you started.

Instead of using `fillText()`, you can use the other text-drawing method, `strokeText()`. It draws an outline around your text, using the `strokeStyle` property for its color and the `lineWidth` property for its thickness. Here's an example:

```
context.font = "bold 40px Verdana,sans-serif";
context.lineWidth = "1";
context.strokeStyle = "red";
context.strokeText("I'm an OUTLINE", 20, 50);
```

When you use `strokeText()`, the middle of the text stays blank. Of course, you can use `fillText()` followed by `strokeText()` if you want colored, outlined text. Figure 7-2 shows both pieces of text in a canvas.

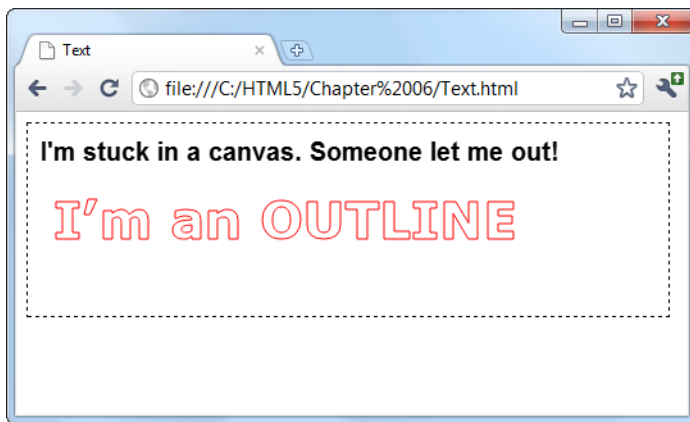

Figure 7-2:
*The canvas makes it easy to draw
solid text and outlined text.*

Tip: Drawing text is much slower than drawing lines and images. The speed isn't important if you're creating a static, unchanging image (like a chart), but it may be an issue if you're creating an interactive, animated application. If you need to optimize performance, you may find that it's better to save your text in an image file, and then draw it on the canvas with `drawImage()`.

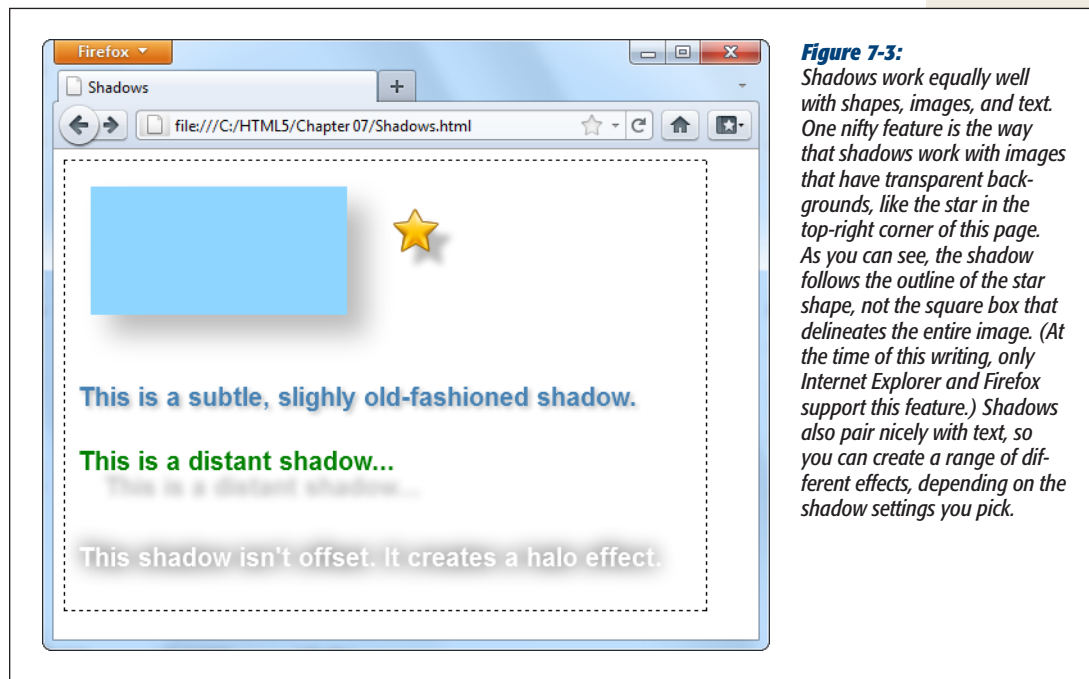

Shadows and Fancy Fills

So far, when you've drawn lines and filled shapes on the canvas, you've used solid colors. And while there's certainly nothing wrong with that, ambitious painters will be happy to hear that the canvas has a few fancier drawing techniques. For example, the canvas can draw an artfully blurred shadow behind any shape. Or, it can fill a shape by tiling a small graphic across its surface. But the canvas's fanciest painting frill is almost certainly *gradients*, which you can use to blend two or more colors into a kaleidoscope of patterns.

In the following sections, you'll learn to use all these features, simply by setting different properties in the canvas's drawing context.

Adding Shadows

One handy canvas feature is the ability to add a shadow behind anything you draw. Figure 7-3 shows some snazzy shadow examples.

Essentially, a shadow looks like a blurry version of what you would ordinarily draw (lines, shapes, images, or text). You control the appearance of shadows using several drawing context properties, as outlined in Table 7-1.

Table 7-1. Properties for creating shadows

Property	Description
shadowColor	Sets the shadow's color. You could go with black or a tinted color, but a nice midrange gray is generally best. Another good technique is to use a semitransparent color (page 185) so the content that's underneath still shows through. When you want to turn shadows off, set shadowColor back to transparent.
shadowBlur	Sets the shadow's "fuzziness." A shadowBlur of 0 creates a crisp shadow that looks just like a silhouette of the original shape. By comparison, a shadowBlur of 20 is a blurry haze, and you can go higher still. Most people agree that some fuzz (a blur of at least 3) looks best.
shadowOffsetX and shadowOffsetY	Positions the shadow, relative to the content. For example, set both properties to 5, and the shadow will be bumped 5 pixels to the right and 5 pixels down from the original content. You can also use negative numbers to move the shadow the other way (left and up).

The following code creates the assorted shadows shown in Figure 7-3:

```
// Draw the shadowed rectangle.
context.rect(20, 20, 200, 100);
context.fillStyle = "#8ED6FF";
context.shadowColor = "bbbbbb";
context.shadowBlur = 20;
context.shadowOffsetX = 15;
context.shadowOffsetY = 15;
context.fill();

// Draw the shadowed star.
context.shadowOffsetX = 10;
context.shadowOffsetY = 10;
context.shadowBlur = 4;
img = document.getElementById("star");
context.drawImage(img, 250, 30);

context.textBaseline = "top";
context.font = "bold 20px Arial";

// Draw three pieces of shadowed text.
context.shadowBlur = 3;
context.shadowOffsetX = 2;
context.shadowOffsetY = 2;
context.fillStyle = "steelblue";
context.fillText("This is a subtle, slightly old-fashioned shadow.", 10, 175);

context.shadowBlur = 5;
context.shadowOffsetX = 20;
context.shadowOffsetY = 20;
context.fillStyle = "green";
context.fillText("This is a distant shadow...", 10, 225);

context.shadowBlur = 15;
context.shadowOffsetX = 0;
context.shadowOffsetY = 0;
```

```
context.shadowColor = "black";
context.fillStyle = "white";
context.fillText("This shadow isn't offset. It creates a halo effect.", 10,
300);
```

Filling Shapes with Patterns

So far, you've filled the shapes you've drawn with solid or semitransparent colors. But the canvas also has a fancy fill feature that lets you slather the inside with a pattern or a gradient. Using these fancy fills is a sure way to jazz up plain shapes. Using a fancy fill is a two-step affair. First, you create the fill. Then, you attach it to the `fillStyle` property (or, occasionally, the `strokeStyle` property).

To make a pattern fill, you start by choosing a small image that you can tile seamlessly over a large area (see Figure 7-4). You need to load the picture you want to tile into an image object using one of the techniques you learned about earlier, such as putting a hidden `` on your page (page 200), or loading it from a file and handling the `onLoad` event of the `` element (page 201). This example uses the first approach:

```
var img = document.getElementById("brickTile");
```

Once you have your image, you can create a pattern object using the drawing context's `createPattern()` method. At this point, you pick whether you want the pattern to repeat horizontally (`repeat-x`), vertically (`repeat-y`), or in both dimensions (`repeat`):

```
var pattern = context.createPattern(img, "repeat");
```

The final step is to use pattern object to set the `fillStyle` or `strokeStyle` property:

```
context.fillStyle = pattern;
context.rect(0, 0, canvas.width, canvas.height);
context.fill();
```

This creates a rectangle that fills the canvas with the tiled image pattern, as shown in Figure 7-4.

Figure 7-4:

Left: An image that holds a single tile.

Right: The pattern created by tiling the image over an entire canvas.

Filling Shapes with Gradients

The second type of fancy fill is a gradient, which blends two or more colors. The canvas supports linear gradients and radial gradients, and Figure 7-5 compares the two.

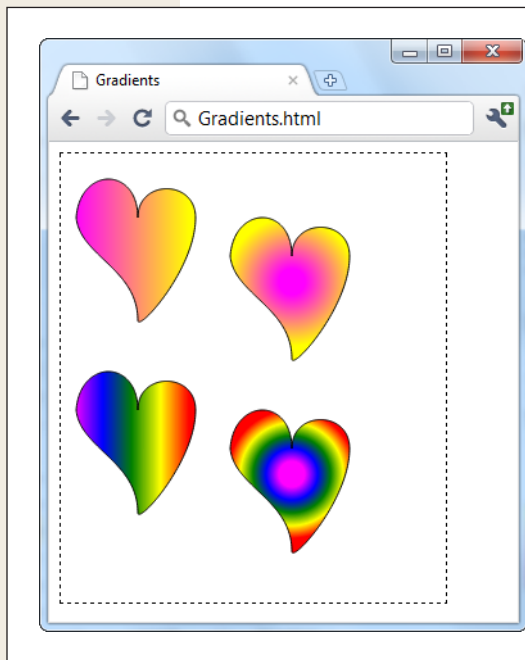

Figure 7-5:

A linear gradient (top left) blends from one line of color to another. A radial gradient (top right) blends from one point of color to another. Both types support more than two colors, allowing you to create a banded effect with linear gradients (bottom left) or a ring effect with radial gradients (bottom right).

Tip: If you're looking at these gradients in a black-and-white print copy of this book, give your head a shake and try out the examples at www.prosetech.com/html5, so you can see the wild colors for yourself. (The sample code also includes the drawing logic for the hearts, which stitches together four Bézier curves in a path.)

Unsurprisingly, the first step to using a gradient fill is creating the right type of gradient object. The drawing context has two methods that handle this task: `createLinearGradient()` and `createRadialGradient()`. Both work more or less the same way: They hold a list of colors that kick in at different points.

The easiest way to understand gradients is to start by looking at a simple example. Here's the code that's used to create the gradient for the top-left heart in Figure 7-5:

```
// Create a gradient from point (10,0) to (100,0).
var gradient = context.createLinearGradient(10, 0, 100, 0);

// Add two colors.
gradient.addColorStop(0, "magenta");
gradient.addColorStop(1, "yellow");
```

```
// Call another function to draw the shape.
drawHeart(60, 50);

// Paint the shape.
context.fillStyle = gradient;
context.fill();
context.stroke();
```

When you create a new linear gradient, you supply two points that represent the starting point and ending point of a *line*. This line is the path over which the color change takes place.

The gradient line is important, because it determines what the gradient looks like (see Figure 7-6). For example, consider a linear gradient that transitions from magenta to yellow. It could make this leap in a few pixels, or it could blend it out over the entire width of the canvas. Furthermore, the blend could be from left to right, top to bottom, or slanted somewhere in between. The line determines all these details.

Figure 7-6:

Left: Here's the gradient generated for the bottom-left heart from Figure 7-5. When you use that gradient to fill a shape, you see just a portion of it.

Right: The same is true for this radial gradient, which is used for the bottom-right heart in Figure 7-5.

Tip: Think of a gradient as a colorful design just under the surface of your canvas. When you create a gradient, you're creating this colorful, but hidden, surface. When you fill a shape, you cut a hole that lets part of that gradient show through. The actual result—what you see in your canvas—depends on both the settings of your gradient and the size and position of your shape.

In this example, the gradient line starts at point (10,0) and ends at point (100,0). These points tell you several important things:

- **The gradient is horizontal.** That means it blends colors from left to right. You know this because the two points have the same y-coordinate. If, on the other hand, you wanted to blend from top to bottom, you could use points like (0,10) and (0,100). If you wanted it to stretch diagonally from top left to bottom right, you could use (10,10) and (100,100).
- **The actual color blend spans just 90 pixels (starting when the x-coordinate is 10 and ending when the x-coordinate is 100).** In this example, the heart shape is just slightly smaller than the gradient dimensions, which means you see most of the gradient in the heart.
- **Beyond the limits of this gradient, the colors become solid.** So if you make the heart wider, you'll see more solid magenta (on the left) and solid yellow (on the right).

Tip: Often, you'll create a gradient that's just barely bigger than the shape you're painting, as in this example. However, other approaches are possible. For example, if you want to paint several shapes using different parts of the same gradient, you might decide to create a gradient that covers the entire canvas.

To actually set the colors in a gradient, you call the gradient's `addColorStop()` method. Each time you do, you supply an offset from 0 to 1, which sets where the color appears in the blend. A value of 0 means the color appears at the very start of the gradient, while a value of 1 puts the color at the very end. Change these numbers (for example, to 0.2 and 0.8), and you can compress the gradient, exposing more solid color on either side.

When you create a two-color gradient, 0 and 1 make most sense for your offsets. But when you create a gradient with more colors, you can choose different offsets to stretch out some bands of colors while compressing others. The bottom-left heart in Figure 7-5 splits its offsets evenly, giving each color an equal-sized band:

```
var gradient = context.createLinearGradient(10, 0, 100, 0);
gradient.addColorStop("0", "magenta");
gradient.addColorStop(".25", "blue");
gradient.addColorStop(".50", "green");
gradient.addColorStop(".75", "yellow");
gradient.addColorStop("1.0", "red");

drawHeart(60, 200);
context.fillStyle = gradient;
context.fill();
context.stroke();
```

Note: If the room is starting to revolve around you, don't panic. After all, you don't need to understand everything that happens in a gradient. There's nothing to stop you from just tweaking the numbers until an appealing blend of colors appears in your shape.

You use the same process to create a radial gradient as you do to create a linear one. But instead of supplying two points, you must define two circles. That's because a radial gradient is a blend of color that radiates out from a small circle to a larger, containing circle. To define each of these circles, you supply the center point and radius.

In the radial gradient example shown in the top right of Figure 7-5, the colors blend from a center point inside the heart, at (180,100). The inner color is represented by a 10-pixel circle, and the outer color is a 50-pixel circle. Once again, if you go beyond these limits, you get solid colors, giving the radial gradient a solid magenta core and solid yellow surroundings.

Here's the code that draws the two-color radial gradient:

```
var gradient = context.createRadialGradient(180, 100, 10, 180, 100, 50);
gradient.addColorStop(0, "magenta");
gradient.addColorStop(1, "yellow");

drawHeart(180, 80);
context.fillStyle = gradient;
context.fill();
context.stroke();
```

Note: Most often, you'll choose the same center point for both the inner and outer circles. However, you could offset one from the other, which can stretch, squash, and distort the blend of colors in interesting ways.

Using this example, you can create the final, multicolored radial gradient that's in the bottom-right corner of Figure 7-5. You simply need to move the center point of the circles to the location of the heart, and add a different set of color stops—the same ones that you used for the multicolored linear gradient:

```
var gradient = context.createRadialGradient(180, 250, 10, 180, 250, 50);
gradient.addColorStop("0", "magenta");
gradient.addColorStop(".25", "blue");
gradient.addColorStop(".50", "green");
gradient.addColorStop(".75", "yellow");
gradient.addColorStop("1.0", "red");

drawHeart(180, 230);
context.fillStyle = gradient;
context.fill();
context.stroke();
```

You now you have the smarts to create more psychedelic patterns than a 1960s revival party.

Putting It Together: Drawing a Graph

Now that you've slogged your way through the better part of the canvas's drawing features, it's time to pause and enjoy the fruits of your labor. In the following example, you'll take some humdrum text and numbers and use the canvas to create simple, standout charts.

Figure 7-7 shows the starting point: a two-page personality test that's light on graphics. The user answers the questions on the first page and then clicks Get Score to move to the second page. The second page reports the personality scores according to the infamous five-factor personality model (see the box on page 213).

Figure 7-7:

Click your way through the questions (top), and then review the scores (bottom). Unfortunately, without a scale or any kind of visual aid, it's difficult for ordinary people to tell what these numbers are supposed to mean.

UP TO SPEED

How to Convert One Personality into Five Numbers

This five-factor personality test ranks you according to five personality “ingredients,” which are usually called openness, conscientiousness, extraversion, agreeableness, and neuroticism. These factors were cooked up when researchers analyzed the thousands of personality-describing adjectives in the English language.

To pick just five factors, psychologists used a combination of hard-core statistics, personality surveys, and a computer. They identified which adjectives people tend to tick off together and used that to distill the smallest set of personality super-traits. For example, people who describe themselves

as *outgoing* usually also describe themselves as *social* and *gregarious*, so it makes sense to combine all these traits into a single personality factor (which psychologists call *extraversion*). By the time the researchers had finished chewing through their set of nearly 20,000 adjectives, they had managed to boil them down to five closely interrelated factors.

You can learn more about the five-factor personality model at http://en.wikipedia.org/wiki/Big_Five_personality_traits, or in the book *Your Brain: The Missing Manual* (O’Reilly).

The JavaScript code that makes this example work is pretty straightforward. When the user clicks a number button, its background is changed to indicate the user’s choice. When the user completes the quiz, a simple algorithm runs the answers through a set of scoring formulas to calculate the five personality factors. If you want to examine this code or to take the test, visit the try-out site at www.prosetech.com/html5.

So far, there’s no HTML5 magic. But consider how you could improve this two-page personality test by *graphing* the personality scores so that each factor is shown visually. Figure 7-8 shows the revamped version of the personality test results page, which uses this technique.

To show these charts, the page uses five separate canvases, one for each personality factor. Here’s the markup:

```
<hgroup>
  <h1>Five Factor Personality Test</h1>
  <h2>The Results</h2>
</hgroup>

<div class="score">
  <h2 id="headingE">Extraversion: </h2>
  <canvas id="canvasE" height="75" width="550"></canvas>
</div>

<div class="score">
  <h2 id="headingA">Accommodation: </h2>
  <canvas id="canvasA" height="75" width="550"></canvas>
</div>

<div class="score">
  <h2 id="headingC">Conscientiousness: </h2>
  <canvas id="canvasC" height="75" width="550"></canvas>
</div>
```

```
<div class="score">
  <h2 id="headingN">Neuroticism: </h2>
  <canvas id="canvasN" height="75" width="550"></canvas>
</div>

<div class="score">
  <h2 id="heading0">Openness: </h2>
  <canvas id="canvas0" height="75" width="550"></canvas>
</div>
```

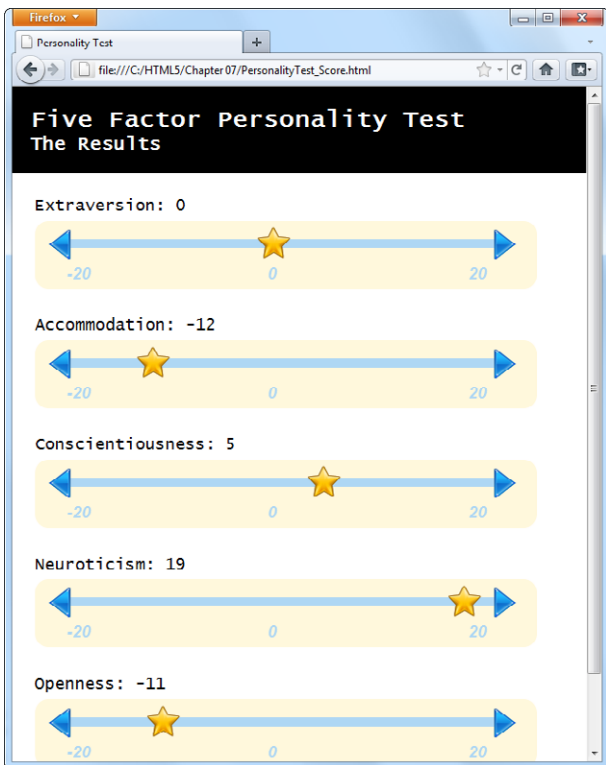

Figure 7-8:

This page combines several different types of canvas drawing, including lines, images, and text. But the most interesting part of it is the way it dynamically draws these simple graphs, based on your answers in the personality quiz.

Each chart is drawn by the same custom JavaScript function, named `plotScore()`. The page calls this function five times, using different arguments each time. For example, to draw the extraversion chart at the top of the page, the code passes the topmost canvas element, the extraversion score (as a number from -20 to 20), and the text title ("Extraversion"):

```
window.onload = function() {
  ...
  // Get the <canvas> element for the extraversion score.
  var canvasE = document.getElementById("canvasE");
```

```
// Add the score number to the corresponding heading.
// (The score is stored in a variable named extraversion.)
document.getElementById("headingE").innerHTML += extraversion;

// Plot the score in the corresponding canvas.
plotScore(canvasE, extraversion, "Extraversion");
...
}
```

The `plotScore()` function runs through a bit of drawing code that will seem familiar to you by now. It uses the various drawing context methods to draw the different parts of the score graph:

```
function plotScore(canvas, score, title) {
    var context = canvas.getContext("2d");

    // Draw the arrows on the side of the chart line.
    var img = document.getElementById("arrow_left");
    context.drawImage(img, 12, 10);
    context.drawImage(img, 498, 10);

    // Draw the line between the arrows.
    context.moveTo(39, 25);
    context.lineTo(503, 25);
    context.lineWidth = 10;
    context.strokeStyle = "rgb(174,215,244)";
    context.stroke();

    // Write the numbers on the scale.
    context.fillStyle = context.strokeStyle;
    context.font = "italic bold 18px Arial";
    context.textBaseline = 'top';

    context.fillText("-20", 35, 50);
    context.fillText("0", 255, 50);
    context.fillText("20", 475, 50);

    // Add the star to show where the score ranks on the chart.
    img = document.getElementById("star");
    context.drawImage(img, (score+20)/40*440+35-17, 0);
}
```

The most important bit is the final line, which plots the star at the right position using this slightly messy equation:

```
context.drawImage(img, (score+20)/40*440+35-17, 0);
```

Here's how it works. The first step is to convert the score into a percentage from 0 to 100 percent. Ordinarily, the score falls between -20 and 20, so the first operation the code needs to carry out is to change it to a value from 0 to 40:

```
score+20
```

You can then divide that number by 40 to get the percentage:

```
(score+20)/40
```

Once you have the percentage, you need to multiply it by the length of the line. That way, 0 percent ends up at the far left side, while 100 percent ends up at the opposite end, and everything else falls somewhere in between:

```
(score+20)/40*440
```

This code would work fine if the line stretched from the x-coordinate 0 to the x-coordinate 400. But in reality the line is offset a bit from the left edge, to give it a bit of padding. You need to offset the star by the same amount:

```
(score+20)/40*440+35
```

But this lines the left edge of the start up with the proper position, when really you want to line up its midpoint. To correct this issue, you need to subtract an amount that's roughly equal to half the start's width:

```
(score+20)/40*440+35-17
```

This gives you the final x-coordinate for the star, based on the score.

Note: It's a small jump to move from fixed drawings to dynamic graphics like the ones in this example, which tailor themselves according to the latest data. But once you've made this step, you can apply your skills to build all sorts of interesting data-driven graphics, from traditional pie charts to infographics that use dials and meters. And if you're looking for a way to simplify the task, check out one of the canvas graphic libraries, which include pre-written JavaScript routines for drawing common types of graphs based on your data. Two good examples are RGraph (www.rgraph.net) and ZingChart (www.zingchart.com).

Making Your Shapes Interactive

The canvas is a *non-retained* painting surface. That means that the canvas doesn't keep track of what drawing operations you've performed. Instead, it just keeps the final result—the grid of colored pixels that makes up your picture.

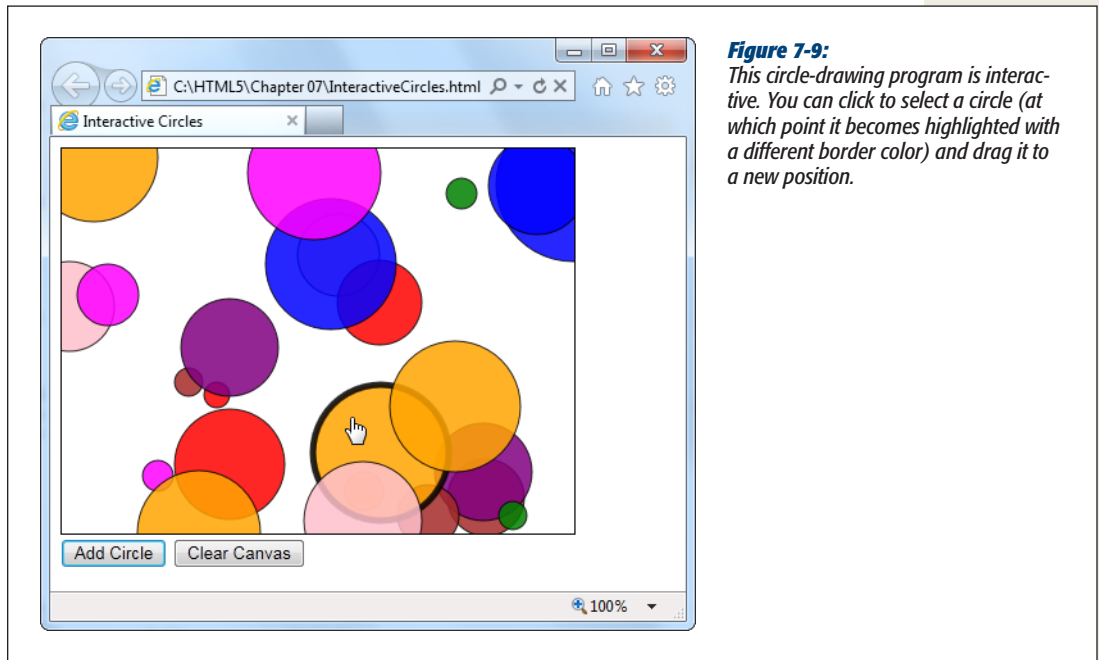

For example, if you draw a red square in the middle of your canvas, the moment you call `stroke()` or `fill()`, that square becomes nothing more than a block of red pixels. It may look like a square, but the canvas has no memory of its squareness.

This model makes drawing fast. However, it also makes life difficult if you want to add interactivity to your drawing. For example, imagine you want to create a smarter version of the painting program you saw on page 188. You want people to be able to not only draw a line, but also draw a rectangle. (That part's easy.) And you want people to be able to not only draw a rectangle, but also select it, drag it to a new place, resize it, change its color, and so on. Before you can give them all that power, you need to deal with several complications. First, how do you know if someone has clicked on the rectangle? Second, how do you know the details about the rectangle—its coordinates, size, stroke color, and fill color? And third, how do you know the details about every *other* shape on the canvas—which you'll need to know if you need to change the rectangle and repaint the canvas?

To solve these problems, and make your canvas interactive, you need to keep track of every object you paint. Then, when someone clicks somewhere, you need to check whether they're clicking one of the shapes (a process known as *hit testing*). If you can tackle these two tasks, the rest—changing one of your shapes and repainting the canvas—is easy.

Keeping Track of What You've Drawn

In order to be able to change and repaint your picture, you need to know everything about its contents. For example, consider the circle-drawing program shown in Figure 7-9. To keep things simple, it consists entirely of separately sized, differently colored circles.

To keep track of an individual circle, you need to know its position, radius, and fill color. Rather than create dozens of variables to store all this information, it makes sense to put all four details in a small package. That package is a *custom object*.

If you haven't created a custom object before, here's the standard technique. First, you create a function that's named after your type of object. For example, if you want to build a custom object for a circle creation, you might name the function `Circle()`, like this:

```
function Circle() {  
}
```

Next, you need your object to store some data. You do that by using a keyword named *this* to create properties. For example, if you want to give your circle object a property named *radius*, you would assign a value to *this.radius*.

Here's a circle-generating function that stores three details: the x- and y-coordinates, and the radius of the circle:

```
function Circle() {  
  this.x = 0;  
  this.y = 0;  
  this.radius = 15;  
}
```

Now, you can use the `Circle()` function to create a new circle object. The trick is that you don't want to call the function—instead, you want to create a new copy of it with the *new* keyword. Here's an example:

```
// Create a new circle object, and store it in a variable named myCircle.  
var myCircle = new Circle();
```

And then you can access all the circle details as properties:

```
// Change the radius.  
myCircle.radius = 20;
```

If you want to get a bit fancier, you can pass arguments to the `Circle()` function. That way, you can create a circle object and set all the circle properties in one step. Here's the version of the `Circle()` function that's used for the page in Figure 7-9:

```
function Circle(x, y, radius, color) {  
  this.x = x;  
  this.y = y;  
  this.radius = radius;  
  this.color = color;  
  this.isSelected = false;  
}
```

The `isSelected` property takes a true or false value. When someone clicks the circle, `isSelected` is set to true, and then the drawing code knows to paint a different border around it.

Using this version of the `Circle()` function, you can use code like this to create a circle object:

```
var myCircle = new Circle(0, 0, 20, "red");
```

Of course, the whole point of the circle-drawing program is to let people draw as many circles as they want. That means just one circle object won't do. Instead, you need to create an array that can hold all the circles. Here's the global variable that makes this work in the current example:

```
var circles = [];
```

The rest of the code is easy. When someone clicks the Add Circle button to create a new circle, it triggers the `addRandomCircle()` function. The `addRandomCircle()` function creates a new circle with a random size, color, and position:

```
function addRandomCircle() {
  // Give the circle a random size and position.
  var radius = randomFromTo(10, 60);
  var x = randomFromTo(0, canvas.width);
  var y = randomFromTo(0, canvas.height);

  // Give the circle a random color.
  var colors = ["green", "blue", "red", "yellow", "magenta",
    "orange", "brown", "purple", "pink"];
  var color = colors[randomFromTo(0, 8)];

  // Create the new circle.
  var circle = new Circle(x, y, radius, color);

  // Store it in the array.
  circles.push(circle);

  // Redraw the canvas.
  drawCircles();
}
```

This code makes use of a custom function named `randomFromTo()`, which generates random numbers in a set range. (To play with the full code, visit www.prosetech.com/html5.)

The final step in this sequence is actually painting the canvas, based on the current collection of circles. After a new circle is created, the `addRandomCircle()` function calls another function, named `drawCircles()`, to do the job. The `drawCircles()` function moves through the array of circles, using this loop:

```
for(var i=0; i<circles.length; i++) {
  var circle = circles[i];
  ...
}
```

This code uses the trusty *for* loop (which is described in Appendix B, page 410). The block of code in the braces runs once for each circle. The first line of code grabs the current circle and stores it in a variable, so it's easy to work with.

Here's the complete `drawCircles()` function, which fills the canvas with the current collection of circles:

```
function drawCircles() {
  // Clear the canvas and prepare to draw.
  context.clearRect(0, 0, canvas.width, canvas.height);
  context.globalAlpha = 0.85;
  context.strokeStyle = "black";

  // Go through all the circles.
  for(var i=0; i<circles.length; i++) {
    var circle = circles[i];
```

```

    // Draw the circle.
    context.beginPath();
    context.arc(circle.x, circle.y, circle.radius, 0, Math.PI*2);
    context.fillStyle = circle.color;

    context.fill();
    context.stroke();
  }
}

```

Note: Each time the circle-drawing program refreshes the display, it starts by clearing everything away with the `clearRect()` method. Paranoid programmers might worry that this step would cause a flicker, as the canvas goes blank and the circles disappear, then reappear. However, the canvas is optimized to prevent this problem. It doesn't actually clear or paint *anything* until all your drawing logic has finished, at which point it copies the final product to the canvas in one smooth step.

Right now, the circles still aren't interactive. However, the page has the all-important plumbing that keeps track of every circle that's drawn. Although the canvas is still just a block of colored pixels, the code knows the precise combination of circles that creates the canvas—and that means it can manipulate those circles at any time.

In the next section, you'll see how you can use this system to let the user select a circle.

Hit Testing with Coordinates

If you're creating interactive shapes, you'll almost certainly need to use *hit testing*, a technique that checks whether a given point has “hit” another shape. In the circle-drawing program, you want to check whether the user's click has hit upon a circle or just empty space.

More sophisticated animation frameworks (like those provided by Flash and Silverlight) handle hit testing for you. And there are add-on JavaScript libraries for the canvas (like Kinetic JS) that aim to offer the same conveniences, but none is mature enough to recommend at this writing. So right now, canvas fans need to write their own hit testing logic.

To do that, you need to examine each shape and calculate whether the point is inside the bounds of that shape. If it is, the click has “hit” that shape. Conceptually, this process is straightforward, but the actual details—the calculations you need to figure out whether a shape has been clicked—can get messy.

The first thing you need is a loop that moves through all the shapes. This loop looks a little different from the one that the `drawCircles()` function uses:

```

for (var i=circles.length-1; i>=0; i--) {
  var circle = circles[i];
  ...
}

```

Notice that the code actually moves backward through the array, from finish to start. It starts at the end (where the index is equal to the total number of items in the array, minus 1), and counts back to the beginning (where the index is 0). The backward looping is deliberate, because in most applications (including this one), the objects are drawn in the same order they're listed in the array. That means later objects are superimposed over earlier ones, and when shapes overlap, it's always the shape on top that should get the click.

To determine if a click has landed in a shape, you need to use some math. In the case of a circle, you need to calculate the straight-line distance from the clicked point to the center of the circle. If the distance is less than or equal to the radius of the circle, then the point lies inside its bounds.

In the current example, the web page handles the `onClick` event of the canvas to check for circle clicks. When the user clicks the canvas, it triggers a function named `canvasClick()`. That function figures out the click coordinates and then sees if they intersect any circle:

```
function canvasClick(e) {
    // Get the canvas click coordinates.
    var clickX = e.pageX - canvas.offsetLeft;
    var clickY = e.pageY - canvas.offsetTop;

    // Look for the clicked circle.
    for (var i=circles.length; i>0; i--) {
        // Use Pythagorean theorem to find the distance from this point
        // and the center of the circle.
        var distanceFromCenter =
            Math.sqrt(Math.pow(circle.x - clickX, 2) + Math.pow(circle.y - clickY, 2))

        // Does this point lie in the circle?
        if (distanceFromCenter <= circle.radius) {
            // Clear the previous selection.
            if (previousSelectedCircle != null) {
                previousSelectedCircle.isSelected = false;
            }
            previousSelectedCircle = circle;

            // Select the new circle.
            circle.isSelected = true;

            // Update the display.
            drawCircles();

            // Stop searching.
            return;
        }
    }
}
```

Note: You'll look at another way to do hit testing—by grabbing raw pixels and checking their color—when you create a maze game, on page 234.

To finish this example, the drawing code in the `drawCircles()` function needs a slight tweak. Now it needs to single out the selected circle for special treatment (in this case, a thick, bold border):

```
function drawCircles() {
    ...

    // Go through all the circles.
    for(var i=0; i<circles.length; i++) {
        var circle = circles[i];

        if (circle.isSelected) {
            context.lineWidth = 5;
        }
        else {
            context.lineWidth = 1;
        }
        ...
    }
}
```

There's no end of ways that you can build on this example and make it smarter. For example, you can add a toolbar of commands that modify the selected circle—for example, changing its color or deleting it from the canvas. Or, you can let the user drag the selected circle around the canvas. To do that, you simply need to listen for the `onMouseMove` event of the canvas, change the circle coordinates accordingly, and call the `drawCircles()` function to repaint the canvas. (This technique is essentially a variation of the mouse-handling logic in the paint program on page 190, except now you're using mouse movements to drag a shape, not draw a line.) The try-out site (www.prosetech.com/html5) includes a variation of this example named `InteractiveCircles_WithDrag.html` that demonstrates this technique.

The lesson is clear: If you keep track of what you draw, you have unlimited flexibility to change it and redraw it later on.

Animating the Canvas

Drawing one perfect picture can seem daunting enough. So it's no surprise that even seasoned web developers approach the idea of drawing several dozen each second with some trepidation. The whole challenge of animation is to draw and redraw canvas content fast enough that it looks like it's moving or changing right in front of your visitors.

Animation is an obvious and essential building block for certain types of applications, like real-time games and physics simulators. But simpler forms of animation make sense in a much broader range of canvas-powered pages. You can use animation to highlight user interactivity (for example, making a shape glow, pulse, or twinkle when someone hovers over it). You can also use animation to draw attention to

changes in content (for example, fading in a new scene, or creating graphs and charts that “grow” into the right positions). Used in these ways, animation is a powerful way to give your web applications some polish, make them feel more responsive, and even help them stand out from the crowd of web competitors.

A Basic Animation

It’s easy enough to animate a drawing on an HTML5 canvas. First, you set a timer that calls your drawing over and over again—typically 30 or 40 times each second. Each time, your code repaints the entire canvas from scratch. If you’ve done your job right, the constantly shifting frames will blend into a smooth, lifelike animation.

JavaScript gives you two ways to manage this repetitive redrawing:

- **Use the `setTimeout()` function.** This tells the browser to wait a few milliseconds and then run a piece of code—in this case, that’s your canvas-drawing logic. Once your code finishes, you call `setTimeout()` to ask the browser to call it again, and so on, until you want your animation to end.
- **Use the `setInterval()` function.** Tells your browser to run a piece of code at regular intervals (say, every 20 milliseconds). It has much the same effect as `setTimeout()`, but you need to call `setInterval()` only once. To stop the browser from calling your code, you call `clearInterval()`.

If your drawing code is quick, both of these have the same effect. If your drawing code is less than snappy, then the `setInterval()` approach will do a better job keeping your redraws precisely on time, but possibly at the expense of performance. (In the worst-case situation, when your drawing code takes a bit longer than the interval you’ve set, your browser will struggle to keep up, your drawing code will run continuously, and your page may briefly freeze up.) For this reason, the examples in this chapter use the `setTimeout()` approach.

When you call `setTimeout()`, you supply two pieces of information: The name of the function you want to run, and the amount of time to wait before running it. You give the amount of time as a number of milliseconds (thousandths of a second), so 20 milliseconds (a typical delay for animation) is 0.02 seconds. Here’s an example:

```
var canvas;
var context;

window.onload = function() {
  canvas = document.getElementById("canvas");
  context = canvas.getContext("2d");

  // Draw the canvas in 0.02 seconds.
  setTimeout("drawFrame()", 20);
};
```

This call to `setTimeout()` is the heart of any animation task. For example, imagine you want to make a square fall from the top of the page to the bottom. To do this, you need to keep track of the square's position using two global variables:

```
// Set the square's initial position.
var squarePosition_y = 0;
var squarePosition_x = 10;
```

Now, you simply need to change the position each time the `drawFrame()` function runs, and then redraw the square in its new position:

```
function drawFrame() {
  // Clear the canvas.
  context.clearRect(0, 0, canvas.width, canvas.height);

  // Call beginPath() to make sure you don't redraw
  // part of what you were drawing before.
  context.beginPath();

  // Draw a 10x10 square, at the current position.
  context.rect(squarePosition_x, squarePosition_y, 10, 10);
  context.strokeStyle = "black";
  context.lineWidth = 1;
  context.stroke();

  // Move the square down 1 pixel (where it will be drawn
  // in the next frame).
  squarePosition_y += 1;

  // Draw the next frame in 20 milliseconds.
  setTimeout("drawFrame()", 20);
}
```

Run this example, and you'll see a square that plummets from the top of the canvas and carries on, disappearing past the bottom edge.

In a more sophisticated animation, the calculations get more complex. For example, you may want to make the square accelerate to simulate gravity, or bounce at the bottom of the page. But the basic technique—setting a timer, calling a drawing function, and redrawing the entire canvas—stays exactly the same.

Animating Multiple Objects

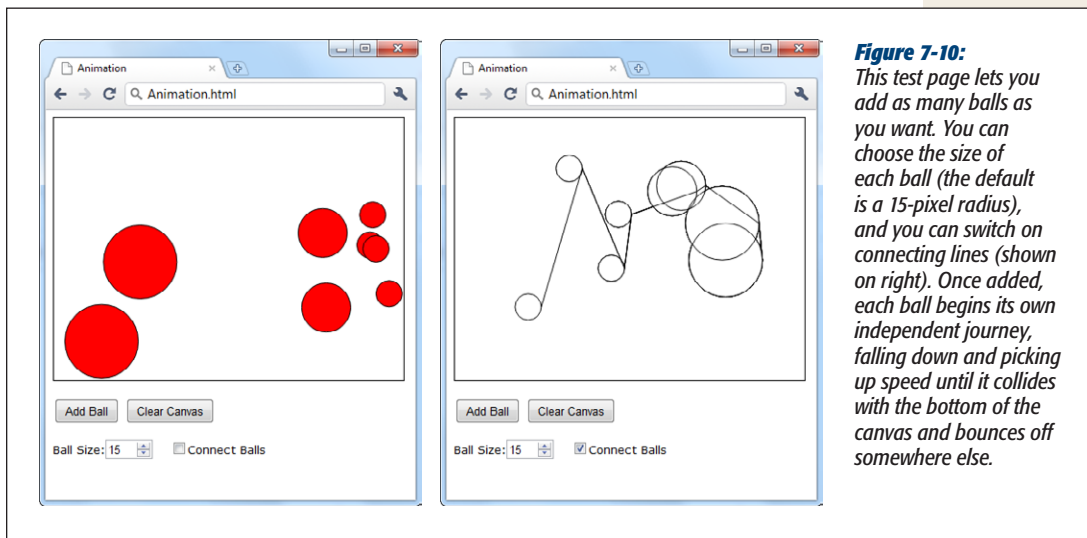

Now that you've learned the basics of animation and the basics of making interactive canvas drawings, it's time to take the next step and merge them together. Figure 7-10 shows a test page with an animation of falling, bouncing balls. The page uses the familiar `setTimeout()` method you met in the last section, but now the drawing code has to manage an essentially unlimited number of flying balls.

UP TO SPEED

Animation Performance

Because of these rapid redraws, it's clear that animation will tax the abilities of the canvas far more than ordinary drawing does. However, the canvas holds up surprisingly well. Modern browsers use performance-enhancing features like *hardware acceleration*, which farms out some of the graphical work to the computer's video card, rather than using its CPU for everything. And even though JavaScript isn't the fastest language on the block, it's quite possible to create a complex, high-speed animation—even a real-time arcade game—without using anything except script code and the canvas.

However, canvas performance *can* become a problem for people using underpowered mobile devices, like iPhones or phones running Google's Android operating system. Tests have shown that an animation that can run at 60 fps (frames per second) on a desktop browser probably tops out at a jerky 10 fps on a smartphone. So if you want to create an application for mobile visitors, make sure you test before you get too far into your design, and be prepared to sacrifice some of the animation eye candy to keep things running smoothly.

Tip: Pictures can't do justice to animations. To find out how animations like the one in Figure 7-10 look and feel, you can try out the examples for yourself at www.prosetech.com/html5.

To manage all these balls, you need to reuse the custom object trick you picked up on page 217. Only now you need to track an array of ball objects, and each ball needs not only a position (represented by the properties `x` and `y`), but also a speed (represented by `dx` or `dy`):

```
// These are the details that represent an individual ball.
function Ball(x, y, dx, dy, radius) {
    this.x = x;
    this.y = y;
    this.dx = dx;
    this.dy = dy;
    this.radius = radius;
    this.color = "red";
}

// This is an array that will hold all the balls on the canvas.
var balls = [];
```

Note: In mathematics lingo, `dx` is the rate that `x` is changing, and `dy` is the rate that `y` is changing. So as the ball is falling, each frame `x` increases by the `dx` amount and `y` increases by the `dy` amount.

When the visitor clicks the Add Ball button, a simple bit of code creates a new ball object and stores it in the balls array:

```
function addBall() {
    // Get the requested size.
    var radius = parseFloat(document.getElementById("ballSize").value);

    // Create the new ball.
    var ball = new Ball(50,50,1,1,radius);

    // Store it in the balls array.
    balls.push(ball);
}
```

The Clear Canvas button has the complementary task of emptying the balls array:

```
function clearBalls() {
    // Remove all the balls.
    balls = [];
}
```

However, neither the `addBall()` nor the `clearBalls()` function actually draws anything. Neither one even calls a drawing function. Instead, the page sets itself up to call the `drawFrame()` function, which paints the canvas in 20 milliseconds intervals:

```
var canvas;
var context;

window.onload = function() {
    canvas = document.getElementById("canvas");
    context = canvas.getContext("2d");

    // Redraw every 20 milliseconds.
    setTimeout("drawFrame()", 20);
};
```

The `drawFrame()` function is the heart of this example. It not only paints the balls on the canvas, but it also calculates their current position and speed. The `drawFrame()` function uses a number of calculations to simulate more realistic movement—for example, making balls accelerate as they fall and slow down when they bounce off of obstacles. Here's the complete code:

```
function drawFrame() // Clear the canvas.
    context.clearRect(0, 0, canvas.width, canvas.height);
    context.beginPath();

    // Go through all the balls.
    for(var i=0; i<balls.length; i++) {
        // Move each ball to its new position.
        var ball = balls[i];
        ball.x += ball.dx;
        ball.y += ball.dy;

        // Add in a "gravity" effect that makes the ball fall faster.
        if ((ball.y) < canvas.height) ball.dy += 0.22;

        // Add in a "friction" effect that slows down the side-to-side motion.
        ball.dx = ball.dx * 0.998;

        // If the ball has hit the side, bounce it.
        if ((ball.x + ball.radius > canvas.width) || (ball.x - ball.radius < 0)) {
            ball.dx = -ball.dx;
        }

        // If the ball has hit the bottom, bounce it, but slow it down slightly.
        if ((ball.y + ball.radius > canvas.height) || (ball.y - ball.radius < 0))
        {
            ball.dy = -ball.dy*0.96;
        }

        // Check if the user wants lines.
        if (!document.getElementById("connectedBalls").checked) {
            context.beginPath();
            context.fillStyle = ball.fillColor;
        }
        else {
            context.fillStyle = "white";
        }

        // Draw the ball.
        context.arc(ball.x, ball.y, ball.radius, 0, Math.PI*2);
        context.lineWidth = 1;
        context.fill();
        context.stroke();
    }

    // Draw the next frame in 20 milliseconds.
    setTimeout("drawFrame()", 20);
}
```

Tip: If you're fuzzy about how the *if* statements work in this example, and what operators like `!` and `||` really mean, check out the summary of logical operators on page 409 in Appendix B.

The sheer amount of code can seem a bit intimidating. But the overall approach hasn't changed. The code performs the same steps:

1. Clear the canvas.
2. Loop through the array of balls.
3. Adjust the position and velocity of each ball.
4. Paint each ball.
5. Set a timeout so the `drawFrame()` method will be called again, 20 milliseconds later.

The complex bit is step 3, where the ball is tweaked. This code can be as complicated as you like, depending on the effect you're trying to achieve. Gradual, natural movement is particularly difficult to model, and it usually needs more math.

Finally, now that you've done all the work tracking each ball, it's easy to add interactivity. In fact, you can use virtually the same code you used to detect clicks in the circle-drawing program on page 220. Only now, when a ball is clicked, you want something else to happen—for example, you might choose to give the clicked ball a sudden boost in speed, sending it ricocheting off to the side. (The downloadable version of this example, available at www.prosetech.com/html5, does exactly that.)

FREQUENTLY ASKED QUESTION

Canvas Animations for Busy (or Lazy) People

Do I really need to calculate everything on my own? For real?

The most significant drawback to canvas animation is the fact that you need to do everything yourself. For example, if you want a picture to fly from one side of the canvas to the other, you need to calculate its new position in each frame, and then draw the picture in its proper location. If you have several things being animated at the same time in different ways, your logic can quickly get messy. By comparison, life is much easier for programmers who are using a browser plug-in like Flash or Silverlight. Both technologies have built-in animation systems, which allow developers to give instructions like “move this shape from here to there,

taking 45 seconds.” Or, even better, “move this shape from the top of the window to the bottom, using an accelerating effect that ends with a gentle bounce.”

There's no doubt that someone, at some point in the future, will layer a higher-level animation system on top of the canvas. Ideally, you'll be able to use this animation system to pick the effects you want, without having to slog through all the math. It's most likely that this higher-level animation system will be a JavaScript library, not a core enhancement to the HTML specification. However, it's still too early to know which toolkits will be the most capable, the least buggy, and the best supported.

To see this example carried to its most impressive extreme, check out the bouncing Google balls at <http://tinyurl.com/6byvnk5>. When left alone, the balls are pulled, magnet-like, to spell the word “Google.” But when your mouse moves in, they’re repulsed, flying off to the far corners of the canvas and bouncing erratically. And if you’re still hungry for more animation examples, check out the poke-able blob at <http://www.blobsallad.se> and the somewhat clichéd flying star field at <http://tinyurl.com/crn3ed>.

A Practical Example: the Maze Game

So far, you’ve explored how to combine the canvas with some key programming techniques to make interactive drawings and to perform animations. These building blocks take the canvas beyond mere drawing and into the realm of complete, self-contained applications—like games or Flash-style mini-apps.

Figure 7-11 shows a more ambitious example that takes advantage of what you’ve learned so far and builds on both concepts. It’s a simple game that invites the user to guide a small happy face icon through a complex maze. When the user presses an arrow key, the happy face starts moving in that direction (using animation) and stops only when it hits a wall (using hit testing).

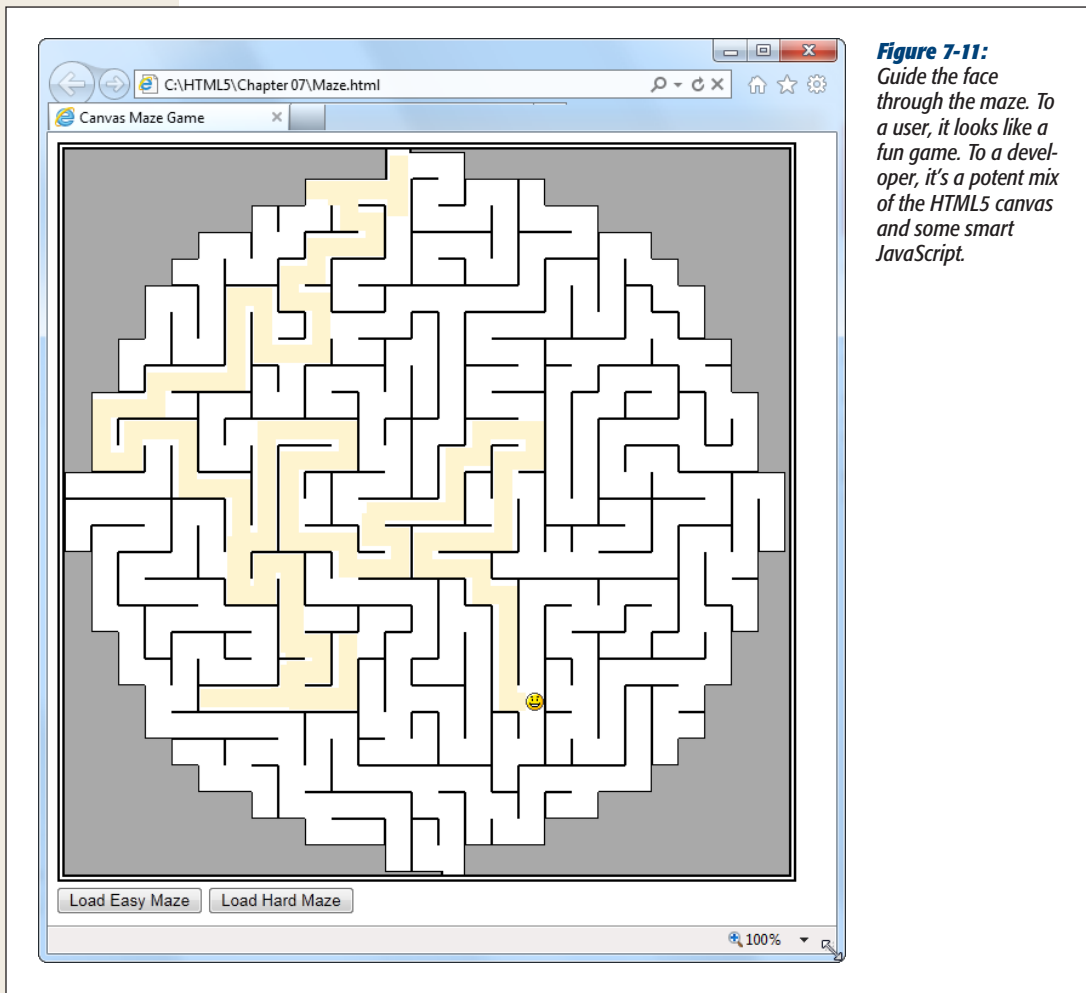

Of course, there’s a trade-off. If you’re going to rely on the canvas to build something sophisticated, you’ll need to dig your way through a significant amount of code. The following sections show you the essentials, but be prepared to flex your JavaScript muscles.

Note: You can run this example from your local computer if you’re using Internet Explorer 9. But on other browsers, it works only if you first put your page (and the graphics it uses) on a test web server. To save the trouble, run this example from the try-out site at www.prosetech.com/html5.

Setting Up the Maze

Before anything can happen, the page needs to set up the canvas. Although you could paint the entire maze out of lines and rectangles, you’d need a lot of drawing code. Writing that drawing code by hand would be extremely tedious. You’d need to have a mental model of the entire maze, and then draw each short wall segment using a separate drawing operation. If you went this route, you’d almost certainly use a tool that automatically creates your drawing code. For example, you might draw the maze in Adobe Illustrator and then use a plug-in to convert it to canvas code (page 183).

Another option is to take a preexisting graphic of a maze and paint that on the canvas. This is particularly easy, because the web is filled with free pages that will create mazes for you. Using one of these pages, you set a few details—for example, the size, shape, colors, density, and complexity of the maze—and the page creates a downloadable graphic. (To try it out for yourself, just Google *maze generator*.)

This example uses maze pictures. When the page first loads, it takes a picture file (named *maze.png*) and draws that on the canvas. Here's the code that kicks that process off when the page first loads:

```
// Define the global variables for the canvas and drawing context.
var canvas;
var context;

window.onload = function() {
  // Set up the canvas.
  canvas = document.getElementById("canvas");
  context = canvas.getContext("2d");
}
```

```
// Draw the maze background.
drawMaze("maze.png", 268, 5);

// When the user presses a key, run the processKey() function.
window.onkeydown = processKey;
};
```

This code doesn't actually draw the maze background. Instead, it hands the work off to another function, named `drawMaze()`.

Because this example uses a separate maze-drawing function, it's not limited to a single maze. Instead, it lets you load any maze graphic you want. You simply need to call `drawMaze()` and pass in the file name of the maze picture, along with the coordinates for where the happy face should start. Here's the `drawMaze()` code that does the job:

```
// Keep track of the current face position.
var x = 0;
var y = 0;

function drawMaze(mazeFile, startingX, startingY) {
  // Load the maze picture.
  imgMaze = new Image();
  imgMaze.onload = function() {
    // Resize the canvas to match the size of the maze picture.
    canvas.width = imgMaze.width;
    canvas.height = imgMaze.height;

    // Draw the maze.
    var imgFace = document.getElementById("face");
    context.drawImage(imgMaze, 0,0);

    // Draw the face.
    x = startingX;
    y = startingY;

    context.drawImage(imgFace, x, y);
    context.stroke();

    // Draw the next frame in 10 milliseconds.
    setTimeout("drawFrame()", 10);
  };
  imgMaze.src = mazeFile;
}
```

This code uses the two-step image drawing method explained on page 201. First, it sets a function that will handle the image's `onLoad` event and draw the maze image, after it loads. Second, it sets the `src` attribute on the image object, which loads the image and triggers the code. This two-step process is a bit more complicated than just pulling the picture out of a hidden `` element on the page, but it's necessary if you want to create a function that's flexible enough to load any maze picture you want.

When the maze image is loaded, the code adjusts the size of the canvas to match, places the face at its proper position, and then paints the face image. Finally, it calls `setTimeout()` to start drawing frames.

Note: The downloadable version of this example (at www.prosetech.com/html5) is slightly more sophisticated. It lets the user load a new maze at any time—even while the happy face is still moving around the current maze. To make this work, it adds a bit of extra code in the `drawMaze()` function to stop the happy face (if it's currently moving) and halt the animating process, before loading the background and starting it again.

Animating the Face

When the user hits a key, the face begins moving. For example, if the user presses the down key, the happy face continues moving down until it hits a barrier or another key is pressed.

To make this work, the code uses two global variables that track the happy face's speed—in other words, how many pixels it will move in the x or y dimension, per frame. The variables that do this are named *dx* and *dy*, just as they were in the bouncing ball example (page 226). The difference is that you don't need an array for this page, because there's only one happy face:

```
var dx = 0;
var dy = 0;
```

When the user presses a key, the canvas calls the `processKey()` function. The function then checks if one of the arrow keys was pressed, and adjusts the speed accordingly. To identify an arrow key, the code checks its key code against a known value. For example, a key code of 38 always represents the up arrow key. The `processKey()` function ignores all other keys except the arrow keys:

```
function processKey(e) {
    // If the face is moving, stop it.
    dx = 0;
    dy = 0;

    // The up arrow was pressed, so move up.
    if (e.keyCode == 38) {
        dy = -1;
    }

    // The down arrow was pressed, so move down.
    if (e.keyCode == 40) {
        dy = 1;
    }

    // The left arrow was pressed, so move left.
    if (e.keyCode == 37) {
        dx = -1;
    }
}
```

```

    // The right arrow was pressed, so move right.
    if (e.keyCode == 39) {
        dx = 1;
    }
}

```

The `processKey()` function doesn't change the current position of the happy face, or attempt to draw it. Instead, this task happens every 10 milliseconds, when the `drawFrame()` function is called.

The `drawFrame()` code is fairly straightforward, but detailed. It performs several tasks. First, it checks if the face is moving in either direction. If not, there's really no work to be done:

```

function drawFrame() {
    if (dx != 0 || dy != 0) {

```

If the face is moving, the `drawFrame()` code draws a yellow patch in the current face position (which creates the "trail" effect. It then moves the face to its new position:

```

        context.beginPath();
        context.fillStyle = "rgb(254,244,207)";
        context.rect(x, y, 15, 15);
        context.fill()

```

```

        // Increment the face's position.
        x += dx;
        y += dy;

```

Next, the code calls `checkForCollision()` to see if this new position is valid. (You'll see the code for this hit testing function in the next section.) If the new position isn't valid, the face has hit a wall, and the code must move the face back to its old position and stop it from moving:

```

        if (checkForCollision()) {
            x -= dx;
            y -= dy;
            dx = 0;
            dy = 0;
        }

```

Now the code is ready to draw the face, where it belongs:

```

        var imgFace = document.getElementById("face");
        context.drawImage(imgFace, x, y);

```

And check if the face reached the bottom of the maze (and has thus completed it). If so, the code shows a message box:

```

        if (y > (canvas.height - 17)) {
            alert("You win!");
            return;
        }
    }
}

```

If not, the code sets a timeout so the `drawFrame()` method will be called again, 10

milliseconds later:

```
// Draw a new frame in 10 milliseconds.  
setTimeout("drawFrame()", 10);  
}
```

You’ve now seen all the code for the maze game code, except the innovative bit of logic in the `checkForCollision()` function, which handles the hit testing. That’s the topic you’ll tackle next.

Hit Testing with Pixel Colors

Earlier in this chapter, you saw how you can use mathematical calculations to do your hit testing. However, there’s another approach you can use. Instead of looking through a collection of objects you’ve drawn, you can grab a block of pixels and look at their colors. This approach is simpler in some ways, because it doesn’t need all the objects and the shape tracking code. But it works only if you can make clear-cut assumptions about the colors you’re looking for.

Note: The pixel-based hit-testing approach is the perfect approach for the maze example. Using this sort of hit testing, you can determine when the happy face runs into one of the black walls. Without this technique, you’d need a way to store all the maze information in memory, and then determine if the current happy-face coordinates overlap one of the maze’s wall lines.

The secret to the color-testing approach is the canvas’s support for manipulating individual pixels—the tiny dots that comprise every picture. The drawing context provides three methods for managing pixels: `getImageData()`, `putImageData()`, and `createImageData()`. You use `getImageData()` to grab a block of pixels from a rectangular region and examine them (as in the maze game). You can also modify the pixels and use `putImageData()` to write them back to the canvas. And finally, `createImageData()` lets you create a new, empty block of pixels that exists only in memory, the idea being that you can customize them and then write them to the canvas with `putImageData()`.

To understand a bit more about the pixel-manipulation methods, consider the following code. First, it grabs a 100×50 square of pixels from the current canvas, using `getImageData()`:

```
// Get pixels starting at point (0,0), and stretching out 100 pixels to  
// the right and 50 pixels down.  
var imageData = context.getImageData(0, 0, 100, 50);
```

Then, the code retrieves the array of numbers that has the image data, using the *data* property:

```
var pixels = imageData.data;
```

You might expect that there’s one number for each pixel, but life isn’t that simple.

There are actually *four* numbers for each pixel, one each to represent its red, green, blue, and alpha components. So if you want to examine each pixel, you need a loop that bounds through the array four steps at a time, like this:

```
// Loop over each pixel and invert the color.
for (var i = 0, n = pixels.length; i < n; i += 4) {

    // Get the data for one pixel.
    var red = pixels[i];
    var green = pixels[i+1];
    var blue = pixels[i+2];
    var alpha = pixels[i+3];

    // Invert the colors.
    pixels[i] = 255 - red;
    pixels[i+1] = 255 - green;
    pixels[i+2] = 255 - blue;
}
```

Each number ranges from 0 to 255. The code above uses one of the simplest image manipulation methods around—it inverts the colors. Try this with an ordinary picture, and you get a result that looks like a photo negative.

To see the results, you can write the pixels back to the canvas, in their original position (although you could just as easily paint the content somewhere else):

```
context.putImageData(imageData, 0, 0);
```

The pixel-manipulation methods certainly give you a lot of control. However, they also have drawbacks. The pixel operations are slow, and the pixel data in the average canvas is immense. If you grab off a large chunk of picture data, you'll have tens of thousands of pixels to look at. And if you were already getting tired of drawing complex pictures using basic ingredients like lines and curves, you'll find that dealing with individual pixels is even more tedious.

That said, the pixel-manipulation methods can solve certain problems that would be difficult to deal with in any other way. For example, they provide the easiest way to create fractal patterns and Photoshop-style picture filters. In the maze game, they let you create a concise routine that checks the next move of the happy face icon, and determine whether it collides with a wall. Here's the `checkForCollision()` function that handles the job:

```
function checkForCollision() {
    // Grab the block of pixels where the happy face is, but extend
    // the edges just a bit.
    var imgData = context.getImageData(x-1, y-1, 15+2, 15+2);
    var pixels = imgData.data;

    // Check these pixels.
    for (var i = 0; n = pixels.length, i < n; i += 4) {
        var red = pixels[i];
        var green = pixels[i+1];
        var blue = pixels[i+2];
        var alpha = pixels[i+3];
    }
}
```

```
// Look for black walls (which indicates a collision).
if (red == 0 && green == 0 && blue == 0) {
    return true;
}
// Look for gray edge space (which indicates a collision).
if (red == 169 && green == 169 && blue == 169) {
    return true;
}
}
// There was no collision.
return false;
}
```

This completes the canvas maze page, which is the longest and most code-packed example you'll encounter in this book. It may take a bit more review (or a JavaScript brush-up) before you really feel comfortable with all the code it contains, but once you do you'll be able to use similar techniques in your own canvas creations.

POWER USERS' CLINIC

Eye-Popping Canvas Examples

There's virtually no limit to what you can do with the canvas. If you want to look at some even more ambitious examples that take HTML5 into the world of black-belt coding, the Web is your friend. Here's a list of websites that demonstrate some mind-blowing canvas mojo:

- **Canvas Demos.** This canvas example site has enough content to keep you mesmerized for days. Recent entries at the time of this writing include the game *Mutant Zombie Masters* and the stock-charting tool *TickerPlot*. Visit www.canvasdemos.com to browse them all.
- **Wikipedia knowledge map.** This impressive canvas application shows a graphical representation of Wikipedia articles, with linked topics connected together by slender, web-like lines. Choose a new topic

and you zoom into that part of the knowledge map, pulling new articles to the forefront with a slick animation. See it at <http://en.inforapid.org>.

- **3D Walker.** This example lets you walk through a simple 3-D world of walls and passages (similar to the ancient *Wolfenstein 3-D* game that kicked off the first-person-shooter gaming craze way back in 1992). Take it for a spin at www.benjoffe.com/code/demos/canvascape.
- **Chess.** This HTML5 chess simulator lets you try your hand against a computer opponent with a canvas-drawn board that's rendered from above or with a three-dimensional perspective, depending on your preference. Challenge yourself to a game at <http://htmlchess.sourceforge.net/demo/example.html>.

Boosting Styles with CSS3

It would be almost ludicrous to build a modern website *without* CSS. The standard is fused into the fabric of the Web almost as tightly as HTML. Whether you're laying out pages, building interactive buttons and menus, or just making things look pretty, CSS is a fundamental tool. In fact, as HTML has increasingly shifted its focus to content and semantics (page 44), CSS has become the heart and soul of web *design*.

Along the way, CSS has become far more detailed and far more complex. When CSS evolved from its first version to CSS 2.1, it quintupled in size, reaching the size of a modest novel. Fortunately, the creators of the CSS standard had a better plan for future features. They carved the next generation of enhancements into a set of separate standards, called *modules*. That way, browser makers were free to implement the most exciting and popular parts of the standard first—which is what they were already doing, modules or not. All together, the new CSS modules fall under the catchall name CSS3 (note the curious lack of a space, as with *HTML5*).

CSS3 has roughly 50 modules in various stages of maturity. They range from features that provide fancy eye candy (like rich fonts and animation) to ones that serve a more specialized, practical purpose (for example, speaking text aloud or varying styles based on the capabilities of the computer or mobile device). Altogether, they include features that are reliably supported in the most recent versions of all modern browsers and features so experimental that *no* browser yet supports them.

In this chapter, you'll tour some of the most important (and best supported) parts of CSS3. First, you'll learn how to jazz up your text with virtually any font. Then, you'll learn how to tailor your styles to suit different sized browser windows and different types of web-connected devices, like iPads and iPhones. Next, you'll see how to use

shadows, rounded corners, and other refinements to make your boxes look better. Finally, you'll learn how you can use transitions to create subtle effects when the visitor hovers over an element, clicks on it, or tabs over to a control. (And you'll make these effects even better with two more CSS3 features: transforms and transparency.)

But first, before you get to any of these hot new features, it's time to consider how you can plug in the latest and most stylin' styling features without leaving a big chunk of your audience behind.

Using CSS3 Today

CSS3 is the unchallenged future of web styling, and it's not finished yet. Most modules are still being refined and revised, and no browser supports them all. This means CSS has all the same complications as HTML5. Website authors like yourself need to decide what to use, what to ignore, and how to bridge the gaping support gaps.

There are essentially three strategies you can use when you start incorporating CSS3 into a website. The following sections describe them.

Note: CSS3 is not part of HTML5. The standards were developed separately, by different people working at different times in different buildings. However, even the W3C encourages web developers to lump HTML5 and CSS3 together as part of the same new wave of modern web development. For example, if you check out the W3C's HTML5 logo-building page at www.w3.org/html/logo, you'll see that it encourages you to advertise CSS3 in its HTML5 logo strips.

Strategy 1: Use What You Can

It makes sense to use features that already have solid browser support across all browser brands. One example is the web font feature (page 244). With the right font formats, you can get it working with browsers all the way back to IE 6. Unfortunately, very few CSS3 features fall into this category. The word-wrap property works virtually everywhere, and older browsers can do transparency with a bit of fiddling, but just about every other feature leaves the still-popular IE 7 and IE 8 browsers in the dust.

Note: Unless otherwise noted, the features in this chapter work on the latest version of every modern browser, including Internet Explorer 9. However, they don't work on older versions of IE.

Strategy 2: Treat CSS3 Features as Enhancements

CSS3 fans have a rallying cry: “Websites don't need to look exactly the same on every browser.” Which is certainly true. (They have a website, too—see <http://DoWebsitesNeedToBeExperiencedExactlyTheSameInEveryBrowser.com>.)

The idea behind this strategy is to use CSS3 to add fine touches that won't be missed by people using less-capable browsers. One example is the `border-radius` property that you can use to gently round the corners of a floating box. Here's an example:

```
header {
  background-color: #7695FE;
  border: thin #336699 solid;
  padding: 10px;
  margin: 10px;
  text-align: center;
  border-radius: 25px;
}
```

Browsers that recognize the `border-radius` property will know what to do. Older browsers will just ignore it, keeping the plain square corners (Figure 8-1).

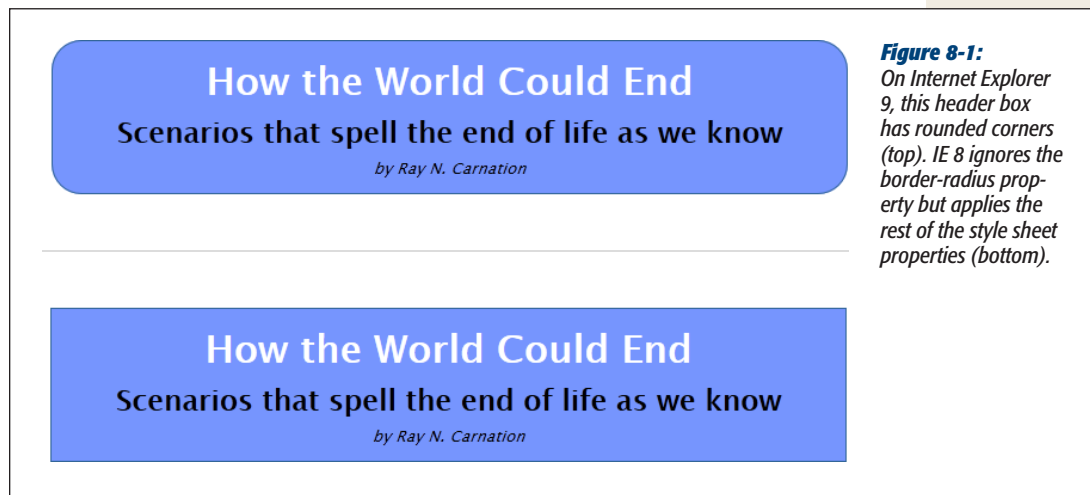

Figure 8-1:

On Internet Explorer 9, this header box has rounded corners (top). IE 8 ignores the border-radius property but applies the rest of the style sheet properties (bottom).

There's an obvious appeal to this strategy, because it gives web designers justification to play with all the latest technology toys. However, there's a definite downside if you go too far. No matter how good a website looks in the latest version of your favorite browser, it can be deeply deflating if you fire up an older browser that's used by a significant slice of your clientele and find that it looks distinctly less awesome. After all, you want your website to impress everyone, not just web nerds with the best browsers.

For this reason, you may want to approach some CSS3 enhancements with caution. Limit yourself to features that are already in multiple browsers (and are at least promised for IE 10). And don't use them in ways that change the experience of your website so dramatically that some people are getting second-rate status.

Tip: When it comes to CSS3, Internet Explorer is the straggler. There's a militant minority of web designers who believe that web designers should ignore IE and start using CSS3 features as soon as other browsers support them. Otherwise, who will keep pressure on Microsoft and encourage the Web to get better? This is all well and fine, if the primary purpose of your website is the political one of promoting advanced web standards. But otherwise, keep in mind that dismissing a large segment of the web world will reflect poorly on you—because no matter how much you dislike someone's browser, that person is still using it to look at *your* work.

Strategy 3: Add Fallbacks with Modernizr

Using a partially supported CSS3 feature is a great idea if the website still looks great without it. But sometimes, a vital part of your website design can go missing, or the downgraded version of your website just looks ugly. For example, consider what happens if you use the Firefox-only multicolored border settings, as shown in Figure 8-2.

Dig this multicolored border on Firefox.

But it's not so nice on Chrome.

Figure 8-2:

This multicolored border looks snazzy in Firefox (top). But try the same thing out in Chrome, and you'll get a thick, plain black border (bottom)—and that never looks good.

Sometimes, you can solve the problem by stacking properties in the right order. The basic technique is to start with more general properties, followed by new properties that *override* these settings. When this works, it satisfies every browser—the old browsers get the standard settings, while the new browsers override these settings with newer ones. For example, you can use this technique to replace an ordinary background fill with a gradient:

```
.stylishBox {
  ...
  background: yellow;
  background: radial-gradient(ellipse, red, yellow);
}
```

Figure 8-3 shows the result.

If you see a yellow background,
you're lingering in the past.

If you see a radial gradient, you're
rocking it, HTML5 style.

Figure 8-3:

Top: In browsers that don't understand CSS3, the `stylishBox` rule paints a yellow background.

Bottom: In browsers that do understand CSS3, the yellow background is replaced with a radial gradient that blends from a red center point to yellow at the edges. (At least, that's the plan. This example doesn't work exactly as written, because the radial-gradient standard is still being revised. To get the result shown here, you need vendor prefixes, as described on page 243.)

If you see a yellow background,
you're lingering in the past.

If you see a radial gradient, you're
rocking it, HTML5 style.

In some cases, overriding style properties doesn't work, because you need to set properties in *combination*. The multicolored border in Figure 8-2 is an example. The multicolored effect is set with the `border-colors` property, but appears only if the border is made thick with the `border-thickness` property. On browsers that don't support multicolored borders, the thick border is an eyesore, no matter what single color you use.

One way to address problems like these is with Modernizr, the JavaScript library that tests HTML5 feature support (page 38). It lets you define alternate style settings for browsers that don't support the style properties you really want. For example, imagine you want to create two versions of the header box shown in Figure 8-1. You want to use rounded corners if they're supported, but substitute a double-line border if they aren't. If you've added the Modernizr script reference to your page, then you can use a combination of style rules, like this:

```
/* Settings for all headers, no matter what level of CSS3 support. */
header {
  background-color: #7695FE;
  padding: 10px;
  margin: 10px;
  text-align: center;
}
```

```

/* Settings for browsers that support border-radius. */
.borderradius header {
    border: thin #336699 solid;
    border-radius: 25px;
}

/* Settings for browsers that don't support border-radius. */
.no-borderradius header {
    border: 5px #336699 double;
}

```

So how does this nifty trick work? When you use Modernizr in a page, you begin by adding the `class="no-js"` attribute to the root `<html>` element:

```
<html class="no-js">
```

When you load Modernizr on a page, it quickly checks if a range of HTML5, JavaScript, and CSS3 features are supported. It then applies a pile of classes to the root `<html>` element, separated by spaces, changing it into something like this:

```

<html class="js flexbox canvas canvastext webgl no-touch geolocation
postmessage no-websql database indexeddb hashchange history draganddrop
no-websockets rgba hsla multiplebgs backgroundsize borderimage borderradius
boxshadow textshadow opacity no-cssanimations csscolumns cssgradients
no-cssreflections csstransforms no-csstransforms3d csstransitions fontface
generatedcontent video audio localstorage sessionstorage webworkers
applicationcache svg inlinesvg smil svgclippaths">

```

If a feature appears in the class list, that feature is supported. If a feature name is prefixed with the text “no-” then that feature is not supported. Thus, in the example shown here, JavaScript is supported (js) but web sockets are not (no-websockets). On the CSS3 side of things, the border-radius property works (borderradius) but CSS3 reflections do not (no-cssreflections).

You can incorporate these classes into your selectors to filter out style settings based on support. For example, a selectors like `.borderradius header` gets all the `<header>` elements inside the root `<html>` element—if the browser supports the border-radius property. Otherwise, there will be no `.borderradius` class, the selector won’t match anything, and the rule won’t be applied.

The catch is that Modernizr provides classes for only a subset of CSS3 features. This subset includes some of CSS3’s most popular and mature features, but the border-color feature in Figure 8-2 doesn’t qualify because it’s still Firefox-only. For that reason, it’s a good idea to hold off on using multicolored borders in your pages, at least for now.

Note: You can also use Modernizr to create JavaScript fallbacks. In this case, you simply need to check the appropriate property of the Modernizr object, as you do when checking for HTML5 support. You could use this technique to compensate if you’re missing more advanced CSS3 features, like transitions or animations. However, there’s so much work involved and the models are so different that it’s usually best to stick with a JavaScript-only solution for essential website features.

Browser-Specific Styles

When the creators of CSS develop new features, they often run into a chicken-and-egg dilemma. In order to perfect the feature, they need feedback from browser makers and web designers. But in order to get this feedback, browser makers and web designers need to implement these new-and-imperfect features. The result is a cycle of trial and feedback that takes many revisions to settle down. While this process unfolds, the syntax and implementation of features change. This raises a very real danger—unknowing web developers might learn about a dazzling new feature and implement it in their real-life websites, not realizing that future versions of the standard could change the rules and break the websites.

To avoid this threat, browser makers use a system of *vendor prefixes* to change CSS property and function names while they're still under development. For example, consider the new radial-gradient property described on page 271. To use it with Firefox, you need to set the “in progress” version of this property called *-moz-radial-gradient*. That's because Firefox uses the vendor prefix *-moz-* (which is short for Mozilla, the organization that's behind the Firefox project).

Every browser engine has its own vendor prefix (Table 8-1). This complicates life horrendously, but it has a good reason. Different browser makers add support at different times, often using different draft versions of the same specification. Although all browsers will support the same syntax for final specification, the syntax of the vendor-specific properties and functions often varies.

Table 8-1. *Vendor prefixes*

Prefix	For Browsers
-moz-	Firefox
-webkit-	Chrome and Safari (the same rendering engine powers both browsers)
-ms-	Internet Explorer
-o-	Opera

So, if you want to use a radial gradient today and support all the browsers you can (including the forthcoming IE 10), you'll need to use a bloated CSS rule like this one:

```
.stylishBox {
  background: yellow;
  background-image: -moz-radial-gradient(circle, green, yellow);
  background-image: -webkit-radial-gradient(circle, green, yellow);
  background-image: -o-radial-gradient(circle, green, yellow);
  background-image: -ms-radial-gradient(circle, green, yellow);
}
```

In this example, each rule sets the radial gradient using the same syntax. This indicates that the standard is settling down, and browser makers may soon be able to drop the vendor prefix and support the radial-gradient property directly (as they currently support corner-radius). However, this is a fairly recent development, as old versions of Chrome used completely different gradient syntax.

Note: Using vendor prefixes is a messy business. Web developers are split on whether they're a necessary evil of getting the latest and greatest frills, or a big fat warning sign that should scare clear-thinking designers away. But one thing is certain: If you don't use the vendor prefixes, a fair bit of CSS3 will be off-limits for now.

Web Typography

With all its pizzazzy new features, it's hard to pick the best of CSS3. But if you had to single out just one feature that opens an avalanche of new possibilities and is ready to use *right now*, that feature may just be web fonts.

In the past, web designers had to work with a limited set of web-safe fonts. These are the few fonts that are known to work on different browsers and operating systems. But as every decent designer knows, type plays a huge role in setting the overall atmosphere of a document. With the right font, the same content can switch from coolly professional to whimsical, or from old-fashioned to futuristic.

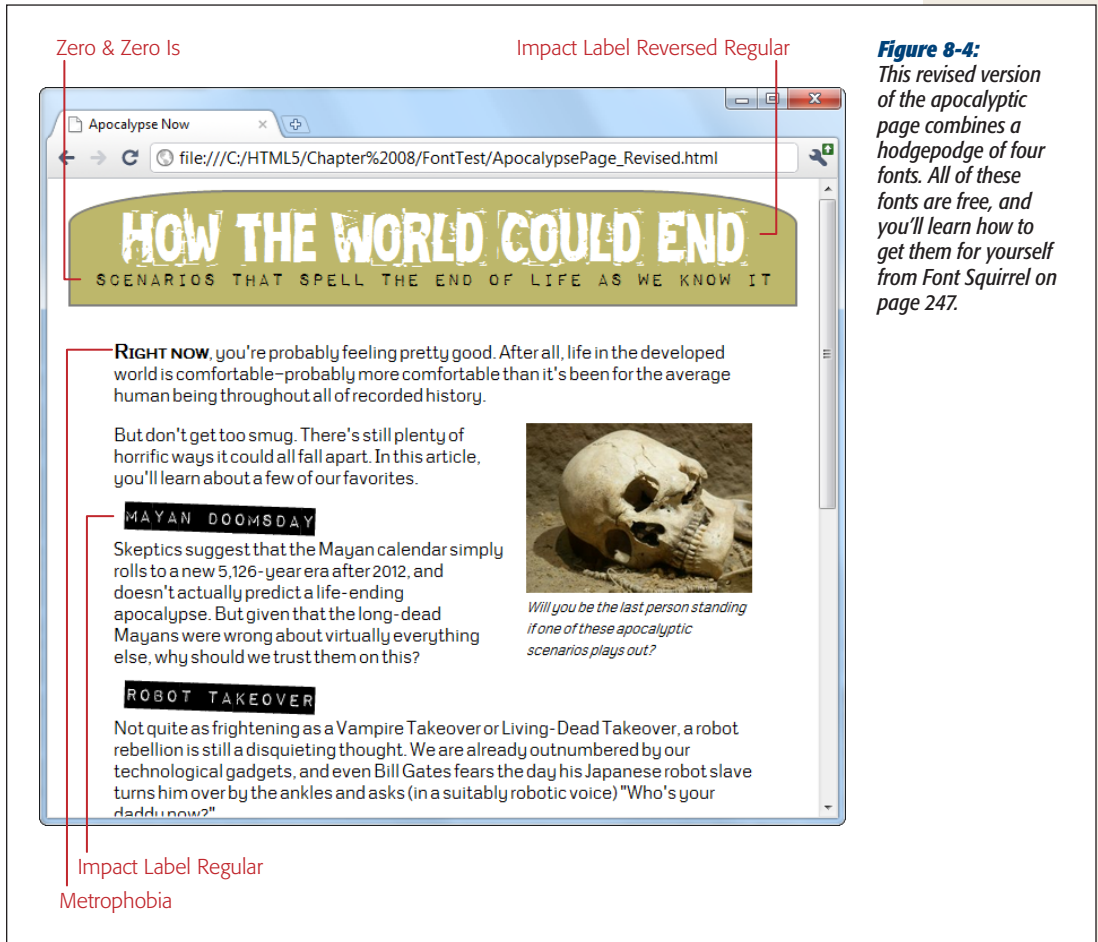

Note: There were good reasons why web browsers didn't rush to implement custom web fonts. First, there are optimization issues, because computer screens offer far less resolution than printed documents. If a web font isn't properly tweaked for onscreen viewing, it'll look like a blurry mess at small sizes. Second, most fonts aren't free. Big companies like Microsoft were understandably reluctant to add a feature that could encourage web developers to take the fonts installed on their computers and upload them to a website without proper permission. As you'll see in the next section, font companies now have good solutions for both problems.

CSS3 adds support for fancy fonts with the `@font-face` feature. Here's how it works:

1. You upload the font to your website (or, more likely, multiple versions of that font to support different browsers).
2. You register each font-face you want to use in your style sheet, using the `@font-face` command.
3. You use the registered font in your styles, by name, just as you use the web-safe fonts.
4. When a browser encounters a style sheet that uses a web font, it downloads the font to its temporary cache of pages and pictures. It then uses that font for just your page or website (Figure 8-4). If other web pages want to use the same font, they'll need to register it themselves and provide their own font files.

Note: Technically, `@font-face` isn't new. It was a part of CSS 2, but dropped in CSS 2.1 when the browser makers couldn't cooperate. Now, in CSS3, there's a new drive to make `@font-face` a universal standard.

The following sections walk you through these essential steps.

Web Font Formats

Although all current browsers support @font-face, they don't all support the same *types* of font files. Internet Explorer, which has supported @font-face for years, supports only EOT (Embedded OpenType) font files. This format has a number of advantages—for example, it uses compression to reduce the size of the font file, and it allows strict website licensing so a font can't be stolen from one website and used on another. However, the .eot format never caught on, and no other browser uses it. Instead, other browsers have (until recently) stuck with the more familiar font standards used in desktop computer applications—that's TTF (TrueType) and OTF (OpenType PostScript). But the story's still not complete without two more acronyms—SVG and WOFF. Table 8-2 puts all the font formats in perspective.

Table 8-2. *Embedded font formats*

Format	Description	Use with
TTF (TrueType) OTF (OpenType PostScript)	Your font will probably begin in one of these common desktop formats.	Firefox (before version 3.6), Chrome (before version 6), Safari, and Opera
EOT (Embedded Open Type)	A Microsoft-specific format that never caught on with browsers except Internet Explorer.	Internet Explorer (before IE 9)
SVG (Scalable Vector Graphics)	An all-purpose graphics format you can use for fonts, with good but not great results (it's slower to display and produces lower-quality text).	Safari Mobile (on the iPhone and iPad before iOS 4.2), and mobile devices using the Android operating system.
WOFF (Web Open Font Format)	The single format of the future, probably. Newer browsers support it.	Any browser that supports it, starting with Internet Explorer 9, Firefox 3.6, and Chrome 6.

Bottom line: If you want to use the `@font-face` feature and support a wide range of browsers, you need to distribute your font in several different formats. At a minimum, you need to supply your font in TTF or OTF format (either one is fine), the EOT format, and the SVG format. It's a good idea (but not essential) to also supply a WOFF font, which is likely to become more popular and better supported in the future. (Among its advantages, WOFF files are compressed, which minimizes the download time.)

TROUBLESHOOTING MOMENT

Ironing Out the Quirks

Even if you follow the rules and supply all the required font formats, expect a few quirks. Here are some problems that occasionally crop up with web fonts:

- Many fonts look bad on the still-popular Windows XP operating system, because Windows XP computers often have the anti-aliasing display setting turned off. (And fonts without anti-aliasing look as attractive as mascara on a mule.)
- Some people have reported that some browsers (or some operating systems) have trouble printing certain embedded fonts.
- Some browsers suffer from a problem known as FOUT (which stands for Flash of Unstyled Text). This phenomenon occurs when an embedded font takes

a few seconds to download, and the page is rendered first using a fallback font, and then re-rendered using the embedded font. This problem is most noticeable on old builds of Firefox. If it really bothers you, Google provides a JavaScript library that lets you define fallback styles that kick in for unloaded fonts, giving you complete control over the rendering of your text at all times (see http://code.google.com/apis/webfonts/docs/webfont_loader.html).

Although these quirks are occasionally annoying, most are being steadily ironed out in new browser builds. For example, Firefox now minimizes FOUT by waiting for up to 3 seconds to download an embedded font before using the fallback font.

Using a Font Kit

At this point, you're probably wondering where you can get the many font files you need. The easiest option is to download a ready-made font kit from the Web. That way, you get all the font files you need. The disadvantage is that your selection is limited to whatever you can find online. One of the best places to find web font kits is the Font Squirrel website; you can see its handpicked selection at www.fontsquirrel.com/fontface (see Figure 8-5).

Figure 8-5: Font Squirrel provides a few hundred high-quality fonts, organized into sections by type (“Calligraphic,” “Grunge,” and “Retro,” for example). Best of all, every font is free to use—on your personal computer to create documents, or on the Web to build web pages. When you find a font you like, click View Font to get a closer look at every letter, “View @ff Demo” to see the font in a sample web page via the @font-face feature, and “Get Kit” to download the font to your computer.

When you download a font kit, you get a compressed Zip file that contains a number of files. For example, download the Chantelli Antiqua font shown in Figure 8-5, and you get these files:

```
Bernd Montag License.txt
Chantelli_Antiqua-webfont.eot
Chantelli_Antiqua-webfont.svg
Chantelli_Antiqua-webfont.ttf
Chantelli_Antiqua-webfont.woff
demo.html
stylesheet.css
```

The text file (Bernd Montag License.txt) provides licensing information that basically says you can use the font freely, but never sell it. The Chantelli_Antiqua-webfont files provide the font in four different file formats. (Depending on the font you pick, you may get additional files for different variations of that font—for example, in bold, italic, and extra-dark styles.) Finally, the *stylesheet.css* file contains the style sheet rule you need to apply the font to your web page, and *demo.html* displays the font in a sample web page.

To use the Chantelli Antiqua font, you need to copy all the Chantelli_Antiqua-webfont files to the same folder as your web page. Then you need to register the font so that it's available for use in your style sheet. To do that, you use a complex `@font-face` rule at the beginning of your style sheet, which looks like this (with the lines numbered for easy reference):

```

1  @font-face {
2      font-family: 'ChantelliAntiquaRegular';
3      src: url('Chantelli_Antiqua-webfont.eot');
4      src: local('Chantelli Antiqua'),
5           url('Chantelli_Antiqua-webfont.woff') format('woff'),
6           url('Chantelli_Antiqua-webfont.ttf') format('truetype'),
7           url('Chantelli_Antiqua-webfont.svg') format('svg');
8  }
```

To understand what's going on in this rule, it helps to break it down line by line:

- **Line 1:** `@font-face` is the tool you use to officially register a font so you can use it elsewhere in your style sheet.
- **Line 2:** You can give the font any name you want. This is the name you'll use later, when you apply the font.
- **Line 3:** The first format you specify has to be the file name of the EOT file. That's because Internet Explorer gets confused by the rest of the rule, and ignores the other formats. The `url()` function is a style sheet technique that tells a browser to download another file at the location you specify. If you put the font in the same folder as your web page, then you can simply provide the file name here.
- **Line 4:** The next step is to use the `local()` function. This function tells the browser the font name, and if that font just happens to be installed on the visitor's computer, the browser uses it. However, in rare cases this can cause a problem (for example, it could cause Mac OS X to show a security dialog box, depending on where your visitor has installed the font, or it could load a different font that has the same name). For these reasons, web designers sometimes use an obviously fake name to ensure that the browser finds no local font. One common choice is to use a meaningless symbol like `local('☺')`.
- **Lines 5 to 7:** The final step is to tell the browser about the other font files it can use. If you have a WOFF font file, suggest that first, as it offers the best quality. Next, tell the browser about the TTF or OTF file, and finally about the SVG file.

Tip: Of course, you don't need to type the `@font-face` rule by hand (and you definitely don't need to understand all the technical underpinnings described above). You can simply copy the rule from the `stylesheet.css` file that's included in the web font kit.

Once you register an embedded font using the `@font-face` feature, you can use it in any style sheet. Simply use the familiar `font-family` property, and refer to the font family name you specified with `@font-face` (in line 2). Here's an example that leaves out the full `@font-face` details:

```
@font-face {
  font-family: 'ChantelliAntiquaRegular';
  ...
}

body {
  font-family: 'ChantelliAntiquaRegular';
}
```

This rule applies the font to the entire web page, although you could certainly restrict it to certain elements or use classes. However, you must register the font with `@font-face` *before* you use it in a style rule. Reverse the order of these two steps, and the font won't work properly.

Tip: The Font Squirrel website provides more fonts beyond its prepackaged font kits. You can also find more fonts by looking at the list of most popular fonts (click Most Downloaded) and most recent (click Newly Added). In these lists, you'll find the web font kits along with other free font files that don't have the support files or need to be downloaded from another website. You can convert your font to the other formats you need using Font Squirrel's font-kit generator, as described on page 252.

FREQUENTLY ASKED QUESTION

Using a Font on Your Computer

Can I use the same font for web work and printed documents?

If you find a hot new font to use in your website, you can probably put it to good use on your computer, too. For example, you might want to use it in an illustration program to create a logo. Or, your business might want to use it for other print work, like ads, fliers, product manuals, and financial reports.

Modern Windows and Mac computers support TrueType (.ttf) and OpenType (.otf) fonts. Every font package includes a font in one of these formats—usually, TrueType. To install it in Windows, make sure you've pulled it out of the ZIP download file. Then, right-click it and choose Install. (You can do this with multiple font files at once.) On a Mac, double-click the font file to open the Font Book utility. Then, click the Install Font button.

Using Google Web Fonts

If you want a simpler way to use a fancy font on your website, Google has got you covered. It provides a service called Google Web Fonts, which hosts free fonts that anyone can use. The beauty of Google Web Fonts is that you don't need to worry about font formats, because Google detects the browser and automatically sends the right font file.

To use a Google font in your pages, follow these steps:

1. Go to www.google.com/webfonts.

Google shows you a long list of available fonts (Figure 8-6).

2. At the top of the page, click a tab title (Word, Sentence, or Paragraph) to choose how you preview fonts.

For example, if you're hunting for a font to use in a heading, you'll probably choose Word or Sentence to take a close up look at a single word or line of text. But if you're looking for a font to use in your body text, you'll probably choose Paragraph to study a whole paragraph of text at once. No matter what option you choose, you can type in your own preview text and set an exact font size for your previews.

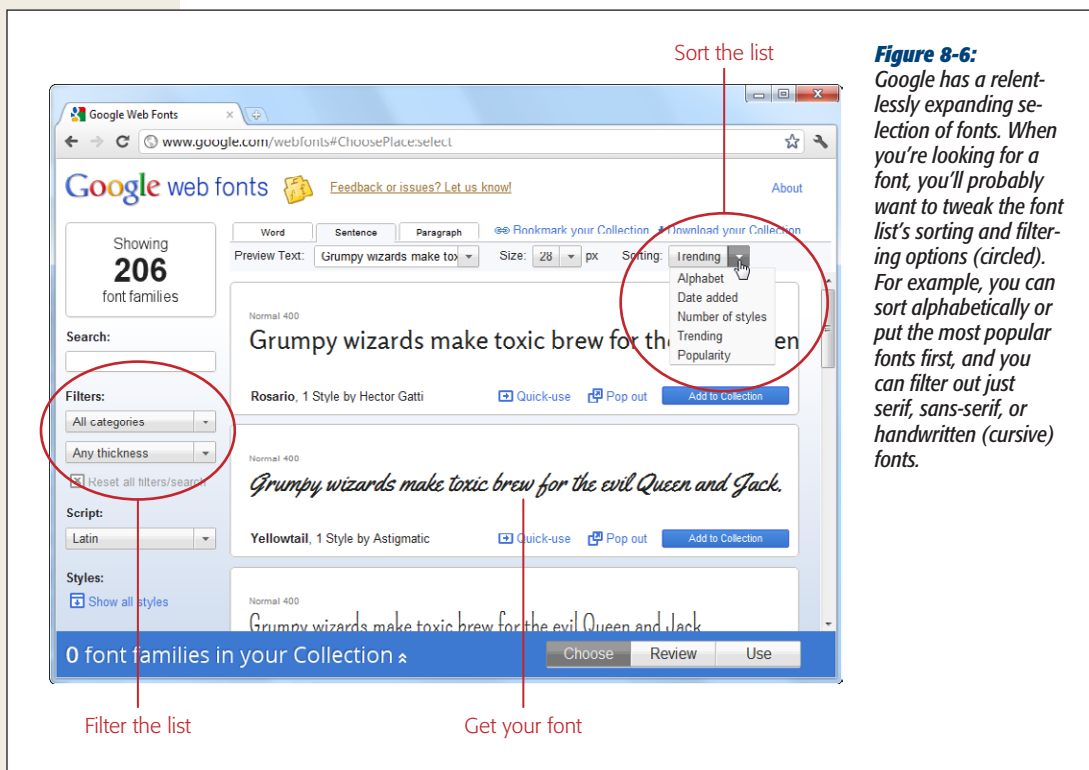

Figure 8-6: Google has a relentlessly expanding selection of fonts. When you're looking for a font, you'll probably want to tweak the font list's sorting and filtering options (circled). For example, you can sort alphabetically or put the most popular fonts first, and you can filter out just serif, sans-serif, or handwritten (cursive) fonts.

3. Set your search options.

If you have a specific font in mind, type it into the search box. Otherwise, you'll need to scroll down, and that could take ages. To help you get what you want more quickly, start by setting a sort order and some filtering options, if they apply (for example, you might want to find the most popular bold sans-serif fonts). Figure 8-6 shows you where to find these options.

4. When you see a font that's a candidate for your site, click "Pop out."

Google pops open an informative window that describes the font and shows each of its characters.

5. If you like the font, click "Quick-use" to get the information you need to use it.

Google shows you the code you need to use this font. It consists of a style sheet link (which you must add to your web page) and an example of a style sheet rule that uses the font.

6. Add a style sheet link to your web page.

For example, if you picked the Metrophobic font, Google wants you to place this link in the `<head>` section of your page:

```
<link href="http://fonts.googleapis.com/css?family=Metrophobic"
      rel="stylesheet">
```

This style sheet registers the font, using `@font-face`, so you don't have to. Best of all, Google provides the font files, so you don't need to upload anything extra to your website.

Note: Remember to put the link for the Google font style sheet before your other style sheet links. That way, your other style sheets can use the Google font.

7. Use the font, by name, wherever you want.

For example, here's how you could use the newly registered Metrophobic font in a heading, with fallbacks in case the browser fails to download the font file:

```
h1 {
  font-family: 'Metrophobic', arial, serif;
}
```

POWER USER'S CLINIC

Creating a Font Collection

These steps show the fastest way to get the markup you need for a font. However, you can get more options by creating a *font collection*.

A font collection is a way to package up multiple fonts. To start creating one, you simply click the “Add to Collection” button next to a font you like. As you add fonts to your collection, each one appears in the fat blue footer at the bottom of the page.

When you’re finished picking the fonts you want, click the footer’s big Use button. Google then shows a page that’s

similar to the “Quick-use” page, except it allows you to create a single style sheet reference that supports *all* the fonts from your custom-picked collection.

When you create a font collection, you can also use two links that appear at the top-right of the page. Click “Bookmark your Collection” to create a browser bookmark that lets you load up the same collection at some point in the future, so you can tweak it. Choose “Download your collection” to download copies of the fonts to your computer, so you can install the fonts and use them for print work.

Using Your Own Fonts

Font fanatics are notoriously picky about their typefaces. If you have a specific font in mind for your web pages, even the biggest free font library isn’t enough. Fortunately, there’s a fairly easy way to adapt any font for the Web. Using the right tool, you can take a TTF or OTF font file you already have and create the other formats you need (EOT, SVG, and WOFF).

But before you take this road, it’s important to get one issue out of the way: Ordinary fonts aren’t free. That means it’s not kosher to take a font you have on your computer and use it on your website, unless you have explicit permission from the font’s creator. For example, Microsoft and Apple pay to include certain fonts with their operating systems and applications so you can use them to, say, create a newsletter in a word processor. However, this license doesn’t allow you to put these fonts on a web server and use them in your pages.

Tip: If you have a favorite font, the only way to know whether you need to pay for it is to contact the company or individual that made it. Some font makers charge licensing fees based on the amount of traffic your website receives. Other font creators may let you use their fonts for a nominal amount or for free, provided you meet certain criteria (for example, you include some small-print note about the font you’re using, or you have a noncommercial website that isn’t out to make boatloads of money). There’s also a side benefit to reaching out: Skilled font makers often provide display-optimized versions of their creations.

Once you know that you're allowed to use a specific font, you can convert it using a handy tool from Font Squirrel (the same website that offers the nifty free web font kits). To do so, surf to www.fontsquirrel.com/fontface/generator. Figure 8-7 shows you the three-step process you need to follow.

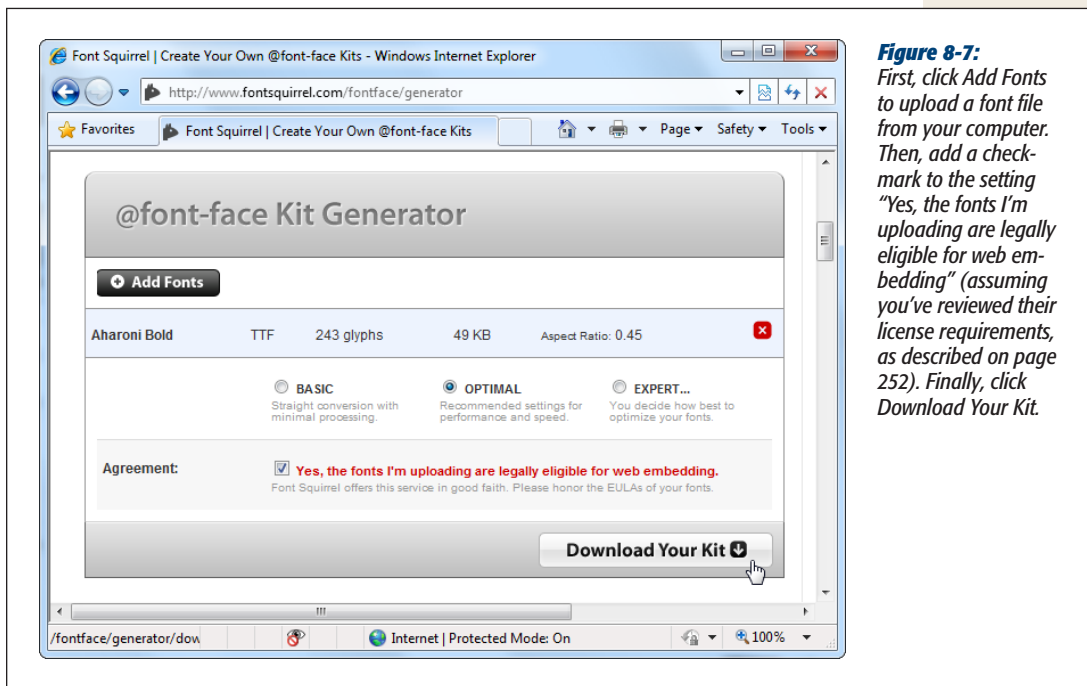

Figure 8-7: First, click **Add Fonts** to upload a font file from your computer. Then, add a checkmark to the setting “Yes, the fonts I’m uploading are legally eligible for web embedding” (assuming you’ve reviewed their license requirements, as described on page 252). Finally, click **Download Your Kit**.

The web kit that Font Squirrel generates is just like the free ones described earlier. It even includes a style sheet that has the `@font-face` section you need, along with a test web page.

Tip: Still looking for more places to get fonts? If you haven’t found that perfect typeface yet, spend some time at <http://webfonts.info>. There you’ll find links to other websites that provide free fonts, as well as professional font foundries like the legendary Monotype. Although font-pricing models are changing fast, most font foundries offer some free fonts, and paid subscriptions can give website developers dozens of ultra-high-quality typefaces for as little as \$10 per year. Some provide fonts through a hosting service like Google Fonts, so there’s no need to upload font files to your web server.

Putting Text in Multiple Columns

Fancy fonts aren’t the only innovation CSS3 has for displaying text. It also adds an entirely new module for multicolumn text, which gives you a flexible, readable way to deal with lengthy content.

Using multiple columns is almost effortless, and you have two ways to create them. Your first option is to set the number of columns you want using the *column-count* property, like this:

```
article {
  text-align: justify;
  column-count: 3;
}
```

At the time of this writing, this works for Opera only. To get the same support in Firefox, Chrome, and Safari, you need to add vendor-prefixed versions of the *column-count* property, like this:

```
article {
  text-align: justify;
  -moz-column-count: 3;
  -webkit-column-count: 3;
  column-count: 3;
}
```

You won't find any support in Internet Explorer 9 (although IE 10 is likely to join the party).

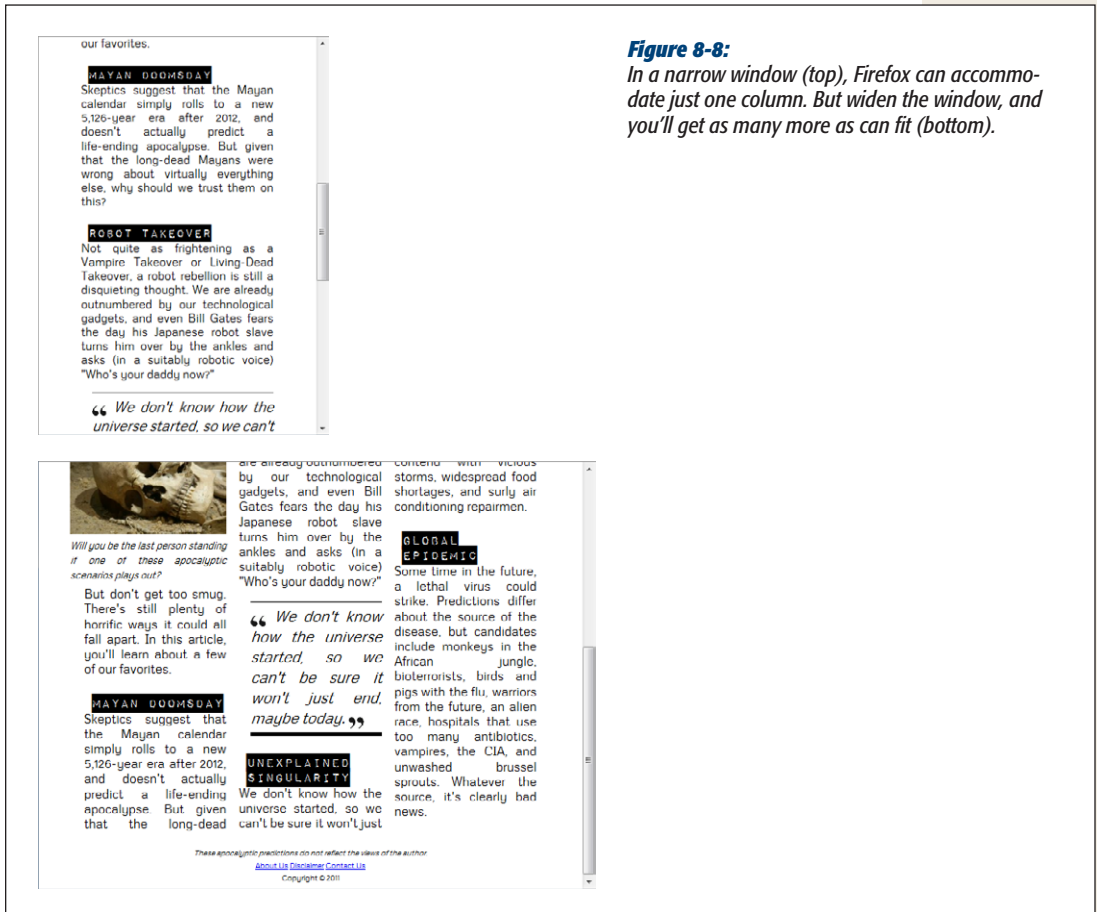

This approach—creating a set number of columns—works well for fixed-size layouts. But if you have a space that grows and shrinks with the browser window, your columns may grow too wide and become unreadable. In this situation, it's better *not* to set the exact number of columns. Instead, tell the browser how big each column should be using the *column-width* property:

```
article {
  text-align: justify;
  -moz-column-width: 10em;
  -webkit-column-width: 10em;
  column-width: 10em;
}
```

The browser can then create as many columns as it needs to fill up the available space (see Figure 8-8).

Note: You can use pixel units to size a column, but em units make more sense. That's because em units adapt to the current font size. So if a web page visitor ratchets up the text size settings in her browser, the column width grows proportionately to match. To get a sense of size, 1 em is equal to the two times the current font size. So if you have a 12 pixel font, 1 em works out to 24 pixels.

You can also adjust the size of the spacing between columns (with *column-gap*) and even add a vertical line that separates them (with *column-rule*). For more information about all your column-creating options, including ways to control where text breaks into columns and tricks that let figures and other elements span columns, refer to the full multicolumn standard at www.w3.org/TR/css3-multicol. Unfortunately, at this writing no browser supports these advanced features.

**Figure 8-8:**

In a narrow window (top), Firefox can accommodate just one column. But widen the window, and you'll get as many more as can fit (bottom).

Adapting to Different Devices

If you've ever gone on an extended web surfing spree using a mobile device (and odds are you have), you've discovered that a tiny screen isn't the best window onto the Web. Sure, you can scroll and zoom your way around virtually any website, but the process is often laborious. Life gets much better if you find a specifically designed mobile site that scales down its content to fit your device.

Today, it's not unusual to find developers creating custom versions of the same website for specific devices, like iPhones and iPads. These sites are often hosted on different web domains (like <http://m.nytimes.com> for the mobile version of the New York Times). But here's the rub: As mobile browsing becomes more popular, and mobile devices become increasingly numerous and varied, web developers like you can end up with big headaches managing all those device-specific sites.

Of course, separate sites aren't the only way to deal with different devices. You can also write web server code that checks every request, figures out what web browser is on the other end, and sends the appropriate type of content. This sort of solution is great, if you have the time and skills. But wouldn't it be nice to have a simple mechanism that tweaks your styles for different types of devices, with no web application framework or server-side code required?

Enter *media queries*. This CSS3 feature gives you a simple way to vary styles for different devices and viewing settings. Used carefully, they can help you serve everything from an ultra-widescreen desktop computer to an iPhone—without altering a single line of HTML.

Media Queries

Media queries work by latching onto a key detail about the device that's viewing your page (like its size, resolution, color capabilities, and so on). Based on that information, you can apply different styles, or even swap in a completely different style sheet. Figure 8-9 shows a media query in action.

NOSTALGIA CORNER

CSS Media Types

Interestingly, the creators of CSS took a crack at the multiple-device problem in CSS 2.1, using a feature called *media types*. You might already be using this standard to supply a separate style sheet for printouts:

```
<head>
...
<!-- Use this stylesheet to display the
      page on-screen. -->
<link rel="stylesheet" media="screen"
      href="styles.css">
<!-- Use this stylesheet to print the
      page. -->
<link rel="stylesheet" media="print"
      href="print_styles.css">
</head>
```

The media attribute also accepts the value *handheld*, which is meant for low-bandwidth, small-screen mobile devices. Most mobile devices make some attempt to pay attention to the media attribute and use the handheld style sheet, if it exists. But there are quirks aplenty, and the media attribute is woefully inadequate for dealing with the wide range of web-connected devices that exists today. (However, it's still a good way to clean up printouts.)

To use media queries, you must first choose the property you want to examine. In Figure 8-9, that key detail is *max-width*, which gets the current size of the page, in the browser window. Even more useful is *max-device-width*, which checks the maximum screen width. If this value is small, it's clear that you're working with a webphone or a similarly tiny device.

The easiest way to use media queries is to start with the standard version of your website, and then override it selectively. In the example in Figure 8-9, the content is broken into two sections:

```

<article>
...
</article>
<aside>
...
</aside>

```

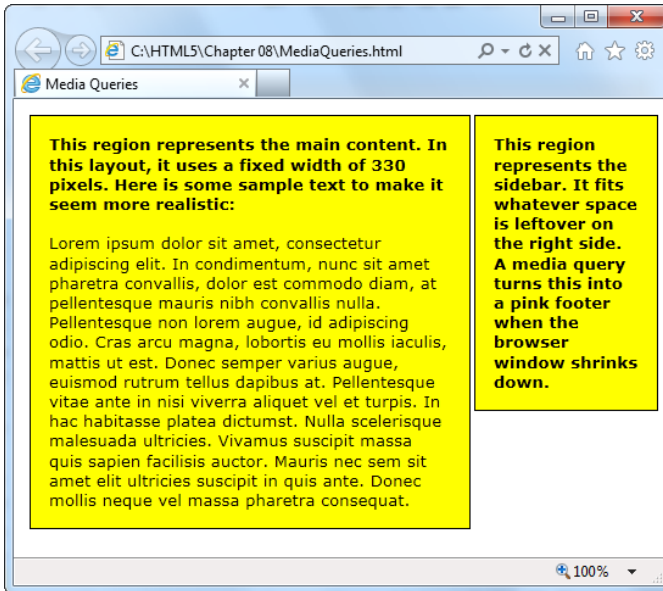

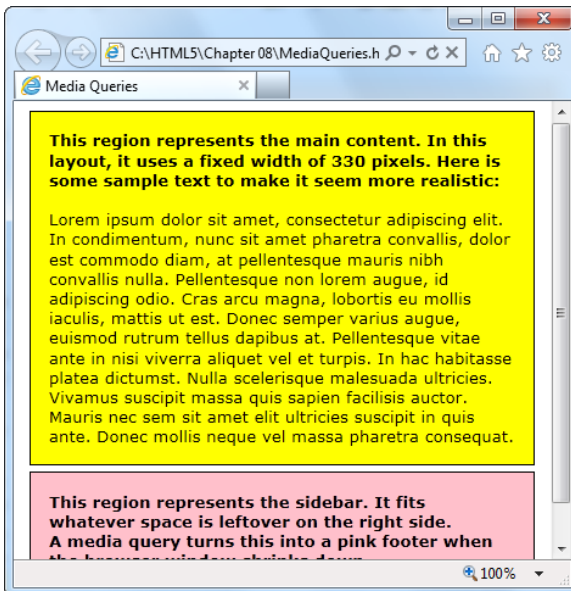

Figure 8-9:

Here's the same page viewed in a wide browser window (top) and in a narrow browser window (bottom). The media query magic automatically switches a portion of the page's style rules when the window shrinks, turning a sidebar into a footer. You don't even need to refresh the page.

And the style sheet starts with two rules, one for each section:

```
article {
    border: solid 1px black;
    padding: 15px;
    margin: 5px;
    background: yellow;
    float: left;
    width: 330px;
}

aside {
    border: solid 1px black;
    padding: 15px;
    margin: 5px;
    background: yellow;
    position: absolute;
    float: left;
    margin-left: 370px;
}
```

These rules implement a standard two-column layout, with a fixed 330-pixel column on the left, and a sidebar on the right that expands to fill up the remaining space. (Of course, you're free to use any sort of CSS-powered layout you want in your examples.)

The magic happens when you define a separate part of your style sheet that comes into effect for a given media-query value. The syntax takes this form:

```
@media (media-query-property-name: value) {
    /* New styles go here. */
}
```

In the current example, this new set of styles comes into effect when the width of the browser window is 480 pixels or less. That means you need a section in your style sheet that looks like this:

```
@media (max-width: 480px) {
    ...
}
```

Tip: Right now, the most popular media queries are `max-device-width` (for creating mobile versions of your pages), `max-width` (for varying styles based on the current size of the browser window), and `orientation` (for changing your layout based on whether an iPad is turned horizontally or vertically). But the media queries specification defines a handful of other details you can examine. For the full list, check out the standard at www.w3.org/TR/css3-mediaqueries.

Although you're free to put anything inside the media query block, this example simply adds new style rules for the `<article>` and `<aside>` elements:

```
@media (max-width: 480px) {
    article {
        float: none;
        width: auto;
    }
}
```

```

aside {
  position: static;
  float: none;
  background: pink;
  margin-left: 5px;
}

```

These styles are applied in addition to the normal styles you’ve already defined. Thus, you may need to reset properties you’ve already changed to their default values. In this example, the media query styles reset the position property to *static*, the float property to *none*, and the width property to *auto*. These are the default values, but the original sidebar style changed them.

Note: Browsers that don’t understand media queries, like Internet Explorer 8, will simply ignore these new styles and keep applying the original styles, no matter how big or small the browser window becomes.

If you want, you could add another media query section that overrides these rules at a still-smaller size. For example, this section would apply new rules when the browser width creeps under 250 pixels:

```

@media (max-width: 250px) {
  ...
}

```

Just remember that these rules are overriding everything that’s been applied so far—in other words, the cumulative set of properties that have been set by the normal styles and the media query section for under 450 pixels. If this seems too confusing, don’t worry—you’ll learn to work around it with more tightly defined media queries in the next section.

Tip: When trying to identify mobile devices like webphones, you need to use the *max-device-width* property, not *max-width*. That’s because the *max-width* property uses the size of the phone’s viewport—the segment of the web page that the phone user can scroll around. A typical viewport is twice as wide as the actual device width. For the full scoop (and some pictures that illustrate how viewports work), see the Quirksmode article at <http://tinyurl.com/yyec93n>. And you’ll learn more about media queries for mobile devices on page 261.

More Advanced Media Queries

Sometimes you might want your styles even more specific, so that they depend on multiple conditions. Here’s an example:

```

@media (min-width: 400px) and (max-width: 700px) {
  /* These styles apply to windows from 400 to 700 pixels wide. */
}

```

This comes in handy if you want to apply several sets of mutually exclusive styles, but you don't want the headaches of several layers of overlapping rules. Here's an example:

```
/* Normal styles here */

@media (min-width: 600px) and (max-width: 700px) {
  /* Override the styles for 600-700 pixel windows. */
}

@media (min-width: 400px) and (max-width: 599.99px) {
  /* Override the styles for 400-600 pixel windows. */
}

@media (max-width: 399.99px) {
  /* Override the styles for sub-400 pixel windows. */
}
```

Now, if the browser window is 380 pixels, exactly two sets of style will apply: the standard styles and the styles in the final `@media` block. Whether this approach simplifies your life or complicates it depends on exactly what you're trying to accomplish. If you're using complex styles and changing them a lot, the no-overlap approach shown here is often the simplest way to go.

Notice that you have to take care that your rules don't unexpectedly overlap. For example, if you set the maximum width of one rule to 400 pixels and the minimum width of another rule to 400 pixels, you'll have one spot where both style settings suddenly combine. The slightly awkward solution is to use fractional values, like the 399.99 pixel measurement used in this example.

Another option is to use the *not* keyword. There's really no functional difference, but if the following style sheet makes more sense to you, feel free to use this approach:

```
/* Normal styles here */

@media (not max-width: 600px) and (max-width: 700px) {
  /* Override the styles for 600-700 pixel windows. */
}

@media (not max-width: 400px) and (max-width: 600px) {
  /* Override the styles for 400-600 pixel windows. */
}

@media (max-width: 400px) {
  /* Override the styles for sub-400 pixel windows. */
}
```

In these examples, there's still one level of style overriding to think about. That's because every `@media` section starts off with the standard, no-media-query style rules. Depending on this situation, you might prefer to separate your style logic completely (for example, so a mobile device gets its own, completely independent set of styles). To do so, you need to use media queries with external style sheets, as described next.

Replacing an Entire Style Sheet

If you have simple tweaks to make, the `@media` block is handy, because it lets you keep all your styles together in one file. But if the changes are more significant, you may decide that it's just easier to create a whole separate style sheet. You can then use a media query to create a link to that style sheet:

```
<head>
  <link rel="stylesheet" href="standard_styles">
  <link rel="stylesheet" media="(max-width: 480px)" href="small_styles.css">
  ...
</head>
```

The browser will download the second style sheet (*small_styles.css*) with the page but won't actually apply it unless the browser width falls under the maximum.

As in the previous example, the new styles will override the styles you already have in this place. In some cases, what you really want is completely separate, independent style sheets. First, you need to add a media query to your standard style sheet, to make sure it kicks in only for large sizes:

```
<link rel="stylesheet" media="(min-width: 480.01px)" href="standard_styles">
<link rel="stylesheet" media="(max-width: 480px)" href="small_styles.css">
```

The problem with this approach is that browsers that don't understand media queries will ignore both style sheets. You can fix this up for old versions of Internet Explorer by adding your main style sheet again, but with conditional comments:

```
<link rel="stylesheet" media="(min-width: 480.01px)" href="standard_styles">
<link rel="stylesheet" media="(max-width: 480px)" href="small_styles.css">
<!--[if lt IE 9]>
  <link rel="stylesheet" href="standard_styles">
<![endif]-->
```

This example still has one small blind spot. Old versions of Firefox (earlier than 3.5) don't understand media queries and don't use the conditionally commented IE section. You could solve the problem by detecting the browser in your code, and then using JavaScript to swap in a new page, but it's messy. Fortunately, old versions of Firefox are becoming increasingly rare.

Incidentally, you can combine media queries with the media types described in the box on page 256. When doing this, always start with the media type, and don't put it in parentheses. For example, here's how you could create a print-only style sheet for a specific page width:

```
<link rel="stylesheet" media="print and (min-width: 25cm)"
  href="NormalPrintStyles.css" >
<link rel="stylesheet" media="print and (not min-width: 25cm)"
  href="NarrowPrintStyles.css" >
```

Recognizing Mobile Devices

As you've already learned, you can distinguish between normal computers and mobile devices by writing a media query that uses `max-device-width`. But what widths should you use?

If you're looking for mobile phones, check for a max-device-width of 480 pixels. This is the best, more general rule. It catches the iPhone and the Android phones that exist today:

```
<link rel="stylesheet" media="(max-device-width: 480px)"
      href="mobile_styles.css">
```

If you're a hardware geek, this rule may have raised a red flag. After all, the current crop of mobile devices uses tiny, super-high-resolution screens. For example, the iPhone 4 crams a grid of 960×640 pixels into view at once. You might think you'd need larger device widths for these devices. Surprisingly, though, that isn't the case. Most web devices continue reporting that they have 480 pixels of width, even when they have a fancy high-resolution display. These devices add in a fudge factor called the *pixel ratio*. In the iPhone 4, for instance, every CSS pixel is two physical pixels wide, so the pixel ratio is 2. In fact, you can create a media query that matches the iPhone 4, but ignores older iPhones, using the following media query:

```
<link rel="stylesheet"
      media="(max-device-width: 480px) and (-webkit-min-device-pixel-ratio: 2)"
      href="iphone4.css">
```

The iPad poses a special challenge: Users can turn it around to show content vertically or horizontally. And although this changes the max-width, it doesn't alter the max-device-width. In both portrait and landscape orientation, the iPad reports a device width of 768 pixels. Fortunately, you can combine the max-device-width property with the orientation property if you want to vary styles based on the iPad's orientation:

```
<link rel="stylesheet"
      media="(max-device-width: 768px) and (orientation: portrait)"
      href="iPad_portrait.css">

<link rel="stylesheet"
      media="(max-device-width: 768px) and (orientation: landscape)"
      href="iPad_landscape.css">
```

Of course, this rule isn't limited to iPads. Other devices that have similar screen sizes (in this case, 768 pixels or less) will get the same style rules.

Note: On their own, media queries probably aren't enough to turn a normal website into a mobile-friendly one. You'll also need to think about bandwidth and the user experience. On the bandwidth side, you'll want to use smaller, lightweight images. (You can do this by giving elements background images, and setting these images in your styles. However, this approach is a nightmare for websites with lots of pictures.) On the user experience side, you need to think about breaking content down into smaller pieces (so less scrolling is required) and avoiding effects and interactions that are difficult to navigate with a touch interface (like pop-up menus).

GEM IN THE ROUGH

Media Queries for Video

One obvious difference between desktop websites and mobile websites is the way they use video. A mobile website may still include video, but it will typically use a smaller video window and a smaller media file. The reasons are obvious—not only do mobile browsers have slower, more expensive network connections to download video, they also have less powerful hardware to play it back.

Using the media query techniques you’ve just learned, you can easily change the size of a `<video>` element to suit a mobile user. However, it’s not as easy to take care of the crucial second step, and link to a slimmed-down video file.

HTML5 has a solution: It adds a *media* attribute directly to the `<source>` element. As you learned in Chapter 5, the `<source>` element specifies the media file a `<video>` element should play. By adding the *media* attribute, you can limit certain media files to certain device types.

Here’s an example that hands the *butterfly_mobile.mp4* file out to small-screened devices. Other devices get

butterfly.mp4 or *butterfly.ogv*, depending on which video format they support.

```
<video controls width="400" height="300">
  <source src="butterfly_mobile.mp4"
    type="video/mp4"
    media="(max-device-width: 480px)">
  <source src="butterfly.mp4" type="video/mp4">
  <source src="butterfly.ogv" type="video/ogg">
</video>
```

Of course, it’s still up to you to encode a separate copy of your video for mobile users. Encoding tools usually have device-specific profiles that can help you out. For example, they might have an option for encoding “iPad video.” It’s also still up to you to make sure that you use the right media format for your device (usually, that will be H.264), and supply video formats for every other browser.

Building Better Boxes

From the earliest days of CSS, web designers were using it to format boxes of content. As CSS became more powerful, the boxes became more impressive, creating everything from nicely shaded headers to floating, captioned figures. And when CSS cracked the hovering problem, floating boxes were even turned into rich, glowy buttons, taking over from the awkward JavaScript-based approaches of yore. With this in mind, it’s no surprise that some of the most popular and best-supported CSS3 features can make your boxes look even prettier, no matter what they hold.

Transparency

The ability to make partially transparent pictures and colors is one of the most basic building blocks in CSS3. There are two ways to do it.

Your first option is to use the `rgba()` color function, which accepts four numbers. The first three values are the red, green, and blue components of the color, from 0 to 255. The final value is the *alpha*, a fractional value number from 0 (fully transparent) to 1 (fully opaque).

Here's an example that creates a 50 percent transparent lime green color:

```
.semitransparentBox {
  background: rgba(170,240,0,0.5);
}
```

Browsers that don't support `rgba()` will just ignore this rule, and the element will keep its default, completely transparent background. So the second, and better, approach is to start by declaring a solid fallback color, and then replace that color with a semitransparent one:

```
.semitransparentBox {
  background: rgb(170,240,0);
  background: rgba(170,240,0,0.5);
}
```

This way, browsers that don't support the `rgba()` function will still color the element's background, just without the transparency.

Tip: To make this fallback better, you should use a color that more accurately reflects the semitransparent effect. For example, if you're putting a semitransparent lime green color over a mostly white background, the color will look lighter because the white shows through. Your fallback color should reflect this fact, if possible.

CSS3 also adds a style property named *opacity*, which works just like the alpha value. You can set opacity to a value from 0 to 1 to make any element partially transparent:

```
.semitransparentBox {
  background: rgb(170,240,0);
  opacity: 0.5;
}
```

Figure 8-10 shows two example of semitransparency, one that uses the `rgba()` function and one that uses the `opacity` property.

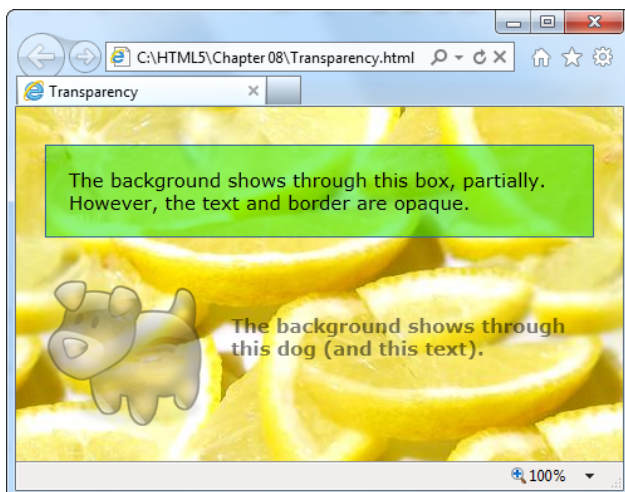

Figure 8-10:

This page serves up semitransparency two different ways: to fade out a picture (using the `opacity` property) and to let the background show through a box (using a background color created with the `rgba()` function).

The opacity property is a better tool than the `rgba()` function if you want to do any of the following:

- Make more than one color semitransparent. With opacity, the background color, text color, and border color of an element can become transparent.
- Make something semitransparent, even if you don't know its color (for example, because it might be set by another style sheet or in JavaScript code).
- Make an image semitransparent.
- Use a transition, an animated effect that can make an element fade away or reappear (page 271).

Rounded Corners

You've already learned about the straightforward `border-radius` property, which lets you shave the hard corners off your boxes. But what you haven't yet seen is the way you can tweak this setting to get the curve you want.

First, you can choose a different, single value for the `border-radius` property. The border radius is the radius of the circle that's used to draw the rounded edge. Of course, you don't see the entire circle—just enough to connect the vertical and horizontal sides of the box. Set a bigger `border-radius` value, and you'll get a bigger curve and a more gently rounded corner. As with most measurements in CSS, you can use a variety of units, including pixels and percentages. You can also adjust each corner separately by supplying four values:

```
.roundedBox {  
  background: yellow;  
  border-radius: 25px 50px 25px 85px;  
}
```

But that's not all—you can also stretch the circle into an ellipse, creating a curve that stretches longer in one direction. To do this, you need to target each corner separately (using properties like *`border-top-left-radius`*) and then supply two numbers: one for the horizontal radius and one for the vertical radius:

```
.roundedBox {  
  background: yellow;  
  border-top-left-radius: 150px 30px;  
  border-top-right-radius: 150px 30px;  
}
```

Figure 8-11 shows some examples.

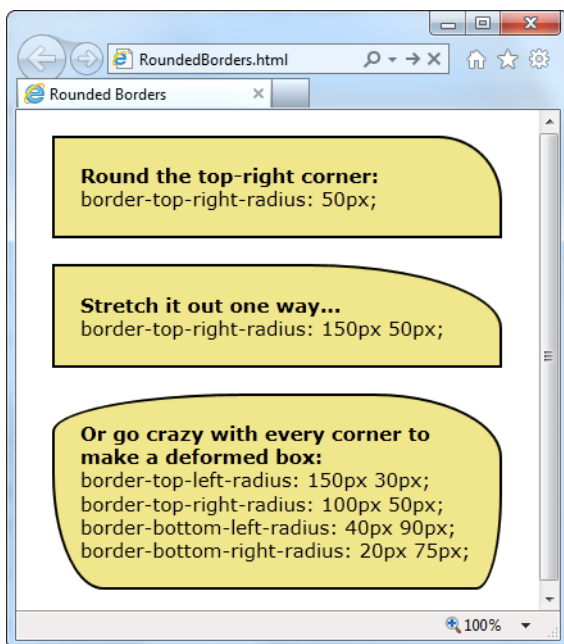

Figure 8-11:
A clever application of border-radius can create virtually any sort of curve.

Backgrounds

One shortcut to attractive backgrounds and borders is to use images. CSS3 introduces two new features to help out here. First is multiple background support, which lets you combine two or more images in a single element's background. Here's an example that uses two backgrounds to embellish the top-left and bottom-right corner of a box:

```
.decoratedBox {
  margin: 50px;
  padding: 20px;
  background-image: url('top-left.png'), url('bottom-right.png');
  background-position: left top, right bottom;
  background-repeat: no-repeat, no-repeat;
}
```

This first step is to supply a list with any number of images, which you use to set the *background-image* property. You can then position each image, and control whether it repeats, using the *background-position* and *background-repeat* properties. The trick is to make sure that the order matches, so the first image is positioned with the first background-position value, the second image with the second background-position value, and so on. Figure 8-12 shows the result.

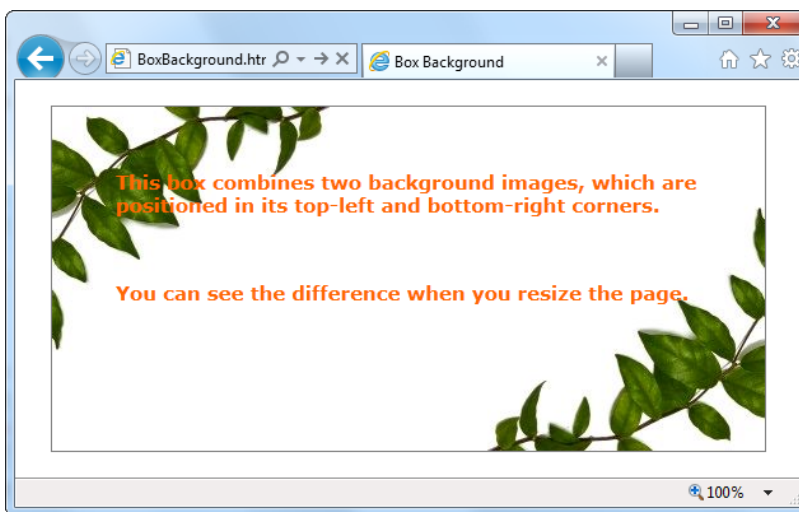

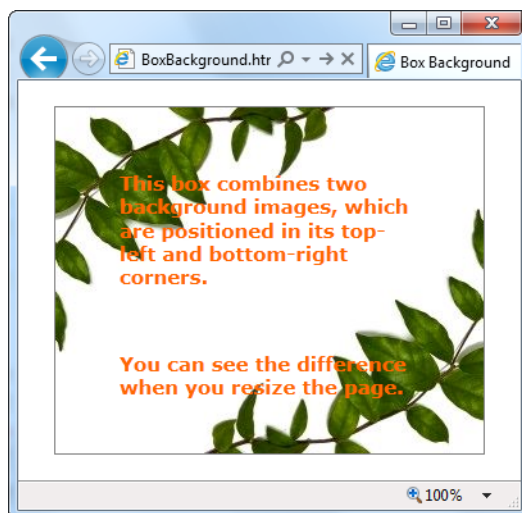

Figure 8-12: It doesn't matter how big this box grows—the two background images stay fixed at either corner.

Note: If browsers don't support multiple backgrounds, they'll completely ignore your attempt to set the background. To avoid this problem, start by setting the background or background-image property with a fallback color or picture. Then, attempt to set multiple backgrounds by setting background-image with a list of pictures.

And here's a revised example that uses the *sliding doors* technique, a time-honored web design pattern that creates a resizable graphic out of three pieces: an image for the left, an image for the right, and an extremely thin sliver that's tiled through the middle:

```
.decoratedBox {
  margin: 50px;
  padding: 20px;
  background-image: url('left.png'), url('middle.png'), url('right.png');
  background-position: left top, left top, right bottom;
  background-repeat: no-repeat, repeat-x, no-repeat;
}
```

You could use markup like this to draw a background for a button. Of course, with all of CSS3's fancy new features, you'll probably prefer to create those using shadows, gradients, and other image-free effects.

Shadows

CSS3 introduces two types of shadows: box shadows and text shadows. Of the two, box shadows are generally more useful and better supported, while text shadows don't work in any version of Internet Explorer. You can use a box shadow to throw a rectangular shadow behind any <div> (but don't forget your border, so it still looks like a box). Shadows even follow the contours of boxes with rounded corners (see Figure 8-13).

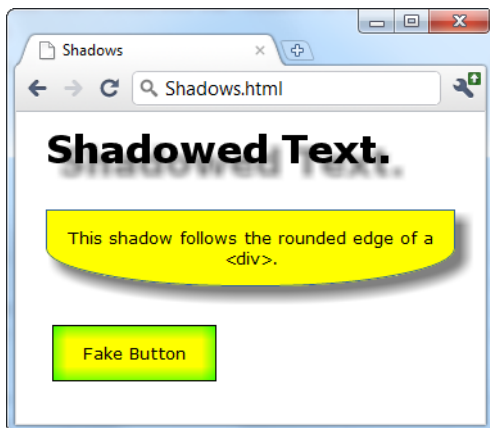

Figure 8-13: Shadows can make text float (top), boxes pop out (middle), or buttons look glowy (bottom).

The two properties that make shadows work are *box-shadow* and *text-shadow*. Here's a basic box shadow example:

```
.shadowedBox {
  border: thin #336699 solid;
  border-radius: 25px;
  box-shadow: 5px 5px 10px gray;
}
```

The first two values set the horizontal and vertical offset of the shadow. Using positive values (like 5 pixels for both, in the above example) displaces the shadow down and to the right. The next value sets the *blur* distance (in this example, 10 pixels), which increases the fuzziness of the shadow. At the end is the shadow color. If there's any content underneath the box, consider using the `rgba()` function (page 185) to supply a semitransparent shadow.

If you want to tweak your shadow, you can tack on two details. You can add another number between the blur and the color to set the shadow *spread*, which expands the shadow by thickening the solid part before the blurred edge starts:

```
box-shadow: 5px 5px 10px 5px gray;
```

And you can add the word *inset* on the end to create a shadow that reflects inside an element, instead of outside. This works best if you use a shadow that's directly on top of the element, with no horizontal or vertical offset:

```
box-shadow: 0px 0px 20px lime inset;
```

This creates the bottom example in Figure 8-13. You can use inset shadows to add hover effects to a button (page 272).

Note: Shadow-crazy developers can even supply multiple shadows, by separating each one with a comma. But this is usually a waste of developer effort and computing power.

The `text-shadow` property requires a similar set of values, but in a different order. The color comes first, followed by the horizontal and vertical offsets, followed by the blur:

```
.textShadow {
  font-size: 30px;
  font-weight: bold;
  text-shadow: gray 10px 10px 7px;
}
```

Gradients

Gradients are blends of color that can create a range of effects, from the subtle shading behind a menu bar to a psychedelic button that's colored like a 1960s revival party. Figure 8-14 shows some examples.

Note: Many web gradients are faked with background images. But CSS3 lets you define the gradient you want, and gets the browser to do the work. The advantage is fewer image files to schlep around and the ability to create gradients that seamlessly resize themselves to fill any amount of space.

You've already had some gradient-building experience with the canvas (page 208), and CSS3 gradients are similar. As with the canvas, CSS supports two types of gradients: linear gradients that blend from one band of color to another, and radial gradients that blend from a central point to the outer edges of your region.

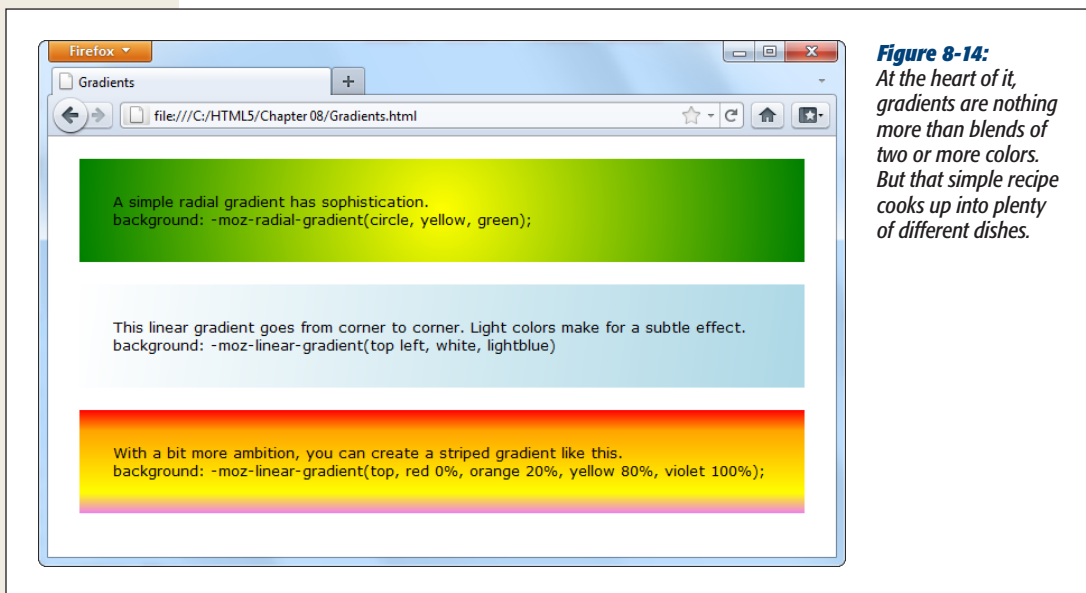

Figure 8-14:
*At the heart of it,
gradients are nothing
more than blends of
two or more colors.
But that simple recipe
cooks up into plenty
of different dishes.*

There aren't any special CSS properties for creating gradients. Instead, you can use a gradient function to set the background property. Just remember to set the property to a solid color first to create a fallback for browsers that don't support gradients. (That includes Internet Explorer, which won't add gradient support until IE 10.)

There are four gradient functions, and they all need the awkward vendor prefixes you learned about on page 243. In this section, you'll look at examples that work on Firefox (and use the `-moz-` prefix). You'll need to add identical `-webkit-` and `-o-` versions to support Chrome, Safari, and Opera.

The first function is *linear-gradient()*. Here it is in one of its simpler forms, shading a region from white at the top to blue at the bottom:

```
.colorBlendBox {
  background: -moz-linear-gradient(top, white, blue);
}
```

Replace *top* with *left* to go from one side to another. Or, use a corner to blend diagonally:

```
background: -moz-linear-gradient(top left, white, lightblue)
```

If you want multiple color bands, you simply need to supply a list of colors. Here's how you create a series of three horizontal color stripes:

```
background: -moz-linear-gradient(top, red, orange, yellow);
```

Finally, you can control where each color starts (bumping some together or off to one side), using *gradient stops*. Each gradient stop is a percentage, with 0 percent being at the very start of the gradient and 100 percent being at the very end. Here's an example that extends the orange-yellow section in the middle:

```
background: -moz-linear-gradient(top, red 0%, orange 20%, yellow 80%,
violet 100%);
```

To get a radial gradient, you use the *radial-gradient()* function. You need to supply a color for the center of the circle and a color for the outer edge of the circle, where it meets the boundaries of the element. Here's a radial gradient that places a white point in the center and fades out to blue on the edges:

```
background: -moz-radial-gradient(circle, white, lightblue)
```

There are a pile more options that let you move the center point of the circle, stretch it into an ellipse, and change exactly where the colors fade. Different browser makers are still nailing down simple, consistent syntax that they can all use. For more gradient examples, and to see the two gradient functions not discussed here—that's *repeating-linear-gradient()* and *repeating-radial-gradient()*—check out the short Safari blog post at www.webkit.org/blog/1424/css3-gradients. Or, try an online Microsoft tool that lets you click-and-pick your way to the gradient you want, and then gives you markup that works with every browser, including IE 10. (Try it at <http://tinyurl.com/5rzocsk>.)

Tip: In all these examples, gradients were used with the `background` property. However, you can also use gradient functions to set the `background-image` property in exactly the same way. The advantage here is that `background-image` lets you use an image fallback. First, set `background-image` to a suitable fallback image for less-equipped browsers, and then set it again using a gradient function. Most browsers are smart enough that they won't download the gradient image unless they need it, which saves bandwidth.

Creating Effects with Transitions

CSS made every web developer's life a whole lot easier when it added *pseudoclasses* (page 389). Suddenly, with the help of *:hover* and *:focus*, developers could create interactive effects without writing any JavaScript code. For example, to create a hover button, you simply supply a set of new style properties for the *:hover* pseudoclass. These styles kick in automatically when the visitor moves the mouse pointer over your button.

Tip: If you're the last web developer on earth who hasn't rolled your own hover button, you can find a detailed tutorial in *Creating a Website: The Missing Manual* (O'Reilly), or in an online article at www.elated.com/articles/css-rollover-buttons.

Great as they are, pseudoclasses aren't cutting edge any longer. The problem is their all-or-nothing nature. For example, if you use the *:hover* pseudoclass, then your style settings spring into action immediately when someone hovers over an element. But in Flash application or in desktop programs, the effect is usually more refined. The hovered-over button may shift its color, move, or begin to glow, using a subtle animation that takes a fraction of a second to complete.

Some web developers have begun to add effects like these to their pages, but it usually requires the help of someone else's JavaScript animation framework. But CSS3 has a simpler solution—a new *transitions* feature that lets you smoothly switch from one group of settings to another.

A Basic Color Transition

To understand how transitions work, you need to see a real example. Figure 8-15 shows a color-changing button that's bolstered with some CSS3 transition magic.

Figure 8-15:

If this were an ordinary rollover button, its background would jump from green to yellow in one step. But with transitions, the green blends into yellow, taking half a second to make the change. Move the mouse off, and the same transition plays out in reverse, returning the button to its normal state. The result is a button that just feels more polished.

Here's the nontransition way to style this button:

```
.slickButton {
  color: white;
  font-weight: bold;
  padding: 10px;
  border: solid 1px black;
  background: lightgreen;
  cursor: pointer;
}

.slickButton:hover {
  color: black;
  background: yellow;
}
```

Here's the button this markup formats:

```
<button class="slickButton">Hover Here!</a>
```

To smooth this change out with a transition, you need to set the *transition* property. You do this in the normal slickButton style (not the :hover pseudoclass).

At a minimum, every transition needs two pieces of information: the CSS property that you want to animate and the time the browser should take to make the change. In this example, the transition acts on the background property, and the duration is 0.5 seconds:

```
.slickButton {
  color: white;
  font-weight: bold;
  padding: 10px;
  border: solid 1px black;
  background: lightgreen;
  cursor: pointer;
  transition: background 0.5s;
```

```

    -webkit-transition: background 0.5s;
    -moz-transition: background 0.5s;
    -o-transition: background 0.5s;
}

.slickButton:hover {
    color: black;
    background: yellow;
}

```

As you'll no doubt notice, this example adds three transition properties instead of the promised one. That's because the CSS3 transitions standard is still under development, and the browsers that support it do it using vendor prefixes. To get your transition to work in Chrome, Safari, Firefox, and Opera, you need to set three versions of the same property—and you'll need to add another one with the `-ms-` prefix if Internet Explorer 10 supports transitions (as it's expected to do). Sadly, using experimental properties can make for some messy style sheets.

There's one quirk in this example. The hovered-over button changes two details: its background color and its text color. But the transition applies to the background color only. As a result, the text blinks from white to black in an instant, while the new background color fades in slowly.

There are two ways to patch this up. Your first option is to set the transition property with a comma-separated list of transitions, like this:

```

.slickButton {
    ...
    -webkit-transition: background 0.5s, color 0.5s;
    -moz-transition: background 0.5s, color 0.5s;
    -o-transition: background 0.5s, color 0.5s;
    ...
}

```

But there's a shortcut if you want to set transitions for all the properties that change, and you want to use the same duration for each one. In this case, you can simply add a single transition and use *all* for the property name:

```

    -webkit-transition: all 0.5s;
    -moz-transition: all 0.5s;
    -o-transition: all 0.5s;

```

Note: There are a few more details that can fine-tune a transition. First, you can choose a *timing function* that controls how the transition effect flows—for example, whether it starts slow and then speeds up or starts fast and then decelerates. In a short transition, the timing function you choose doesn't make much of a difference. But in a longer, more complex animation, it can change the overall feel of the effect. Second, you can also add a delay that holds off the start of the transition for some period of time. For more information about both, check out the official specification at www.w3.org/TR/css3-transitions.

Right now, transitions work in Opera 10.5, Firefox 4, and any version of Safari or Chrome you'll ever meet. They aren't supported in Internet Explorer (although they're planned for IE 10). However, this lack of support isn't the problem it seems.

Even if a browser ignores the transition property, it still applies the effect. It just makes the change immediately, rather than smoothly fading it in. That's good news—it means a website can use transitions and keep the essentials of its visual style intact on old browsers.

More Transition Ideas

It's gratifying to see that CSS transitions can make a simple color change look good. But if you're planning to build a slick rollover effect for your buttons or menus, there are plenty of other properties you can use with a transition. Here are some first-rate ideas:

- **Transparency.** By modifying the opacity property, you can make an image fade away into the background. Just remember not to make the picture completely transparent, or the visitor won't know where to hover.
- **Shadow.** Earlier, you learned how the box-shadow property can add a shadow behind any box (page 268). But the right shadow can also make a good hover effect. In particular, consider shadows with no offset and lots of blur, which create more of a traditional glow effect. You can also use an inset shadow to put the effect inside the box.
- **Gradients.** Change up a linear gradient or add a radial one—either way, it's hard to miss this effect.
- **Transforms.** As you'll learn in the next section, transforms can move, resize, and warp any element. That makes them a perfect tool for transitions.

On the flip side, it's usually not a good idea to use transitions with padding, margins, and font size. These operations take more processing power (because the browser needs to recalculate layout or text hinting), which can make them slow and jerky. If you're trying to make something move, grow, or shrink, you're better off using a transform, as described next.

Transforms

When you explored the canvas, you learned about *transforms*—ways to move, scale, skew, and rotate content. In the canvas, you can use transforms to change the things you draw. With CSS3 transforms, you use them to change the appearance of an element. Like transitions, transforms are a new and experimental feature. To use them, you need to stack up the vendor-prefixed versions of the *transform* property. Here's an example that rotates an element and all its contents:

```
.rotatedElement {  
  -moz-transform: rotate(45deg);  
  -webkit-transform: rotate(45deg);  
  -o-transform: rotate(45deg);  
}
```

WORD TO THE WISE

Don't Leave Old Browsers Behind

As you know, browsers that don't support transitions switch between states immediately, which is usually a good thing. However, if you use CSS3 glitter to make your states look different (for example, you're adding a shadow or a gradient to a hovered-over button), old browsers ignore that too. That's not so good. It means that visitors with less capable browsers get *no* hover-over effect at all.

To solve this problem, use a fallback that older browsers understand. For example, you might create a hover state

that sets a different background color and *then* sets a gradient. This way, older browsers will see the background change to a new solid color when the button is hovered over. More capable browsers will see the background change to a gradient fill. For even more customizing power, you can use Modernizr, which lets you define completely different styles for older browsers (page 240).

In the previous example, the `rotate()` function does the work, twisting an element 45 degrees around its center. However, there are many more transform functions that you can use, separately or at the same time. For example, the following style chains three transforms together. It enlarges an element by half (using the *scale* transform), moves it to 10 pixels to the left (using the *scaleX* transform), and skews it for effect (using the *skew* transform):

```
.rotatedElement {  
  -moz-transform: scale(1.5) scaleX(10px) skew(10deg);  
  -webkit-transform: scale(1.5) scaleX(10px) skew(10deg);  
  -o-transform: scale(1.5) scaleX(10px) skew(10deg);  
}
```

Note: A skew twists an element out of shape. For example, imagine pushing the top edge of a box out to the side, while the bottom edge stays fixed (so it looks like a parallelogram). To learn more about the technical details of transform functions, check out Firefox's helpful documentation at <http://tinyurl.com/6ger2wp>, but don't forget to add the other vendor prefixes if you want it to work in Chrome and Opera.

Transforms don't affect other elements or the layout of your web page. For example, if you enlarge an element with a transform, it simply overlaps the adjacent content.

Transforms and transitions make a natural pair. For example, imagine you want to create an image gallery, like the one shown in Figure 8-16.

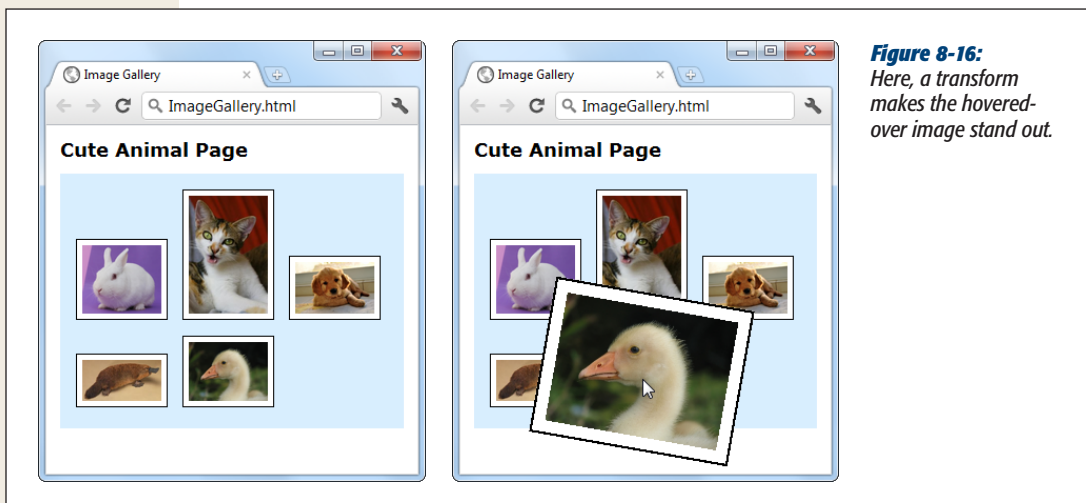

Figure 8-16:
Here, a transform makes the hovered-over image stand out.

This example starts out simple enough, with a bunch of images wrapped in a `<div>` container:

```
<div class="gallery">
  
  
  
  
  
</div>
```

Here's the style for the `<div>` that holds all the images:

```
.gallery {
  margin: 0px 30px 0px 30px;
  background: #D8EEFE;
  padding: 10px;
}
```

And here's how each `` element starts off:

```
.gallery img {
  margin: 5px;
  padding: 5px;
  width: 75px;
  border: solid 1px black;
  background: white;
}
```

You'll notice that all the images are given explicit sizes with the width property. That's because this example uses slightly bigger pictures that are downsized when they're shown on the page. This technique is deliberate: It makes sure the browser has all the picture data it needs to enlarge the image with a transform. If you didn't take this step, and used thumbnail-sized picture files, the enlarged version would be blurry.

Now for the hover effect. When the user moves the mouse over an image, the page uses a transform to rotate and expand the image slightly:

```
.gallery img:hover {
  -webkit-transform: scale(2.2) rotate(10deg);
  -moz-transform: scale(2.2) rotate(10deg);
  -o-transform: scale(2.2) rotate(10deg);
}
```

Right now, this transform snaps the picture to its new size and position in one step. But to make this effect look more fluid and natural, you can define an all-encompassing transition in the normal state:

```
.gallery img {
  margin: 5px;
  padding: 5px;
  width: 75px;
  border: solid 1px black;
  -webkit-transition: all 1s;
  -moz-transition: all 1s;
  -o-transition: all 1s;
  background: white;
}
```

Now the picture rotates and grows itself over 1 second. Move the mouse away, and it takes another second to shrink back to its original position.

POWER USERS' CLINIC

The Future of CSS-Powered Effects

The examples on these pages just scratch the surface of what transforms and transitions can do. Although these features are far from being finalized, you can use several experimental features to extend them further:

- **3-D transforms.** When you get tired of moving an element around in two dimensions, you can use 3-D transforms to move, rotate, and warp it in three-dimensional space. The creators of Safari have a brief walkthrough at www.webkit.org/blog/386/3d-transforms.
- **Animations.** Right now, transitions are limited to fairly simple interactions—mostly, that's when someone hovers with the mouse (using the `:hover` pseudoclass) or changes focus to an input control (using `:focus`). The animation feature extends where you can use transitions, allowing you to apply them dynamically, in response to a JavaScript event. For example, you might create a rotation effect that kicks in when you click a button. You can read the specification at www.w3.org/TR/css3-animations.

- **A sprinkling of JavaScript.** Add a little bit of code to dynamically turn styles on and off, and you can build complex chunks of user interface, like a 3-D image carousel or a collapsible group of panels (often called an accordion control). To see some examples in action, visit <http://css3.bradshawenterprises.com>.

Right now, none of these features are worth the trouble. First, they require lots of messy vendor-specific prefixes, which makes mistakes all too easy and forces you to test the page on every mainstream browser. Second, these features aren't available on many of today's browsers. Animations, for instance, aren't supported on any version of IE or Opera (at the time of this writing), or on Firefox 4. And trying to add a workaround is more work than using a different approach from the start.

Today, the best practical solution for animated effects is a JavaScript library like jQuery UI or MooTools. But CSS3 is the clear future of web effects, once the standards settle down and modern browsers have colonized the computers of the world.

Part Three: Building Web Apps with Desktop Smarts

Chapter 9: Data Storage

Chapter 10: Offline Applications

Chapter 11: Communicating with the Web Server

Chapter 12: More Cool JavaScript Tricks

Data Storage

On the Web, there are two places to store information: on the web server, or on the web client (the viewer's computer). Certain types of data belong on one, while others work better on the other.

The web server is the place to store sensitive information and data you don't want people tampering with. For example, if you fill your shopping cart at an online bookstore, your potential purchases are stored on the web server. The only data your computer keeps is a tiny bit of tracking information that tells the website who you are (so it knows which shopping cart is yours). Even with HTML5, there's no reason to change this setup—it's safe, secure, and efficient.

But server-side storage isn't the best bet for every website. Sometimes, it's easier to keep nonessential information on the web surfer's computer. For example, local storage makes sense for *user preferences* (for example, settings that influence how the web page tailors its display) and *application state* (a snapshot of where the web application is right now, so the web visitor can pick up at the same spot later on).

Before HTML5, the only way to get local storage was to use *cookies*, a mechanism that was originally devised to transmit small bits of identifying information between web browsers and web servers. Cookies work perfectly well for storing small amounts of data, but the JavaScript model for using them is a bit clunky. Cookies also force you to fiddle with expiry dates and needlessly send your data back and forth over the Internet with every web request.

HTML5 introduces a better alternative that lets you store information on your visitor's computer simply and easily. This data stays on the client indefinitely, isn't sent to the web server (unless you do it yourself), has plenty of room, and works through

a couple of simple, streamlined JavaScript objects. This feature—called *web storage*—is a particularly nice fit with the offline application feature explored in Chapter 10, because it lets you build self-sufficient offline applications that can store all the information they need, even when there's no web connection.

In this chapter, you'll explore every corner of the web storage feature. You'll also look at another, even newer standard that lets some web browsers read the content from other files on the computer's hard drive.

Web Storage Basics

HTML5's web storage feature lets a web page store some information on the viewer's computer. That information could be short-lived (so it disappears once the browser is shut down), or it could be long-lived (so it's still available days later, on subsequent visits to the website).

Note: The name *web storage* is more than a little misleading. That's because the information a page stores is never on the Web—in fact, it never leaves the web surfer's computer.

There are two types of web storage, and they revolve around two objects:

- **Local storage** uses the `localStorage` object to store data for your entire website, permanently. That means if a web page stores local data, it will still be there when the visitor returns the next day, the next week, or the next year. Of course, most browsers also include a way to let users clear out local storage. Some web browsers provide an all-or-nothing command that lets people wipe out local data, in much the same way that you can clear out your cookies. (In fact, in some browsers the two features are linked, so that the only way to clear local data is to clear the cookies.) Other browsers may let their users review the storage usage of each website, and clear the local data for specific sites.
- **Session storage** uses the `sessionStorage` object to store data temporarily, for a single window (or tab). The data remains until the visitor closes that tab, at which point the session ends and the data disappears. However, the session data stays around if the user goes to another website and then returns to your site, provided this all happens in the same window tab.

Tip: From the point of view of your web page code, both local storage and session storage work exactly the same. The difference is just how long the data lasts. Using local storage is the best bet for information you want to keep for future visits. Use session storage for data that you want to pass from one page to another. (You can also use session storage to keep temporary data that's used in just one page, but ordinary JavaScript variables work perfectly well for that purpose.)

Both local storage and session storage are linked to your website domain. So if you use local storage on a page at *www.GoatsCanFloat.org/game/zapper.html*, that data will be available on the page *www.GoatsCanFloat.org/contact.html*, because the domain is the same (*www.GoatsCanFloat.org*). However, other websites won't be able to see it or manipulate it.

Also, because web storage is stored on your computer (or mobile device), it's linked to that computer; a web page can't access information that was stored locally on someone else's computer. Similarly, you get different local storage if you log on to your computer with a different user name or fire up a different browser.

Note: Although the HTML5 specification doesn't lay down any hard rules about maximum storage space, most browsers limit local storage to 5 MB. That's enough to pack in a lot of data, but it falls short if you want to use local storage to optimize performance by caching large pictures or videos (and truthfully, this isn't what local storage is designed to do). For space-hoggers, the still-evolving IndexedDB database storage standard (see the box on page 301) offers much more room—typically 50 MB to start and then more if the user agrees.

Storing Data

To put a piece of information away into local storage or session storage, you first need to think of a descriptive name for it. This name is called a *key*, and you need it to retrieve your data later on.

The syntax for storing a piece of data is as follows:

```
localStorage[keyName] = data;
```

For example, imagine you want to store a piece of text with the current user's name. For this data, you might use the key name *user_name*, as shown here:

```
localStorage["user_name"] = "Marky Mark";
```

Of course, it doesn't really make sense to store a hard-coded piece of text. Instead, you'd store something that changes—for example, the current date, the result of a mathematical calculation, or some text that the user has typed into a text box. Here's an example of the latter:

```
// Get a text box.
var nameInput = document.getElementById("userName");

// Store the text from that text box.
localStorage["user_name"] = nameInput.value;
```

Pulling something out of local storage is as easy as putting it in. For example, here's a line of code that grabs the previously stored name and shows it in a message box:

```
alert("You stored: " + localStorage["user_name"]);
```

This code works whether the name was stored five seconds ago or five months ago.

Of course, it's possible that nothing was stored at all. If you want to check whether a storage slot is empty, you can test for a null reference. Here's an example of that technique:

```
if (localStorage["user_name"] == null) {
    alert ("You haven't entered a name yet.");
}
else {
    // Put the name into a text box.
    document.getElementById("userName").value = localStorage["user_name"];
}
```

Session storage is just as simple. The only difference is that you use the `sessionStorage` object instead of the `localStorage` object:

```
// Get the current date.
var today = new Date();

// Store the time as a piece of text in the form HH:mm.
sessionStorage["lastUpdateTime"] = today.getHours() + ":" + today.getMinutes();
```

Figure 9-1 shows a simple test page that puts all of these concepts together.

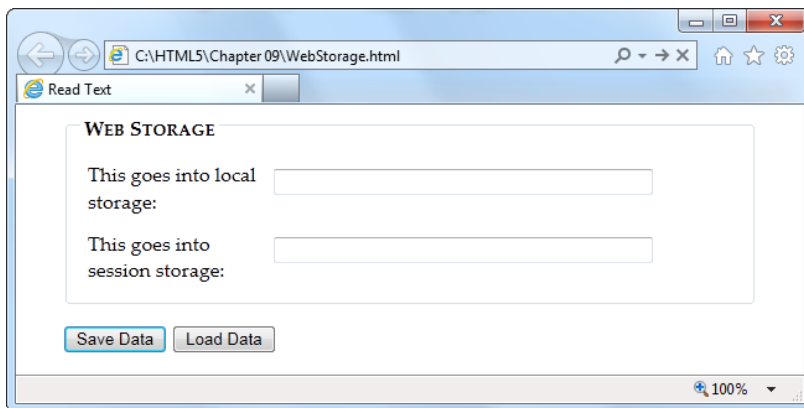

Figure 9-1:

This page has two text boxes, one for session storage and one for local storage. When you click Save, the page stores the values. Click Load Data, and it brings them back. To try this out (and to verify that session storage disappears when the window is closed but that local storage lives forever), run this page at www.prosotech.com/html5.

Note: Web storage also supports an alternate property syntax that's a little less common. With property syntax, you refer to a storage slot called "user_name" as `localStorage.user_name` rather than `localStorage["user_name"]`. There's no reason to prefer one syntax to the other (other than personal preference).

TROUBLESHOOTING MOMENT

Web Storage Fails Without a Web Server

There's an unexpected problem that can trip up your web storage testing. In many browsers, web storage works only when you're requesting the pages from a live web server. It doesn't matter whether that web server is located on the Internet or if it's just a test server running on your own computer—the important detail is that you aren't just launching the pages from your local hard drive.

This quirk is a side effect of the way that browsers dole out their local storage space. As you've already learned, they limit each website to 5 MB, and in order to do that, they need to associate every page that wants to use local storage to a website domain.

So what happens if you break this rule and open a web page that uses web storage, straight from a file? It depends.

In Internet Explorer, the browser appears to lose its web storage support completely. The `localStorage` and `sessionStorage` objects disappear, and trying to use them causes a JavaScript error. In Firefox, the `localStorage` and `sessionStorage` objects remain, and support *appears* to be there (even to Modernizr), but everything you try to store quietly disappears into a void. And in Chrome, the result is different again—most of web storage works fine, but some features (like the `onStorage` event) don't work. You'll see the same issues when you use the File API (page 294). So do yourself a favor and put your pages on a test server, so you're not tripped up by unexpected quirks. Or, run the examples in this chapter from the try-out site at www.prosetech.com/html5.

A Practical Example: Storing the Last Position in a Game

At this point, you might have the impression that there isn't much to web storage, other than remembering to pick a name and put it in square brackets. And you'd be mostly right. But you can put local storage to some more practical purposes without any extra effort.

For example, consider the canvas-based maze game you saw in Chapter 7 (page 229). A maze might be too much trouble to solve in one go, in which case it makes sense to store the current position when the user closes the window or navigates to a new page. When the user returns to the maze page, your code can then restore the happy face to its previous position in the maze.

There are several possible ways to implement this example. You could simply save a new position after each move. Local storage is fast, so this wouldn't cause any problem. Or, you could react to the page's `onBeforeUnload` event to ask the game player if it's worth storing the current position (Figure 9-2).

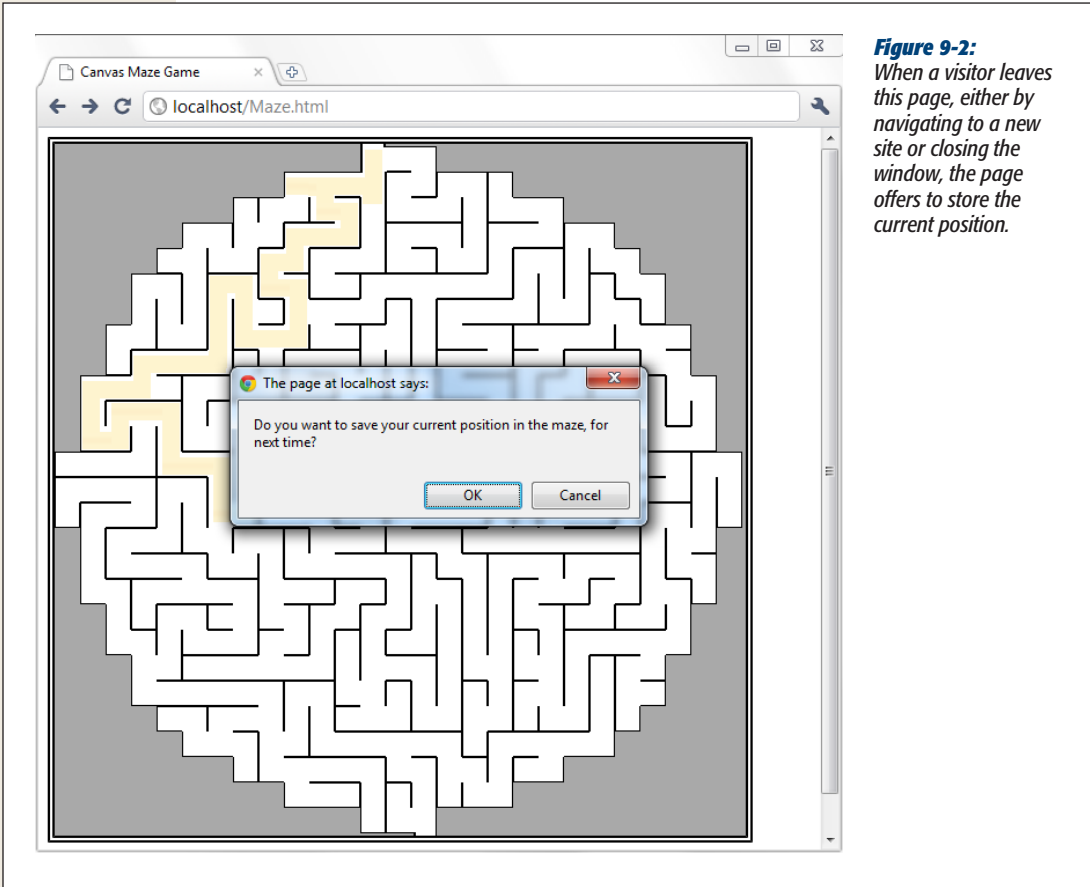

Figure 9-2:
When a visitor leaves this page, either by navigating to a new site or closing the window, the page offers to store the current position.

Here's the code that offers to store the position details:

```

window.onbeforeunload = function(e) {
    // Check if the localStorage object exists (as there's no reason to offer
    // to save the position if it won't work).
    if (localStorage) {

        // Ask to save the position.
        if (confirm(
            "Do you want to save your current position in the maze, for next time?")) {
            // Store the two coordinates in two storage slots.
            localStorage["mazeGame_currentX"] = x;
            localStorage["mazeGame_currentY"] = y;
        }
    }
}

```

Tip: Long key names, like `mazeGame_currentX`, are good. After all, it's up to you to ensure that key names are unique, so two web pages on your website don't inadvertently use the same name to store different pieces of data. With just a single container that holds all your data, it's all too easy to run into naming conflicts, which is the one glaring weakness in the web storage system. To prevent problems, come up with a plan for creating logical, descriptive key names. For example, if you have separate maze games on separate pages, consider incorporating the page name into the key name, as in `Maze01_currentX`.)

When the page loads the next time, you can check to see whether this information exists:

```
// Is the local storage feature supported?
if (localStorage) {
    // Try to get the data.
    var savedX = localStorage["mazeGame_currentX"];
    var savedY = localStorage["mazeGame_currentY"];

    // If the variables are null, no data was saved.
    // Otherwise, use the data to set new coordinates.
    if (savedX != null) x = Number(savedX);
    if (savedY != null) y = Number(savedY);
}
```

This example shows how to store an *application state*. If you wanted to avoid showing the same message each time the user leaves the game, you could add an “Automatically save position” checkbox. You would then store the position if the checkbox is switched on. Of course, you'd want to save the value of the checkbox too, and that would be an example of storing *application preferences*.

This example also uses the JavaScript `Number()` function to make sure the saved data is converted to valid numbers. You'll learn why that's important on page 289.

Browser Support for Web Storage

Web storage is one of the better-supported HTML5 features, with good support in every modern browser. Table 9-1 lists the minimum versions you need.

Table 9-1. Browser support for local storage and session storage

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	8	3.5	5	4	10.5	2	2

All these browsers allow you to store data in local storage and session storage. However, support for the `onStorage` event (a less commonly used feature that you'll consider on page 292) is a bit more recent. For example, you'll need IE 9, Firefox 4, or Chrome 6 to use it.

The browser that's most likely to cause a problem is IE 7, which doesn't support web storage at all. As a workaround, you can simulate web storage using cookies. The fit isn't perfect, but it works. And although there's no official piece of script that plugs that gap, you can find many decent starting points on the GitHub polyfill page at <http://tinyurl.com/polyfill> (just look under the “Web Storage” section heading).

Deeper into Web Storage

You now know the essentials of web storage—how to put information in, and how to get it out again. However, there are several finer points and a few useful techniques left to cover before you put it to use. In the following sections, you'll see how to remove items from web storage and how to examine all the currently stored items. You'll also learn to deal with different data types, store custom objects, and react when the collection of stored items changes.

Removing Items

It couldn't be easier. You use the `removeItem()` method, and the key name, to get rid of a single piece of data you don't want:

```
localStorage.removeItem("user_name");
```

Or, if you want to empty out all the local data your website has stored, use the more radical `clear()` method:

```
sessionStorage.clear();
```

Finding All the Stored Items

To get a single piece of data out of web storage, you need to know its key name. But here's another neat trick. Using the `key()` method you can pull every single item out of local or session storage (for the current website), even if you don't know any key names. This is a nifty technique when you're debugging, or if you just want to review what other pages in your site are storing, and what key names they're using.

Figure 9-3 shows a page that puts this technique into practice.

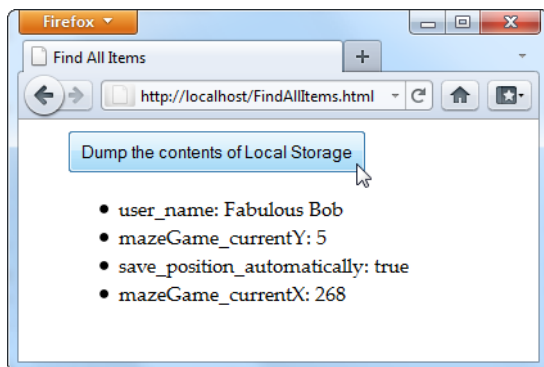

Figure 9-3:
Click the button, and this page fills a list with the local storage contents.

When you click the button in this example, it triggers the `findAllItems()` function, which scans through the collection of items in local storage. Here's the code:

```
function findAllItems() {
    // Get the <ul> element for the list of items.
    var itemList = document.getElementById("itemList");

    // Clear the list.
    itemList.innerHTML = "";

    // Do a loop over all the items.
    for (var i=0; i<localStorage.length; i++) {
        // Get the key for the item at the current position.
        var key = localStorage.key(i);

        // Get the item that's stored with this key.
        var item = localStorage[key];

        // Create a new list item with this information,
        // and add it to the page.
        var newItem = document.createElement("li");
        newItem.innerHTML = key + ": " + item;
        itemList.appendChild(newItem);
    }
}
```

Storing Numbers and Dates

So far, the exploration into web storage has glossed over one important detail. Whenever you store something in the `localStorage` or `sessionStorage` object, that data is automatically converted to text.

For values that are already text (like the user name typed into a text box), there's no problem. But numbers aren't as forgiving. Consider the example on page 287, which stores the most recent face position in local storage. If you forget to convert the coordinates from text to numbers, you can run into this sort of problem:

```
// Get the last x-coordinate position.
// For example, this might return the text "35"
x = localStorage["mazeGame_currentX"];

// Increment the position.
// Unfortunately, JavaScript converts "35"+"5" to "355".
x += 10;
```

This clearly isn't what you want. In fact, this code will cause the happy face to jump to completely the wrong position, or right out of the maze.

The issue here is that JavaScript assumes you're trying to stick two pieces of text together, rather than perform a mathematical operation. To solve the problem, you need to give JavaScript a hint that you're trying to work with numbers. Several solutions are possible, but the `Number()` function works well:

```
x = Number(localStorage["mazeGame_currentX"]);

// Now JavaScript calculates 35+10 properly, and returns 40.
x += 10;
```

Text and numbers are easy to deal with, but if you want to place other sorts of data into web storage, you'll need to handle them with care. Some data types have handy conversion routines. For example, imagine you store a date like this:

```
var today = new Date();
```

This code doesn't store a date object, but a text string, like *Sat Jun 09 2011 13:30:46*. Unfortunately, there's no easy way to convert this text back into a date object when you pull it out of storage. And if you don't have a date object, you won't be able to manipulate the date in same way—say, calling date methods and performing date calculations.

To solve this problem, it's up to you to explicitly convert the date into the text you want, and then convert it back into a proper date object when you retrieve it. Here's an example:

```
// Create a date object.
var today = new Date();

// Turn the date into text string in the standard form YYYY/MM/DD,
// and store that text.
sessionStorage["session_started"] = today.getFullYear() + "/" +
    today.getMonth() + "/" + today.getDate();

...

// Now retrieve the date text, and use it to create a new date object.
// This works because the date text is in a recognizable format.
today = new Date(sessionStorage["session_started"]);

// Use the methods of the date object, like getFullYear().
alert(today.getFullYear());
```

Run this code, and the year appears in a message box, confirming that you've successfully recreated the date object.

Storing Objects

In the previous section, you saw how to convert numbers and dates to text and back again, allowing you to store them with web storage. These examples work because the JavaScript language helps you out, first with the handy `Number()` function, and then with the text-to-date conversion smarts that are hard-wired into date objects. However, there are plenty of other objects that can't be converted this way. This is definitely the case if you create a custom object of your own.

For example, consider the personality quiz you first saw in Chapter 7 (page 212). The personality quiz uses two pages. On the first, the quiz-taker answers some questions and gets a score. On the second, the results are shown. In the original version of this page, the information is passed from the first page to the second using query string arguments that are embedded in the URL. This approach is traditional HTML (although a cookie would work too). But in HTML5, local storage is the best way to shuffle data around.

But here's the challenge. The quiz data consists of five numbers, one for each personality factor. You *could* store each personality factor in a separate storage slot. But wouldn't it be neater and cleaner to create a custom object that packages up all the personality information in one place? Here's an example of a `PersonalityScore` object that does the trick:

```
function PersonalityScore(o, c, e, a, n) {
  this.openness = o;
  this.conscientiousness = c;
  this.extraversion = e;
  this.agreeableness = a;
  this.neuroticism = n;
}
```

If you create a `PersonalityScore` object, you need just one storage slot, instead of five. (For a refresher about how custom objects work in JavaScript, see page 217.)

To store a custom object in web storage, you need a way to convert the object to a text representation. You could write some tedious code that does the work. But fortunately, there's a simpler, standardized approach called *JSON encoding*.

JSON (JavaScript Object Notation) is a lightweight format that translates structured data—like all the values that are wrapped in an object—into text. The best thing about JSON is that browsers support it natively. That means you can call `JSON.stringify()` to turn any JavaScript object into text, complete with all its data, and `JSON.parse()` to convert that text back into an object. Here's an example that puts this to the test with the `PersonalityScore` object. When the test is submitted, the page calculates the score (not shown), creates the object, stores it, and then redirects to the new page:

```
// Create the PersonalityScore object.
var score = new PersonalityScore(o, c, e, a, n);

// Store it, in handy JSON format.
sessionStore["personalityScore"] = JSON.stringify(score);

// Go to the results page.
window.location = "PersonalityTest_Score.html";
```

On the new page, you can pull the JSON text out of storage, and use the `JSON.parse()` method to convert it back to the object you want. Here's that step:

```
// Convert the JSON text to a proper object.
var score = JSON.parse(localStorage["personalityScore"]);

// Get some data out of the object.
lblScoreInfo.innerHTML = "Your extraversion score is " + score.extraversion;
```

To see the complete code for this example, including the calculations for each personality factor, visit www.prosetech.com/html5. To learn more about JSON and take a peek at what JSON-encoded data actually looks like, check out <http://en.wikipedia.org/wiki/JSON>.

Reacting to Storage Changes

Web storage also gives you a way to communicate between different browser windows. That's because whenever a change happens to local storage or session storage, the `window.onStorage` event is triggered in every other window that's viewing the same page or another page on the same website. So if you change local storage on www.GoatsCanFloat.org/storeStuff.html, the `onStorage` event will fire in a browser window for the page www.GoatsCanFloat.org/checkStorage.html. (Of course, the page has to be viewed in the same browser and on the same computer, but you already knew that.)

The `onStorage` event is triggered whenever you add a new object to storage, change an object, remove an object, or clear the entire collection. It doesn't happen if your code makes a storage operation that has no effect (like storing the same value that's already stored, or clearing an already-empty storage collection).

Consider the test page shown in Figure 9-4. Here, the visitor can add any value to local storage, with any key, just by filling out two text boxes. When a change is made, the second page reports the new value.

To create the example shown in Figure 9-4, you first need to create the page that stores the data. In this case, clicking the Add button triggers a short `addValue()` function that looks like this:

```
function addValue() {
    // Get the values from both text boxes.
    var key = document.getElementById("key").value;
    var item = document.getElementById("item").value;

    // Put the item in local storage.
    // (If the key already exists, the new item replaces the old.)
    localStorage[key] = item;
}
```

The second page is just as simple. When the page first loads, it attaches a function to the `window.onStorage` event, using this code:

```
window.onload = function() {
    // Connect the onStorage event to the storageChanged() function.
    window.addEventListener("storage", storageChanged, false);
};
```

This code looks a little different than the event handling code you've seen so far. Instead of setting `window.onstorage`, it calls `window.addEventListener()`. That's because this code is the simplest that works on all current browsers. If you set `window.onstorage` directly, your code will work in every browser except Firefox.

Note: Web graybeards may remember that the `addEventListener()` method doesn't work on Internet Explorer 8 (or older). In this example, that limitation is no cause for concern, because IE 8 doesn't support storage events anyway.

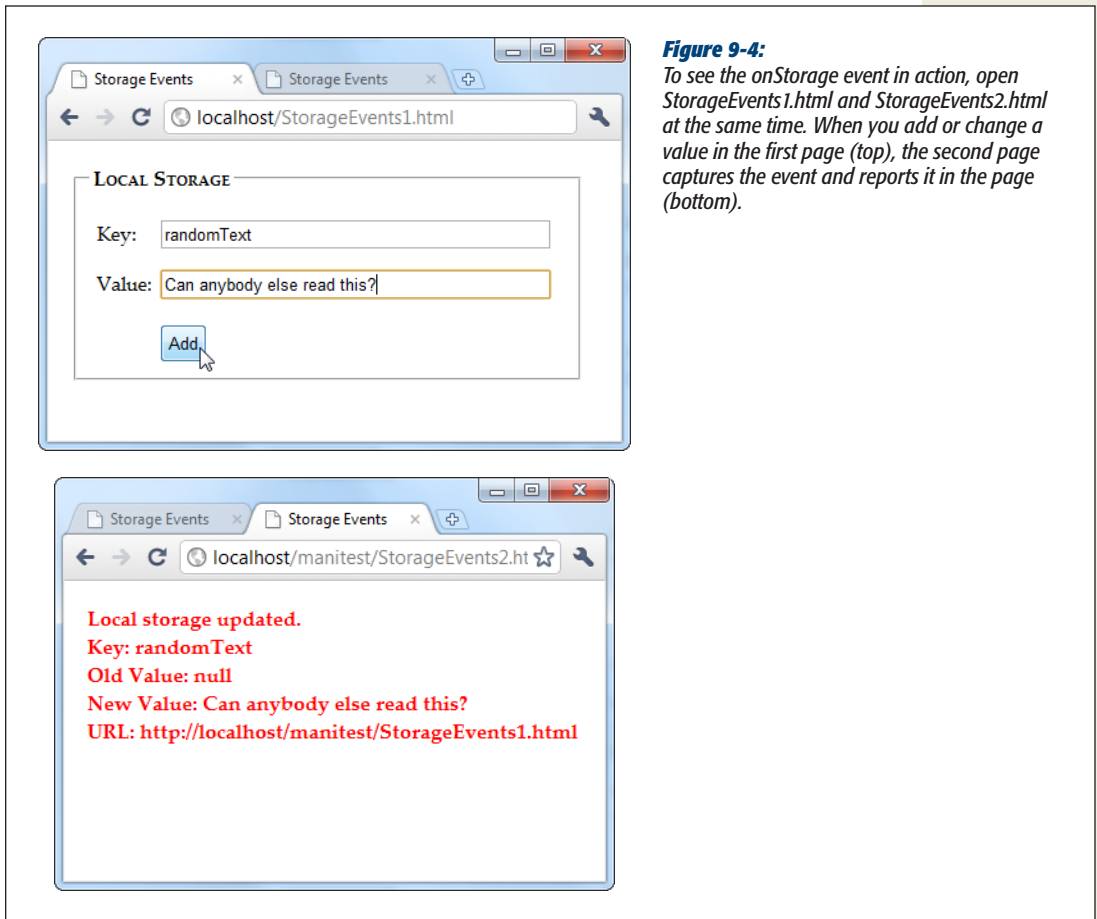

Figure 9-4:

To see the `onStorage` event in action, open `StorageEvents1.html` and `StorageEvents2.html` at the same time. When you add or change a value in the first page (top), the second page captures the event and reports it in the page (bottom).

The `storageChanged()` function has a simple task. It grabs the updated information and displays it in on the page, in a `<div>` element:

```
function storageChanged(e) {
    var message = document.getElementById("updateMessage");
    message.innerHTML = "Local storage updated.";
    message.innerHTML += "<br>Key: " + e.key;
    message.innerHTML += "<br>Old Value: " + e.oldValue;
    message.innerHTML += "<br>New Value: " + e.newValue;
    message.innerHTML += "<br>URL: " + e.url;
}
```

As you can see, the `onStorage` event provides several pieces of information, including the key of the value that was changed, the old value, the newly applied value, and the URL of the page that made the change. If the `onStorage` event is a reaction to the insertion of a new item, the `e.oldValue` property is either null (in most browsers) or an empty string (in Internet Explorer).

Note: If you have several pages open for the same website, the `onStorage` event occurs in each one, except the page that made the change (in the current example, that's `StorageEvents1.html`). However, Internet Explorer is the exception—it doesn't follow this rule, and fires the `onStorage` event in the original page as well.

Reading Files

Web storage is a solidly supported part of HTML5. But it's not the only way to access information. Several new standards are creeping onto the field for different types of storage-related tasks. One example is a standard called the File API, which technically isn't a part of HTML5, but has good support across modern browsers (except IE).

Based on its rather vague name, you might expect that the File API is a sweeping standard for reading and writing files on a web browser's hard drive. However, it's not that ambitious or powerful. Instead, the File API gives a way for a visitor to pick a file from his hard drive, and hand it directly to the JavaScript code that's running on the web page. This code can then open the file and explore its data, whether it's simple text or something more complicated. The key thing is that the file goes directly to the JavaScript code. Unlike a normal file upload, it never needs to travel to the web server.

It's also important to note what the File API *can't* do. Most significantly, it can't change a file or create a new one. If you want to store any data, you'll need to use another mechanism—for example, you can send your data to a web server through XMLHttpRequest (page 325), or you can put it in local storage.

You might think that the File API is less useful than local storage—and for most websites, you'd be right. However, the File API is also a toehold into a world where HTML has never gone before, at least not without a plug-in to help.

Note: Right now, the File API is an indispensable feature for certain types of specialized applications, but in the future its capabilities may expand to make it much more important. For example, future versions may allow web pages to *write* local files, provided the user has control over the file name and location, using a Save dialog box. Browser plug-ins like Flash already have this capability.

Getting Hold of a File

Before you can do anything with the File API, you need to get hold of a file. There are three strategies you can use, but they are the same in one key fact—namely, your web page only gets a file if the visitor explicitly picks it and gives it to you.

Here are your options:

- **The `<input>` element.** Set the type attribute to file, and you’ve got the standard file upload box. But with a bit of JavaScript and the File API, you can open it locally.
- **A hidden `<input>` element.** The `<input>` element is ugly. To get right with the style police, you can hide your `<input>` element and make a nicer browser button. When it’s clicked, use JavaScript to call the `click()` method on the hidden `<input>` element. This shows the standard file-selection dialog box.
- **Drag-and-drop.** If the browser supports it, you can drag a file from the desktop or a file browser window and drop it on a region in the web page.

In the following sections, you’ll see all three approaches. But first, it’s worth taking a look at the current state of browser support, so you can decide whether the File API makes sense for your websites.

Browser Support for the File API

The File API doesn’t enjoy the same broad support as web storage. Table 9-2 shows which browsers include it.

Table 9-2. Browser support for the File API

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	10*	3.6	8	6	11.1	-	3

**Currently, this version is available in early beta builds only.*

The browser versions in this table can use all the examples in this chapter. However, they almost certainly don’t implement all the File API features, because some part of the standard (those that deal with binary blobs of data and “slicing” chunks of data) are still changing.

Because the File API requires some privileges that ordinary web pages don’t have, you can’t patch the missing feature with more JavaScript. Instead, you need to rely on a plug-in like Flash or Silverlight. For example, you can find a polyfill at <http://sandbox.knarly.com/js/dropfiles> that uses Silverlight to intercept a dragged file, open it, and then pass the details to the JavaScript code on the page.

Reading a Text File

One of the easiest things you can do with the File API is read the content from a simple text file. Figure 9-5 shows a web page that uses this technique to read the markup in a web page and then display it.

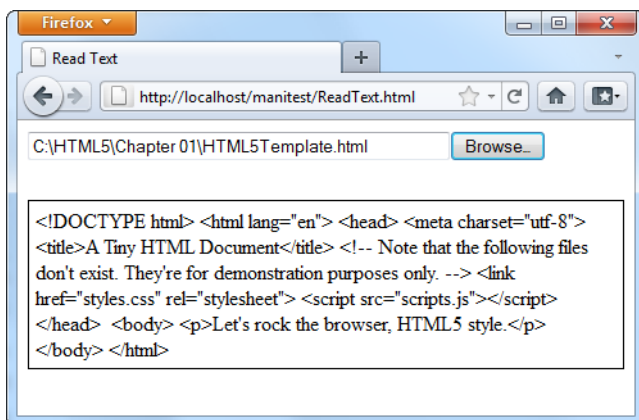

Figure 9-5:

Click the Browse button (or Choose File, as it's named in Chrome), choose a file, and then click OK. Instead of the usual upload, the web page JavaScript takes it from there, copying the content into your page.

To build this example you start with the `<input type="file">` element, which creates the infamous text box and Browse button combination:

```
<input id="fileInput" type="file" onchange="processFiles(this.files)">
```

However, whereas an `<input>` element usually belongs in a `<form>` container so the file can be posted to the web server, this `<input>` element goes its own way. When the web page visitor picks a file, it triggers the `<input>` element's `onChange` event, and that triggers the `processFiles()` function. It's here that the file is opened, in ordinary JavaScript.

Now you'll consider the `processFiles()` function, one piece at a time. The first order of business is to grab the first file from collection of files that the `<input>` element provides. Unless you explicitly allow multiple file selection (with the *multiple* attribute), the files collection is guaranteed to hold just one file, which will be at position 0 in the files array:

```
function processFiles(files) {
    var file = files[0];
```

Note: Every file object has three potentially useful properties. The `name` property gives you its file name (not including the path), the `size` property tells you how many bytes big it is, and the `type` property tells you the MIME type of the file (page 153), if it can be determined. You could read these properties and add additional logic—for example, you could refuse to process files above a certain size, or allow files of only a certain type.

Next, you create a `FileReader` object that allows you to process the file:

```
var reader = new FileReader();
```

It's almost time to call one of the `FileReader`'s methods to extract the file content. All of these methods are *asynchronous*, which means they start the file-reading task but don't wait for the data. To get the data, you first need to handle the `onLoad` event:

```
reader.onload = function (e) {
    // When this event fires, the data is ready.
    // Copy it to a <div> on the page.
    var output = document.getElementById("fileOutput");
    output.textContent = e.target.result;
};
```

Finally, with that event handler in place, you can call the `FileReader`'s `readAsText()` method:

```
    reader.readAsText(file);
}
```

This method dumps all the file content into a single long string, which is provided in the `e.target.result` that's sent to the `onLoad` event.

The `readAsText()` method works properly only if the file holds text content (not binary content). That means it suits HTML files perfectly well, as shown in Figure 9-5. However, there are other useful formats that use plain text. One good example is the CSV format, which is a basic export format supported by all spreadsheet programs. Another example is the XML format, which is a standard way of exchanging bunches of data between programs. (It's also the foundation of the Office XML formats, which means you can hand .docx and .xlsx files directly to the `readAsText()` method as well.)

Note: The JavaScript language even has a built-in XML parser, which means you can browse around an XML file and dig out just the content you need. Of course, the code this requires is considerable, it performs poorly for large files, and it's rarely easier than just uploading the file to a web server and running your file-processing logic there. However, you can start to see how the File API can open up new possibilities that HTML lovers didn't dare imagine even just a few years ago.

The `readAsText()` is only one of a handful of file-reading methods. The `FileReader` object also includes the following: `readAsBinaryString()`, `readAsDataURL()`, and `readAsArrayBuffer()`, although the last one isn't yet supported in Firefox.

The `readAsBinaryString()` method gives your application the ability to deal with binary-encoded data, although it somewhat awkwardly sticks it into a text string, which is inefficient. And if you actually want to *interpret* that data, you need to struggle through some horribly convoluted code. Better support is planned for “slicing” out small pieces of binary data, so you can process one chunk at a time. But at the time of this writing, this feature is still being revised, and has been implemented differently in different browsers. (You can read the latest standard at www.w3.org/TR/FileAPI.)

The `readAsDataURL()` method gives you an easy way to grab picture data. You'll use that on page 301. But first, it's time to make this page a bit prettier.

Replacing the Standard Upload Control

Web developers agree: The standard `<input>` control for file submission is ugly. And although you do need to use it, you don't actually need to let anyone see it. Instead, you can simply hide it, with a style rule like this:

```
#fileInput {
  display: none;
}
```

Now add a new control that will trigger the file-submission process. An ordinary link button will do, which you can make look as pretty as you want:

```
<button onclick="showFileInput()">Analyze a File</button>
```

The final step is to handle the button click and use it to manually trigger the `<input>` element, by calling *its* `click()` method:

```
function showFileInput() {
  var fileInput = document.getElementById("fileInput");
  fileInput.click();
}
```

Now, when the button is clicked, the `showFileInput()` function runs, which clicks the hidden Browse button and shows the dialog box where the visitor can pick a file. This, in turn, triggers the hidden `<input>` element's `onChange` event, which runs the `processFiles()` function, just like before.

Reading Multiple Files at Once

There's no reason to limit people to submitting one file at a time. HTML5 allows multiple file submission, but you need to explicitly allow it by adding the *multiple* attribute to the `<input>` element:

```
<input id="fileInput" type="file" onchange="processFiles(this.files)"
multiple>
```

Now the user can select more than one file in the Open dialog box (for example, by pressing Ctrl on a Windows computer while clicking several files, or by dragging a box around a group of them). Once you allow multiple files, your code needs to accommodate them. That means you can't just grab the first file from the files collection, as in the previous example. Instead, you need a *for* loop that processes each file, one at a time:

```
for (var i=0; i<files.length; i++) {
  // Get the next file
  var file = files[i];

  // Create a FileReader for this file, and run the usual code here.
  var reader = new FileReader();
  reader.onload = function (e) {
    ...
  }
}
```

```

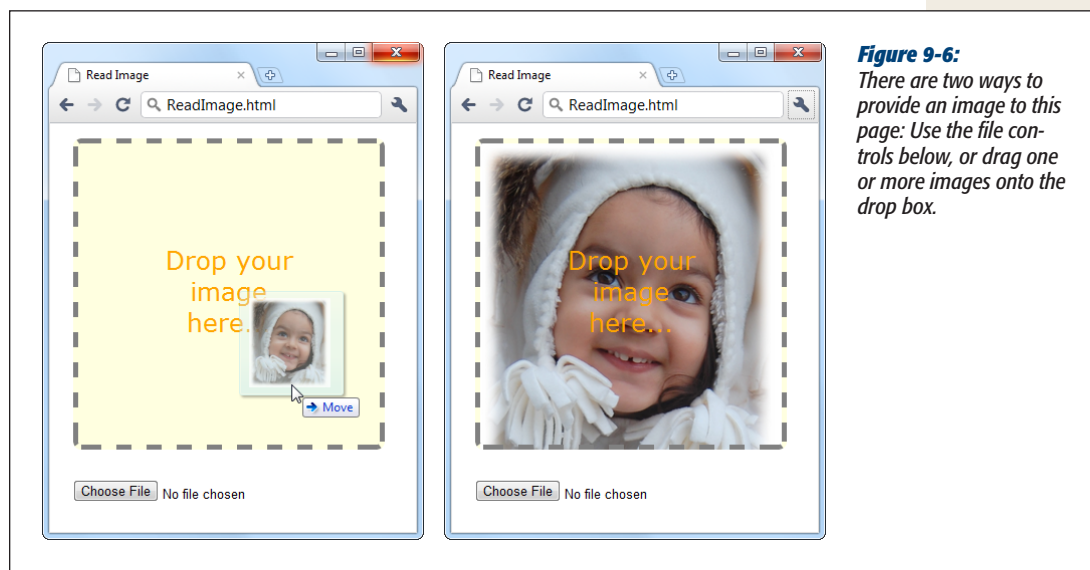

};
reader.readAsText(file);
}

```

Reading an Image File

As you've seen, the `FileReader` handles text content in a single, simple step. It deals with images just as easily, thanks to the `readAsDataURL()` method.

Figure 9-6 shows an example that introduces two new features: image support, and file drag-and-drop. The submitted image is used to paint the background of an element, although you could just as easily paint it on a canvas and process it using the canvas's raw pixel features (page 234). For example, you could use this technique to create a page where someone can drop in a picture, draw on it or modify it, and then upload the final result using an `XMLHttpRequest` call (page 325).

To create this page, you first need to decide what element will capture the dropped files. In this example, it's a `<div>` element named `dropBox`:

```

<div id="dropBox">
  <div>Drop your image here...</div>
</div>

```

Some straightforward style sheet magic gives the drop box the size, borders, and colors you want:

```

#dropBox {
  margin: 15px;
  width: 300px;
  height: 300px;
  border: 5px dashed gray;
  border-radius: 8px;
}

```

```

background: lightyellow;
background-size: 100%;
background-repeat: no-repeat;
text-align: center;
}

#dropBox div {
margin: 100px 70px;
color: orange;
font-size: 25px;
font-family: Verdana, Arial, sans-serif;
}

```

Keen eyes will notice that the drop box sets the *background-size* and *background-repeat* properties in preparation for what comes next. When the image is dropped onto the <div>, it's set as the background. The background-size property ensures that the picture is compressed down so you can see all of it at once. The background-repeat property ensures that the picture isn't tiled to fill the leftover space.

To handle file drops, you need to handle three events: `onDragEnter`, `onDragOver`, and `onDrop`. When this page first loads, it attaches event handlers for all three:

```

var dropBox ;

window.onload = function() {
dropBox = document.getElementById("dropBox");
dropBox.ondragenter = ignoreDrag;
dropBox.ondragover = ignoreDrag;
dropBox.ondrop = drop;
};

```

The `ignoreDrag()` function handles both `onDragEnter` (which fires when the mouse pointer enters the drop box, with a file attached) and `onDragOver` (which fires continuously, as the file-dragging mouse pointer moves over the drop box). That's because you don't need to react to either of these actions, other than to tell the browser to hold off from taking any actions of its own. Here's the code you need:

```

function ignoreDrag(e) {
// Make sure nobody else gets this event, because you're handling
// the drag and drop.
e.stopPropagation();
e.preventDefault();
}

```

The `onDrop` event is more important. It's at this point that you get the file and process it. However, because there are actually two ways to submit files to this page, the `drop()` function calls the `processFiles()` function to do the actual work:

```

function drop(e) {
// Cancel this event for everyone else.
e.stopPropagation();
e.preventDefault();

// Get the dragged-in files.
var data = e.dataTransfer;
var files = data.files;
}

```

```

    // Pass them to the file-processing function.
    processFiles(files);
}

```

The `processFiles()` function is the last stop in the drag-and-drop journey. It creates a `FileReader`, attaches a function to the `onload` event, and calls `readAsDataURL()` to transform the image data into a data URL (page 192):

Note: As you learned when you explored the canvas, a data URL is a way of representing image data in a long text string that's fit for URL. This gives you a portable way to move the image data around. To show the image content in a web page, you can set the `src` property of an `` element (as on page 193), or you can set the CSS `background-image` property (as in this example).

```

function processFiles(files) {
    var file = files[0];

    // Create the FileReader.
    var reader = new FileReader();

    // Tell it what to do when the data URL is ready.
    reader.onload = function (e) {
        // Use the image URL to paint the drop box background
        dropBox.style.backgroundImage = "url('" + e.target.result + "')";
    };

    // Start reading the image.
    reader.readAsDataURL(file);
}

```

The `FileReader` provides several more events, and when reading image files you might choose to use them. The *onProgress* event fires periodically during long operations, to let you know how much data has been loaded so far. (You can cancel an operation that's not yet complete by calling the `FileReader`'s `abort()` method.) The *onError* event fires if there was a problem opening or reading the file. And the *onLoadEnd* event fires when the operation is complete for any reason, including if an error forced it to end early.

POWER USERS' CLINIC

Into the World of Databases

Are you hungering for a more powerful local storage option? If text strings (web storage) and plain files (the File API) aren't exciting you anymore, how about having a complete, miniature database running in your browser?

This ambitious idea isn't just a dream. In fact, it's already been implemented once, in Chrome and Safari, according to the Web Databases standard. However, the standard failed to convince Firefox and is now considered obsolete.

In its place is the very new Indexed DB, which all browser makers seem likely to implement. To get a preview, you can read the scant Firefox documentation at <http://developer.mozilla.org/en/IndexedDB>, or try out the experimental lab for Internet Explorer 9, which is available at <http://tinyurl.com/3fuvu9g>.

Offline Applications

If you want to view a website, you need to connect to the Internet. Everybody knows that by now. So why a chapter about offline applications? The very notion seems so last century. After all, didn't web applications overthrow several generations of offline, desktop applications on their way to conquering the world? And there are plenty of tasks—from following the latest Charlie Sheen sightings to ordering a new office chair—that just wouldn't be possible without a live, real-time connection. But remember, even web applications aren't meant to stay *permanently* online. Instead, they're designed to keep working during occasional periods of downtime when a computer loses its network connection. In other words, an offline web application tolerates intermittent network disruptions.

This fact is particularly important for people using web-enabled phones and tablets. To see the problem, try traveling through a long tunnel while working on a web application with one of these devices. Odds are you'll get a nasty error page, and you'll need to start all over again when you get to the other side. But do the same with an *offline* web application, and you'll avoid interruption. Some of the features of the web application may become temporarily unavailable, but you won't get booted out. (Of course, some tunnels are longer than others. An ambitious offline web application can keep working through a three-hour plane flight—or a three-week trip to the Congo, if that's what you're after. There's really no limit to how long you can stay offline.)

In this chapter, you'll learn how to turn any web page (or group of web pages) into an offline application. You'll also learn how to tell when a website is available and when it's offline, and react accordingly.

FREQUENTLY ASKED QUESTION

When It Makes Sense to Go Offline

Should I make my web page offline-able?

Offline web applications don't suit every sort of web page. For example, there's really no point in turning a stock quote page into an offline web application, because the whole point of its existence is to fetch updated stock data from a web server. However, the offline feature might suit a more detailed stock analysis tool that downloads a bunch of data at once and then lets you choose how to chart it or analyze it. Using a page like this, you could download some data while you're online and then tweak options and fiddle with buttons until you reach the proverbial other side of the tunnel.

The offline feature also suits web pages that are interactive and *stateful*—ones that have piles of JavaScript code maintaining lots of information in memory. These pages do

more on their own, so they make sense as offline applications. And the cost of losing your connection with one of these pages is also higher (because being kicked out in the middle of a complex task is seriously annoying). So while there's no point in making a simple page of content offline-able, it's immediately obvious that a word-processor-in-a-browser tool can benefit from offline support. In fact, an offline application like this might just be able to stand in for a more fully-featured desktop program.

The other consideration is your audience. The offline application feature makes great sense if your visitors include people who don't have reliable Internet connections or are likely to need mobile access (for example, if you're creating a mapping tool for tablet devices). But if not, adding offline support might not be worth the trouble.

Caching Files with a Manifest

The basic technique that makes offline applications work is *caching*—the technique of downloading a file (like a web page) and keeping a copy of it on the web surfer's computer. That way, if the computer loses its web connection, the browser can still use the cached copy of the page.

To create an offline application, you need to complete three steps:

1. **Create a *manifest* file.**

A manifest is a special sort of file that tells browsers what files to store, what files not to store, and what files to substitute with something else. This package of cacheable content is called an *offline application*.

2. **Modify your web page so it refers to the manifest.**

That way, the browser knows to download the manifest file when someone requests the page.

3. **Configure the web server.**

Most importantly, the web server needs to serve manifest files with the proper MIME type. But as you'll see, there are a few more subtle issues that can also trip up caching.

You'll tackle all these tasks in the following sections.

UP TO SPEED

Traditional Caching vs. Offline Applications

Caching is nothing new in the web world. Browsers use caching regularly to avoid repeatedly downloading the same files. After all, if you travel through several pages in a website, and each page uses the same style sheet, why download it more than once? However, the mechanism that controls this sort of caching isn't the same as the one that makes offline applications work.

Traditional caching happens when the web server sends extra information (called *cache-control headers*) along with some file that a web browser has requested. The headers tell the browser if the file should be cached and how long to keep the cached copy before asking the web server if the file has changes. Typically, caching is brief for web pages

and much longer for the resources that web pages use, like style sheets, pictures, and script files.

By comparison, an offline application is controlled a separate file (called a manifest), and it doesn't use any time limit at all. Instead, it applies the following rule: "If a web page is part of an offline application, if the browser has a cached copy of that application, and if the definition of that application hasn't changed, then use the cached copy." You, the web developer, can add in certain exceptions—for example, telling the browser not to cache certain files, or to substitute one file for another. But there's no need to worry about expiration dates and other potentially messy details.

Creating a Manifest

The manifest is the heart of HTML5's offline application feature. It's a text file that lists the files you want to cache.

The manifest always starts with the words "CACHE MANIFEST" (in uppercase), like this:

```
CACHE MANIFEST
```

After that, you list the files you want to cache. Here's an example that grabs two web pages (from the personality test example described on page 212):

```
CACHE MANIFEST
```

```

PersonalityTest.html
PersonalityTest_Score.html

```

Spaces (like the blank line in the manifest shown above) are optional, so you can add them wherever you want.

With an offline application, the browser must cache everything your application needs. That includes web pages and the resources these web pages use (like scripts, graphics, style sheets, and embedded fonts). Here's a more complete manifest that takes these details into account:

```

CACHE MANIFEST
# pages
PersonalityTest.html
PersonalityTest_Score.html

# styles & scripts

```

```
PersonalityTest.css
PersonalityTest.js

# pictures & fonts
Images/emotional_bear.jpg
Fonts/museo_slab_500-webfont.eot
Fonts/museo_slab_500-webfont.woff
Fonts/museo_slab_500-webfont.ttf
Fonts/museo_slab_500-webfont.svg
```

Here, you'll notice two new details. First, you'll see several lines that begin with a number sign (#). These are *comments*, which you can add to remind yourself what goes where. Second, you'll see some files that are in subfolders (for example, *emotional_bear.jpg* in the *Images* folder). As long as these files are on the web server and accessible to the browser, you can bundle them up as part of your offline application package.

Complex web pages will need a lot of supporting files, which can lead to long, complex manifest files. Worst of all, a single mistyped file name will prevent the offline application feature from working *at all*. In the future, leading web editors will improve life. They'll add features that will automatically create manifest files for the pages you pick, and help you modify and maintain them.

Tip: You might decide to leave out some resources that are large or unimportant, like huge pictures or ad banners. That's quite all right, but if you think their absence might cause some trouble (like error messages, odd blank spaces, or scrambled layouts), consider using JavaScript to tweak your pages when the user is offline, by using the connection-checking trick described on page 317.

Once you've filled out the contents of your manifest file, you can save it in the root folder of your website, alongside your web pages. You can use whatever file name you want, although two file extensions are currently popular: *.manifest* and *.appcache*. The first choice (say, *PersonalityTest.manifest*) is the most logical, but it conflicts with a file type already used on some Windows web servers (as part of the ClickOnce deployment process used by .NET applications). The second choice (as in *PersonalityTest.appcache*) is reasonable, but less common. The important thing is that the web server is configured to recognize the file extension. If you're running your own web server, you can use the setup steps described on page 308. If not, you need to talk to your web hosting company and ask them what file extensions they use to support manifest files.

FREQUENTLY ASKED QUESTION

How Much Can You Cache?

Are there limits on how much information can be cached?

Different browsers impose wildly different size restrictions on offline applications.

Mobile browsers are an obvious example. Because they run on space-limited devices, they tend to be stingy with their caching. At this writing, the version of Safari that runs on the iPad and iPhone limits each offline application to 5 MB of space.

Desktop browsers are surprisingly inconsistent. In Firefox, a cached application can swallow up to 50 MB of space with the default settings, and the person using the browser can increase this limit. (To apply custom cache settings, choose Options from the Firefox menu, click the Advanced icon, and choose the Network tab.) However, Chrome grants offline applications a measly 5 MB of space, unless you develop a dedicated Chrome app (<http://code.google.com/chrome/extensions/apps.html>) or use a clumsy configuration hack (<http://tinyurl.com/5w83opp>). Chrome developers plan to remove this limitation in the future and give the user explicit control over how much storage space each

website gets, but for now the 5 MB limit remains as a stop-gap measure.

Unfortunately, the lack of consistency among browsers is a problem. If you create an offline application that attempts to include more than 5 MB of data, it will work fine in Firefox, but not in Chrome. Even worse, every time a Chrome user visits your site, Chrome will attempt to cache the application, fail when it hits the size limit, and then throw all the downloaded data away. Not only will you waste time and bytes, but your Chrome users won't get any offline benefits. They'll be locked out of your application unless they're online.

The bottom line is this: In the future, offline applications will probably have large amounts of space at their disposal. But right now, web developers must assume that they're working with a much more limited 5 MB sliver. As a consequence, it's probably not practical to use the offline application feature to improve performance (by downloading big, commonly used files and storing them permanently). But expect this situation to change someday soon.

Using Your Manifest

Just creating a manifest isn't enough to get a browser to pay attention. To put your manifest into effect, you need to refer to it in your web pages. You do that by adding the *manifest* attribute to the root `<html>` element and supplying the manifest file name, like this:

```
<!DOCTYPE html>
<html lang="en" manifest="PersonalityTest.manifest">
...
```

You need to take this step for every page that's part of your offline application. In the previous example, that means you need to change two files: `PersonalityTest.html` and `PersonalityTest_Score.html`.

Note: A website can have as many offline applications as you want, as long as each one has its own manifest. Offline applications can also use some of the same resources (like style sheets), but each one must have its own distinct collection of web pages.

Putting Your Manifest on a Web Server

Testing manifest files can be a tricky process. Minor problems can cause silent failures and throw off the entire caching process. Still, at some point you'll need to give it a try to make sure your offline application is as self-sufficient as you expect.

It should come as no surprise that you can't test offline applications when you're launching files from your hard drive. Instead, you need to put your application on a web server (or use a test web server that runs on your computer, like the IIS web server that's built into Windows).

To test an offline application, follow these steps:

1. **Make sure the web server is configured to serve manifest files with the MIME type *text/cache-manifest*.**

If the web server indicates that the file is any other type, including a plain text file, the browser will ignore the manifest completely.

Note: Every type of web server software works differently. Depending on your skills, you may need the help of your neighborhood webmaster to set MIME types (step 1) and change caching settings (step 2). Page 153 has more information about MIME types.

2. **Consider turning off traditional caching (page 305) for manifest files.**

Here's the problem. Web servers may tell web browsers to cache manifest files for a short period of time, just as they tell them to cache other types of files. This behavior is reasonable enough, but it can cause king-sized testing headaches. That's because when you update the manifest file, some browsers will ignore it and carry on with the old, cached manifest file, and so they'll keep using the old, cached copies of your web pages. (Firefox has a particularly nasty habit of sticking with out-of-date manifest files.) To avoid this problem, you should configure the web server to tell browsers not to cache manifest files.

3. **Request the page in a web browser that supports offline applications—in other words, virtually any browser other than Internet Explorer. (Get the low-down on page 295.)**

When a web browser discovers a web page that uses a manifest, it may ask for your permission before downloading the files. Mobile devices probably will, because they have limited space requirements. Desktop browsers may or may not—for example, Firefox does (see Figure 10-1), but Chrome and Safari don't.

If you give your browser permission (or if your browser doesn't ask for it), the caching process begins. The browser downloads the manifest and then downloads each of the files it references. This downloading process takes place in the background and doesn't freeze up the page. It's just the same as when a browser downloads a large image or video, while displaying the rest of the page.

Figure 10-1: Firefox shows this message when it loads a web page that uses a manifest. Click **Allow** to grant permission to download and cache all the files that are listed in the manifest. On subsequent visits, when Firefox detects a changed manifest, it will download the new files without asking for permission again.

4. Go offline.

If you're testing on a remote server, just disconnect your network connection. If you're testing on a local web server (one that's running on your computer), shut your website down (Figure 10-2).

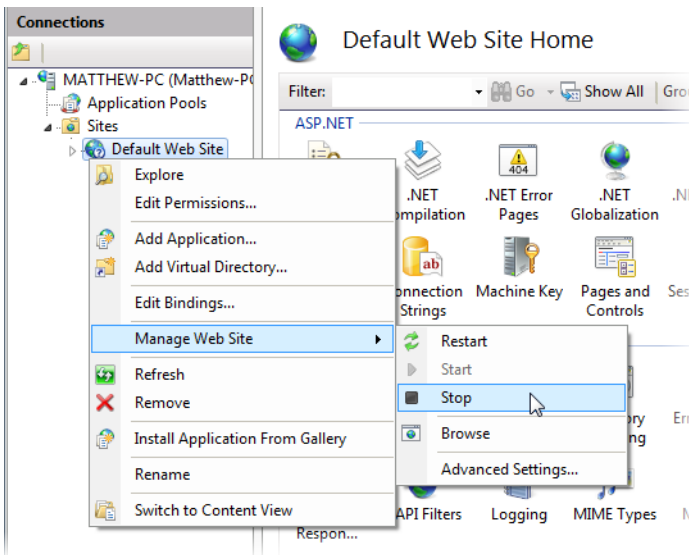

Figure 10-2: The exact way you shut down your test website depends on the type of web server software you're using. In the Windows-based IIS software (shown here), a simple right-click gets you started.

5. Browse to one of the pages in your offline application, and refresh it.

Even if you’ve told a browser not to cache a page, it sometimes will, just so you can step through your surfing history with the Back button. But when you click the Refresh or Reload button, the browser always tries to make contact with the web server. If you’re requesting an ordinary page, this request will fail. But if you’re requesting a page from an offline application, the browser seamlessly substitutes the cached copy, without even informing you of the switch. You can even click links to jump from one page to another, but if you navigate to a page that’s not part of the offline application, you’ll get the familiar “no response” error.

TROUBLESHOOTING MOMENT

My Offline Application Doesn’t Work Offline

The offline application feature is a bit fragile. A minor mistake can throw it all off. If you follow the steps described above, but you get a “no response” error when you attempt to access your offline pages, check for these common problems:

- **Problems downloading the manifest.** If the manifest isn’t there, or isn’t accessible to the browser, you’ll have an obvious problem. But equally important is serving the manifest with the right MIME type (page 153).
- **Problems downloading the files that are listed in the manifest.** For example, imagine that your manifest includes a picture that no longer exists. Or it asks for a web font file, and that font file uses a file type that your web server doesn’t allow. Either way, if the browser fails to download even a single file, it will give up completely (and throw away any cached information it already has). To avoid this problem, start simple, with a manifest that lists just a single web page and no resources. Or, in more complex examples, look at the web server logs to find out exactly what resources the browser has requested (which may tell you the point at which it met an error and gave up).
- **An old manifest is still cached.** Browsers can cache the manifest file (according to the traditional caching rules of the Web) and ignore the fact that you’ve changed it. One of the signs that you’ve stumbled into this problem is when some pages are cached but other, more recently added pages are not. To solve this problem, consider manually clearing the browser cache (see the box on page 312).

Updating the Manifest File

Getting an application to work offline is the first challenge. The next is updating it with new content.

For example, consider the previous example (page 305), which caches two web pages. If you update `PersonalityTest.html`, fire up your browser, and reload the page, you’ll still see the original, cached version of the page—regardless of whether your computer is currently online. The problem here is that once a browser has a cached copy of an application, it uses that. The browser ignores the online versions of the associated web pages and doesn’t bother to check if they’ve changed. And because offline applications never expire, it doesn’t matter how long you wait—even months later, the browser will stubbornly ignore changed pages.

However, the browser *will* check for a new manifest file. So save a new copy of that, put in on the web server, and you’ve solved the problem, right?

Not necessarily. To trigger an update for a cached web application, you need to meet three criteria:

- **The manifest file can’t be cached in the browser.** If the browser has a locally cached copy of the manifest file, it won’t bother to check the web server at all. Browsers differ on how they handle manifest file caching, with some (like Chrome) always checking with the web server for new manifests. But Firefox follows the traditional rules of HTTP caching, and holds onto its cached copy for some time. So if you want to save yourself development headaches, make sure your web server explicitly tells clients that they shouldn’t cache manifests (page 308).
- **The manifest file needs a new date.** When a browser checks the server, the first thing it does is ask if the last-updated timestamp has changed. If it hasn’t, the web browser doesn’t bother to download the manifest file.
- **The manifest file needs new content.** If a browser downloads a newly updated manifest file but discovers the content hasn’t changed, it stops the update process and keeps using the previously cached copy. This potentially frustrating step actually serves a valuable purpose. Re-downloading a cached application takes time and uses up network bandwidth, so browsers don’t want to do it if it’s really not necessary.

If you’ve been following along carefully, you’ll notice a potential problem here. What if there’s no reason to change the manifest file (because you haven’t added any files), but you do need to force browsers to update their application cache (because some of the existing files have changed)? In this situation, you need to make a trivial change to the manifest file, so it appears to be new when it isn’t. The best way to do so is with a comment, like this:

```
CACHE MANIFEST
# version 1.00.001
# pages
PersonalityTest.html
PersonalityTest_Score.html

# styles & scripts
PersonalityTest.css
PersonalityTest.js

# pictures & fonts
Images/emotional_bear.jpg
Fonts/museo_slab_500-webfont.eot
Fonts/museo_slab_500-webfont.woff
Fonts/museo_slab_500-webfont.ttf
Fonts/museo_slab_500-webfont.svg
```

The next time you need browsers to update their caches, simply change the version number in this example to 1.00.002, and so on. Presto—you now have a way to force updates and keep track of how many updates you’ve uploaded.

Updates aren't instantaneous. When the browser discovers a new manifest file, it quietly downloads all the files, and uses them to replace the old cache content. The next time the user visits the page (or refreshes the page), the new content will appear. If you want to switch over to the newly downloaded application right away, you can use the JavaScript technique described on page 319.

Note: There is no incremental way to update an offline application. When the application has changed, the browser tosses out the old and downloads every file again, even if some files haven't changed.

GEM IN THE ROUGH

Clearing The Browser's Cache

When testing an offline application, it's often helpful to manually clear the cache. That way, you can test new updates without needing to change the manifest.

Every browser has a way to clear the cache, but every browser tucks it away somewhere different. The most useful browsers keep track of how much space each offline

application uses (see Figure 10-3). This lets you determine when caching has failed—for example, the application's website isn't listed or the cached size isn't as big as it should be. It also lets you remove the cached files for a single site without disturbing the others.

Browser Support for Offline Applications

By now, you've probably realized that all major browsers support offline applications, aside from the notable HTML5 laggard, Internet Explorer. Support stretches back several versions, which all but ensures that Firefox, Chrome, and Safari users will be able to run your applications offline. Table 10-1 lays out the specifics.

Table 10-1. Browser support for offline applications

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	-	3.5	5	4	10.6	2.1	2

However, the way that different browsers support offline applications isn't completely consistent. The most important difference is the amount of space they allow offline applications to fill. This variation is significant, because it sets the difference between websites that will be cached for offline access and ones that won't (see the box on page 307).

There's no worthwhile way to get offline application support on browsers that don't include it as a feature (like IE 9). However, this shouldn't stop you from using the offline application feature. After all, offline applications are really just a giant frill.

Web browsers that don't support them will still work, they'll just require a live web connection. And people that need offline support—for example, frequent travelers—will discover the value of having a non-IE browser on hand for their disconnected times of need.

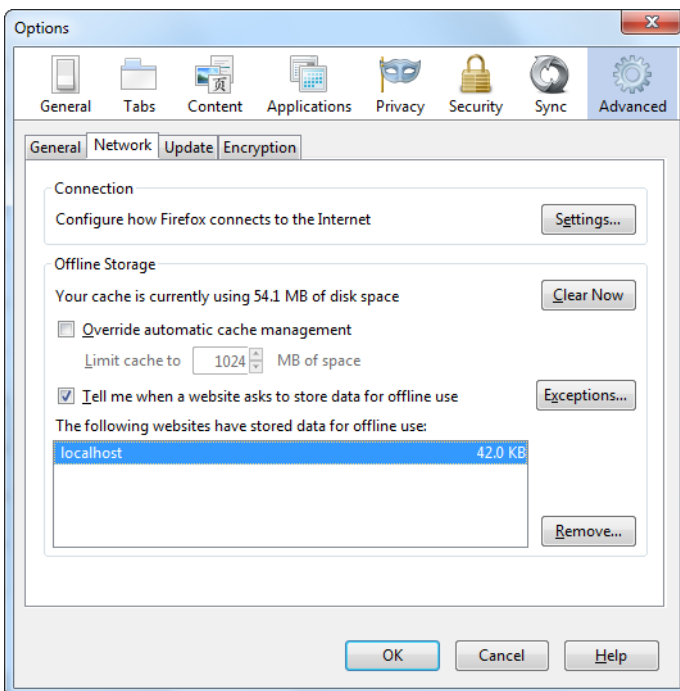

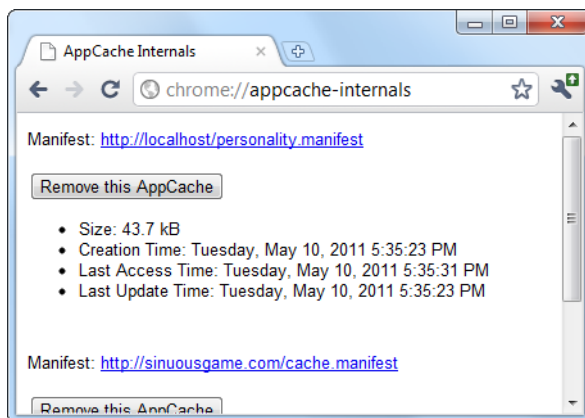

Figure 10-3:

Top: In the Firefox menu, click Options, choose the Advanced icon, and then choose the Network tab to end up here. You can review the space usage of every website, or clear the cached resources of any one, by selecting it and clicking Remove. In this example, there's just one cached website, on the domain localhost (which represents a test server on the current computer).

Bottom: To get a similar display in Chrome, type about:appcache-internals into the address bar.

Practical Caching Techniques

So far, you've seen how to package up a group of pages and resources as an offline application. Along the way, you learned to write a manifest file, update it, and make sure browsers don't ignore your hard work. This knowledge is enough to put simple applications offline. However, more complex websites sometimes need more. For example, you might want to keep some content online, substitute different pages when offline, or determine (in code) whether the computer has a live Internet connection. In the following sections, you'll learn how to accomplish all these tasks with smarter manifest files and a dash of JavaScript.

Accessing Uncached Files

Earlier, you learned that once a page is cached, the web browser uses that cached copy and doesn't bother talking to any web servers. But what you might not realize is that the browser's reluctance to go online applies to *all* the resources an offline web page uses, whether they're cached or not.

For example, imagine you have a page that uses two pictures, using this markup:

```

```

However, the manifest caches just one of the pictures:

```
CACHE MANIFEST
PersonalityTest.html
PersonalityTest_Score.html

PersonalityTest.css
PersonalityTest.js

Images/emotional_bear.jpg
```

You might assume that a browser will grab the *emotional_bear.png* picture from its cache, while requesting *logo.png* from the web server (as long as the computer is online). After all, that's the way it works in your browser when you step from a cached web page to an uncached page. But here, the reality is different. The browser grabs *emotional_bear.jpg* from the cache but ignores the uncached *logo.png* graphic, displaying a broken-image icon or just a blank space on the page, depending on the browser.

To solve this problem, you need to add a new section to your manifest. You title this section with a "NETWORK:" title, followed by a list of the pages that live online:

```
CACHE MANIFEST
PersonalityTest.html
PersonalityTest_Score.html

PersonalityTest.css
PersonalityTest.js
```

```
Images/emotional_bear.jpg
```

```
NETWORK:
```

```
Images/logo.png
```

Now the browser will attempt to get the *logo.png* file from the web server when the computer is online, but not bother to do anything when it's offline.

At this point, you're probably wondering why you would bother to explicitly list files you don't want to cache. It could be for space considerations—for example, maybe you're leaving out large files to make sure your application can be cached on browsers that have only 5 MB of cache space (page 307).

But a more likely situation is that you have content that should be available when requested but never cached—for example, tracking scripts or dynamically generated ads. In this case, the easiest solution is to add an asterisk (*) in your network section. That's a wildcard character that tells the browser to go online to get every resource you haven't explicitly cached:

```
NETWORK:
```

```
*
```

You can also use the asterisk to target files of a specific type (for example, **.jpg* refers to all JPEG images) or all the files on a specific server (for example, *http://www.google-analytics.com/** refers to all the resources on the Google Analytics web domain).

Note: It might occur to you that you could simplify your manifest by using the asterisk wildcard in the list of cached files. That way, you could cache bunches of files at once, rather than list each one individually. Unfortunately, the asterisk isn't supported for picking cached files, because the creators of HTML5 were concerned that careless web developers might try to cache entire mammoth websites.

Adding Fallbacks

Using a manifest, you tell the browser what files to cache and (using the network section) what files to get from the Web. Manifests also support one more trick: a fallback section that lets you swap one file for another, depending on whether the computer is online or offline.

To create a fallback section, start with the “FALLBACK:” title, which you can place anywhere in your manifest. Then, list files in pairs on a single line. The first file name is the file to use when online; the second file name is the offline fallback:

```
FALLBACK:
```

```
PersonalityScore.html PersonalityScore_offline.html
```

The web browser will download the fallback file (in this case, that's *PersonalityScore_offline.html*) and add it to the cache. However, the browser won't use the fallback file unless the computer is offline. While it's online, the browser will request the other file (in this case, *PersonalityScore.html*) directly from the web server.

Note: Remember, you don't have to be disconnected from the Web to be "offline" with respect to a web application. The important detail is whether the web domain is accessible—if it doesn't respond, for any reason, that web application is considered to be offline.

There are plenty of reasons to use a fallback. For example, you might want to substitute a simpler page when offline, a page that doesn't use the same scripts, or smaller resources. You can put the fallback section wherever you want, so long as it's preceded by the section title:

```
CACHE MANIFEST
PersonalityTest.html
PersonalityTest_Score.html

PersonalityTest.css

FALLBACK:
PersonalityScore.html PersonalityScore_offline.html
Images/emotional_bear.jpg Images/emotional_bear_small.jpg
PersonalityTest.js PersonalityTest_offline.js

NETWORK:
*
```

Note: Incidentally, the files that you want to cache are part of the *CACHE*: section in the manifest. You can add the section title if you want, but you don't need it unless you want to list files after one of the other sections.

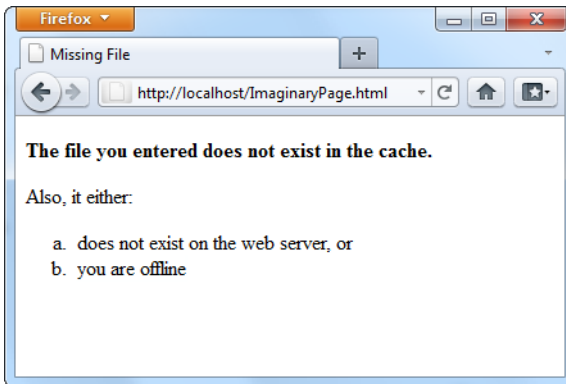

The fallback section also supports wildcard matching. This feature lets you create a built-in error page, like this:

```
FALLBACK:
/ offline.html
```

Now, imagine someone attempts to request a page that's in the same website as the offline application, but isn't in the cache. If the computer is online, the web browser tries to contact the web server and get the real page. But if the computer is offline, or if the website is unreachable, or if the requested page quite simply doesn't exist, the web browser shows the cached *offline.html* page instead (Figure 10-4).

The previous example used the somewhat arbitrary convention of using a single forward slash character (/) to represent any page. This might strike you as a bit odd, considering that the network section uses the asterisk wildcard character for much the same purpose. And some web browsers, like Firefox, do let you use the asterisk in the fallback section. That means you can duplicate the previous example like this:

```
FALLBACK:
* offline.html
```

**Figure 10-4:**

Here the page *ImaginaryPage.html* doesn't exist. Interestingly, the browser doesn't update the address bar, so the visitor has no way of knowing the exact name of the error page.

And you can write more targeted fallbacks that match all the files in a specific subfolder:

```
FALLBACK:
http://www.superAppsOnSteroids.org/paint_app/* offline.html
```

Or ones that match certain types of files:

```
FALLBACK:
*.jpg missig_picture.jpg
```

Unfortunately, other browsers don't understand this sensible syntax—at least not yet.

Checking the Connection

The fallback section is the secret to a handy JavaScript trick that allows you to determine whether the browser is currently online. If you're an old-hand JavaScript developer, you probably know about the `navigator.onLine` property, which provides a slightly unreliable way to check whether the browser is currently online. The problem is that the `onLine` property really reflects the state of the browser's "work offline" setting, not the actual presence of an Internet connection. And even if the `onLine` property were a more reliable indicator of connectivity, it still wouldn't tell you whether the browser failed to contact the web server or whether it failed to download the web page for some other reason.

The solution is to use a fallback that loads different versions of the same JavaScript function, depending on whether the application is online or offline. Here's how you write the fallback section:

```
FALLBACK:
online.js offline.js
```

The original version of the web page refers to the *online.js* JavaScript file:

```
<!DOCTYPE html>
<html lang="en" manifest="personality.manifest">
<head>
  <meta charset="utf-8">
  <title>...</title>
  <script src="online.js"></script>
  ...
```

It contains this very simple function:

```
function isSiteOnline() {
  return true;
}
```

But if the *online.js* file can't be accessed, the browser substitutes the *offline.js* file, which contains a method with the same name, but a different result:

```
function isSiteOnline() {
  return false;
}
```

In your original page, whenever you need to know the status of your application, check with the `isSiteOnline()` function:

```
var displayStatus = document.getElementById("displayStatus");
if (isSiteOnline()) {
  // (It's safe to run tasks that require network connectivity, like
  // contacting the web server through XMLHttpRequest.)
  displayStatus.innerHTML = "You are connected and the web server is online.";
}
else {
  // (The application is running offline. You may want to hide or
  // programmatically change some content, or disable certain features.)
  displayStatus.innerHTML = "You are running this application offline.";
}
```

Pointing Out Updates with JavaScript

You can interact with the offline application feature using a relatively limited JavaScript interface. It all revolves around an object called `applicationCache`.

The `applicationCache` object provides a status property that indicates whether the browser is checking for an updated manifest, downloading new files, or doing something else. This property changes frequently and is nearly as useful as the complementary events (listed in Table 10-2), which fire as the `applicationCache` switches from one status to another.

Table 10-2. Caching events

Event	Description
onChecking	When the browser spots the manifest attribute in a web page, it fires this event and checks the web server for the corresponding manifest file.
onNoUpdate	If the browser has already downloaded the manifest, and the manifest hasn't changed, it fires this event and doesn't do anything further.
onDownloading	Before the browser begins downloading a manifest (and the pages it references), it fires this event. This occurs the first time it downloads the manifest files, and during updates.
onProgress	During a download, the browser fires this event to periodically report its progress.
onCached	This event signals the end of a first-time download for a new offline application. No more events occur after this.
onUpdateReady	This event signals the end of a download to get updated content. At this point, the new content is ready to use, but it won't appear in the browser window until the page is reloaded. No more events occur after this.
onError	Something went wrong somewhere along the process. The web server might not be reachable (in which case the page will have switched into offline mode), the manifest might have invalid syntax, or a cached resource might not be available. If this event occurs, no more follow.
onObsolete	While checking for an update, the browser discovered that the manifest no longer exists. It then clears the cache. The next time the page is loaded, the browser will get the live, latest version from the web server.

Note: At the time of this writing, browsers don't all support the caching events equally. Firefox, for example, ignores useful events like `onChecking` and `onUpdateReady`, although it does fire `onNoUpdate` and `onError`.

The most useful event is `onUpdateReady`, which signals that a new version of the application has been downloaded. Even though the new version is ready for use, the old version of the page has already been loaded into the browser. You may want to inform the visitor of the change, in much the same way that a desktop application does when it downloads a new update:

```
<script>
window.onload = function() {

    // Attach the function that handles the onUpdateReady event.
    applicationCache.onupdateReady = function() {
        var displayStatus = document.getElementById("displayStatus");
        displayStatus.innerHTML = "There is a new version of this application. " +
            "To load it, refresh the page.";
    }
}
</script>
```

Or, you can offer to reload the page *for* the visitor using the `window.location.reload()` method:

```
<script>
window.onload = function() {

    applicationCache.onupdateready = function() {
        if (confirm(
            "A new version of this application is available. Reload now?")) {
            window.location.reload();
        }
    }
}
</script>
```

Figure 10-5 shows this code at work.

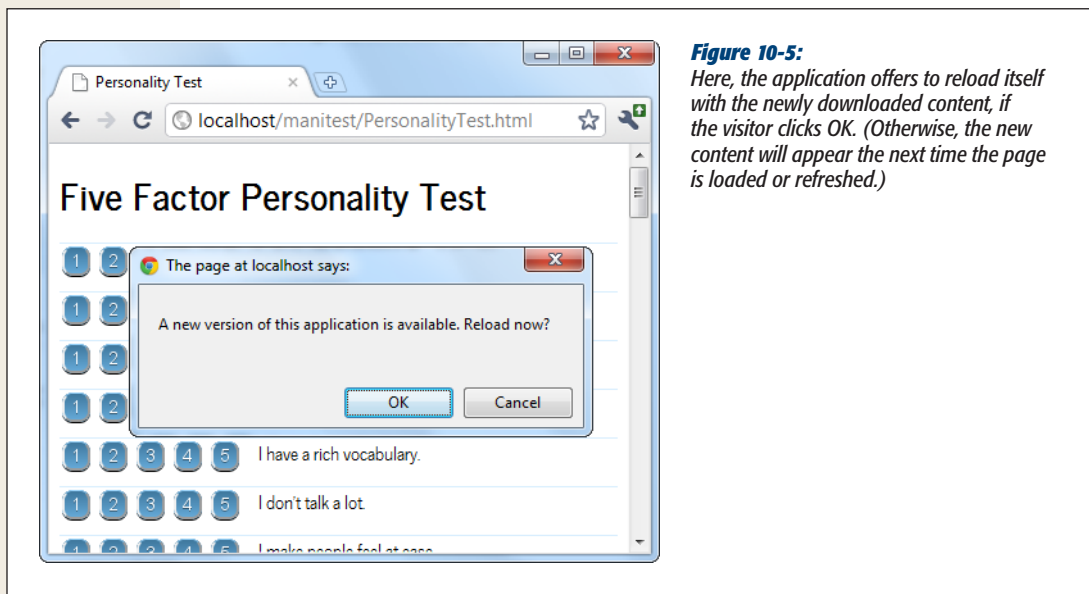

Figure 10-5:

Here, the application offers to reload itself with the newly downloaded content, if the visitor clicks OK. (Otherwise, the new content will appear the next time the page is loaded or refreshed.)

The `applicationCache` also provides two methods for more specialized scenarios. First is the confusingly named `update()` method, which simply checks for a new manifest. If one exists, it starts the download process in the background. Otherwise, it does nothing more.

Although browsers check for updates automatically, you can call `update()` if you think the manifest has changed since the user first loaded the page. This method might be important in a very long-lived web application—for example, one that users leave open on the same page, all day.

The second method is `swapCache()`, which tells the browser to start using the newly cached content, if it has just downloaded an update. However, `swapCache()` doesn't change the page that's currently on display—for that, you need a reload. So what good is `swapCache()`? Well, by changing over to the new cache, anything that you load from that point on—say, a dynamically loaded image—comes from the new cache, not the old one. If managed carefully, `swapCache()` could give your page a way to get access to new content without forcing a complete page reload (and potentially resetting the current application to its initial state). But in most applications, `swapCache()` is more trouble than it's worth, and it can cause subtle bugs by mixing old and new bits of the cache.

Communicating with the Web Server

When you started your journey with HTML5, you began with its markup-based features (like semantic elements, web forms, and video). But as you progressed through this book, you slowly shifted your focus to web page *programming*, and the JavaScript-powered parts of HTML5. Now, you're about to dip your toe into a few HTML5 features that take web page programming to the next level. They not only require JavaScript code but also some *server-side code*—code that runs on the web server, in whatever server-side programming language you want to use.

Adding a server-side language to the mix poses a bit of a problem. On one hand, it doesn't matter what server-side programming language you pick, as long as it can work with pure HTML5 pages (and they all can). On the other hand, there's not much point in getting knee-deep learning a technology that you don't plan to use or that your web host doesn't support. And there's no shortage of good choices for server-side programming, including PHP, ASP.NET, Ruby, Java, Python, and many more.

This chapter tackles the problem by using a small amount of very simple server-side code. It's just enough to round out each example and to let you test the HTML5 part of the equation (that's the JavaScript code in the web page). In your websites, you'll change and extend this server-side code, depending on what you're trying to accomplish and which server-side language you prefer.

So what are these features that require server-side interaction? HTML5 provides two new ways for your web pages to talk with a web server. The first feature is *server-sent events*, which lets the web server call up your page and pass it information at

periodic intervals. The second feature is the much more ambitious *web sockets* framework, which lets browsers and web servers carry out a freewheeling back-and-forth conversation. But before you explore either of these, you'll start with a review of the current-day tool for web server communication: the XMLHttpRequest object.

Note: Server-sent events and web sockets seem deceptively simple. It's easy enough to learn how they work and to create a very basic example (as in this chapter). But building on that to create something that will work reliably on a professional website, and provide the sort of features you want, is an entirely different matter. The bottom line is this: To implement these features in your website, you'll probably need to get the help of someone with some serious server-side programming experience.

Sending Messages to the Web Server

Before you can understand the new server communication features in HTML5, you need to understand the situation that web pages were in before. That means exploring XMLHttpRequest, the indispensable JavaScript object that lets a web page talk to its web server. If you already know about XMLHttpRequest (and are using it in your own pages), feel free to skip right over this section. But if your web page design career so far consists of more traditional web pages, keep reading to get the essentials.

UP TO SPEED

The History of Web Server Involvement

In the early days of the Web, communicating with a web server was a straightforward and unexciting affair. A browser would simply ask for a web page, and the web server would send it back. That was that.

A little bit later, software companies began to get clever. They devised web server tools that could get in between the first step (requesting the page) and the second step (sending the page), by running some sort of code on the web server. The idea was to change the page dynamically (for example, by blurting out a block of markup in the middle of it) or even to create a new page from scratch (for example, by reading a record in a database and generating a tailor-made page with product details).

And then web developers got even more ambitious, and wanted to build pages that were more interactive. The server-side programming tools could handle this, with a bit of juggling, as long as the web browser was willing to refresh the page. For example, if you wanted to add a product

to your e-commerce shopping cart, you would click a button that would submit the current page (using web forms; see Chapter 4) and ask for a new one. The web server could then send back the same page or a different page (for example, one that shows the contents of the shopping cart). This strategy was wildly successful, and just a bit clunky.

Then, web developers got ambitious again. They wanted a way to build slick web applications (like email programs) without constantly posting back the page and regenerating everything from scratch. The solution was a set of techniques that are sometimes called Ajax, but almost always revolve around a special JavaScript object called XMLHttpRequest. This object lets web pages contact the web server, send some data, and get a response, without posting or refreshing anything. That clears the way for JavaScript to handle every aspect of the page experience, including updating content. It also makes web pages seem slicker and more responsive.

The XMLHttpRequest Object

The chief tool that lets a web page speak to a web server is the XMLHttpRequest object. The XMLHttpRequest object was originally created by Microsoft to improve the web version of its Outlook email program, but it steadily spread to every modern browser. Today, it's a fundamental part of most modern web applications.

The basic idea behind XMLHttpRequest is that it lets your JavaScript code make a web request on its own, whenever you need some more data. This web request takes place *asynchronously*, which means the web page stays responsive even while the request is under way. In fact, the visitor never knows that there's a web request taking place behind the scenes (unless you add some sort of message or progress indicator to your page).

The XMLHttpRequest object is the perfect tool when you need to get some sort of data from the web server. Here are some examples:

- **Data that's stored on the web server.** This information might be in a file or, more commonly, a database. For example, you might want a product or customer record.
- **Data that only the web server can calculate.** For example, you might have a piece of server-side code that performs a complex calculation. You could try to perform the same calculation in JavaScript, but that might not be appropriate—for example, JavaScript might not have the mathematical smarts you need, or it might not have access to some of the data the calculation involves. Or, your code might be super-sensitive, meaning you need to hide it from prying eyes or potential tamperers. Or, the calculation might be so intensive that it's unlikely a desktop computer could calculate it as quickly as a high-powered web server (think, for example, of a page that renders a 3-D scene). In all these cases, it makes sense to do the calculation on the web server.
- **Data that's on someone else's web server.** Your web page can't access someone else's web server directly. However, you can call a program on your web server (using XMLHttpRequest), and that program can then call the other web server, get the data, and return it to you.

The best way to really understand XMLHttpRequest is to start playing with it. In the following sections, you'll see two straightforward examples.

Asking the Web Server a Question

Figure 11-1 shows a web page that asks the web server to perform a straightforward mathematical calculation. The message is sent through the XMLHttpRequest object.

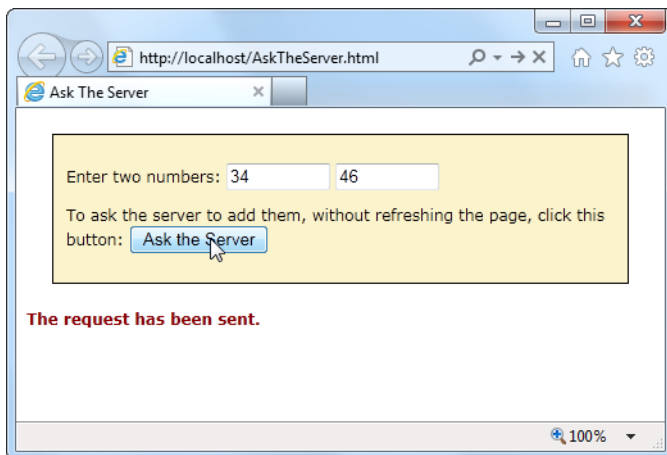

Figure 11-1:
Click the “Ask the Server” button, and this web page creates an XMLHttpRequest object and sends the two numbers to the web server. The web server runs a simple script to calculate the answer and then returns the result (shown later, in Figure 11-2).

Before you can create this page, you need some sort of server-side script that will run, process the information you send it (in this case, that’s the two typed-in numbers), and then send back a result. This trick is possible in every server-side programming language ever created (after all, sending back a single scrap of text is easier than sending a complete HTML document). This example uses a PHP script, largely because PHP is relatively simple and supported by almost all web hosting companies.

Creating the script

To create a PHP script, you first create a new text file. Inside that text file, you start by adding the funny-looking codes shown here, which delineate the beginning and end of your script:

```
<?php
// (Code goes here.)
?>
```

In this example the code is straightforward. Here’s the complete script:

```
<?php
$num1 = $_GET['number1'];
$num2 = $_GET['number2'];
$sum = $num1 + $num2
echo($sum);
?>
```

Even if you aren’t a PHP expert, you probably have a pretty good idea of what this code does, just by looking over it. The first order of business is to retrieve the two numbers that the web page will have sent:

```
$num1 = $_GET['number1'];
$num2 = $_GET['number2'];
```

The `$` symbol indicates a variable, so this code creates a variable named `$num1` and another named `$num2`. To set the variables, the code pulls a piece of information out of a built-in collection named `$_GET`. The `$_GET` collection holds all the information from the URL that was used to request the script.

For example, if you place the PHP script in a file named `WebCalculator.php`, a web request might look like this:

```
http://www.magicalXMLHttpRequestTest.com/WebCalculator.php?number1=34&number2=46
```

Here, the URL holds two pieces of information tacked onto the end (in the URL section known as the *query string*). First, there's a value named `number1`, which is set to 34. Next is a value named `number2`, which is set to 46. The question mark (?) denotes the start of the query string, and the ampersand symbol (&) precedes each value after the first one. When the PHP engine fires up, it retrieves these details and stuffs them into the `$_GET` collection, so your code can access them. (Most server-side programming platforms support a model like this. For example, in ASP you can access the same information through the `Request.QueryString` collection.)

Note: HTML veterans know that there are two ways to send data to a web server—through the query string, or by posting it in the body of the request message. With either technique, the data is encoded in the same way, and it's accessed in the web server in a similar way as well. For example, PHP has a `$_POST` collection that provides access to any posted data.

Once the PHP script has the two numbers in hand, it simply needs to add them together:

```
$sum = $num1 + $num2
```

The last step is to send the result back to the web page that's making the request. You could package the result up in a scrap of HTML markup or even some data-friendly XML. But that's overkill in this example, since plain text does just fine. But no matter what you choose, sending the data back is simply a matter of using PHP's `echo` command:

```
echo($sum);
```

Altogether, this script contains a mere four lines of PHP code. However, it's enough to establish the basic pattern: The web page asks a question, and the web server returns a result.

Note: Could you write this page entirely in JavaScript, with no web server request? Of course. But the actual calculation isn't important. The PHP script shown here is an example that stands in for whatever server task you want to perform. You could make the PHP script as complex as you like, but the basic exchange of data will stay the same.

Calling the web server

The second step is to build the page that uses the PHP script, with the help of XMLHttpRequest. It all starts out simply enough. In script code, an XMLHttpRequest object is created, so it will be available in all your functions:

```
var req = new XMLHttpRequest();
```

When the user clicks the “Ask the Server” button, it calls a function named askServer():

```
<div>
  <p>Enter two numbers:
    <input id="number1" type="number">
    <input id="number2" type="number">
  </p>
  <p>To ask the server to add them, without refreshing the page, click
    this button:<button onclick="askServer()">Ask the Server</button>
  </p>
</div>
<p id="result"></p>
```

The askServer() function uses the XMLHttpRequest object to make its behind-the-scenes request. First, it gathers the data it needs—the two numbers:

```
function askServer() {
  var number1 = document.getElementById("number1").value;
  var number2 = document.getElementById("number2").value;
```

Then, it uses this data to build a proper query string:

```
var dataToSend = "?number1=" + number1 + "&number2=" + number2;
```

Now it's ready to prepare the request. The open() method of the XMLHttpRequest starts you out. It takes the type of HTTP operation (GET or POST), the URL you're using to make your request, and a true or false value that tells the browser whether to do its work asynchronously:

```
req.open("GET", "WebCalculator.php" + dataToSend, true);
```

Note: Web experts agree unanimously—the final open() argument should always be true, which enables asynchronous use. That's because no website is completely reliable, and a synchronous request (a request that forces your code to stop and wait) could crash your whole web page while it's waiting for a response.

Before actually sending the request, you need to make sure you have a function wired up to the XMLHttpRequest's onReadyStateChange event. This event is triggered when the server sends back any information, including the final response when its work is done:

```
req.onreadystatechange = handleServerResponse;
```

Now you can start the process with the XMLHttpRequest's `send()` method. Just remember, your code carries on without any delay. The only way to read the response is through the `onReadyStateChange` event, which may be triggered later on:

```
req.send();

document.getElementById("result").innerHTML = "The request has been sent.";
}
```

When you receive a response, you need to immediately check two XMLHttpRequest properties. First, you need to look at `readyState`, a number that travels from 0 to 4 as the request is initialized (1), sent (2), partially received (3), and then complete (4). Unless `readyState` is 4, there's no point continuing. Next, you need to look at `status`, which provides the HTTP status code. Here, you're looking for a result of 200, which indicates that everything is OK. You'll get a different value if you attempt to request a page that's not allowed (401), wasn't found (404), has moved (302), or is too busy (503), among many others. (See www.addedbytes.com/for-beginners/http-status-codes for a full list.)

Here's how the current example checks for these two details:

```
function handleServerResponse() {
    if ((req.readyState == 4) && (req.status == 200)) {
```

If those criteria are met, you can retrieve the result from the XMLHttpRequest's `responseText` property. In this case, the response is the new sum. The code then displays the answer on the page (Figure 11-2):

```
    var result = req.responseText;
    document.getElementById("result").innerHTML = "The answer is: " +
        result + ".";
}
}
```

Figure 11-2:
The web server has returned a response, triggering a JavaScript function, which changed the page.

XMLHttpRequest doesn't make any assumptions about the type of data you're requesting. The name of the object has XML in it because it was originally designed with XML data in mind, simply because XML is a convenient, logical package for parceling up structured information. However, XMLHttpRequest is also used with requests for simple text (as in this example), JSON data (page 291), HTML (as in the next example), and XML. In fact, non-XML uses are now *more* common than XML uses, so don't let the object name fool you.

Tip: You need to put your web pages on a test web server before you can use any server-side code, including PHP scripts. To run the example pages in this chapter without the frustration, visit the try-out site at www.prosetech.com/html5.

Getting New Content

Another scenario where XMLHttpRequest comes in handy is loading new HTML content into a page. For example, a news article might contain multiple pictures but show just one at a time. You click a button, and some JavaScript fetches the content for the next picture, and inserts it in the page. Or, a page might use the same technique to show the slides in a top-five or top-10 list. Figure 11-3 shows a slideshow example that shows a series of captioned pictures that accompany an article.

There are a number of reasons to use a design like the one shown in Figure 11-3. Done skillfully, this technique can be a great way to tame huge amounts of content, so it's readily available but not immediately overwhelming. (In less capable hands, it's just a desperate attempt to boost page views by forcing readers to make multiple requests to get all the content they want.)

The best way to design this sort of page is with the XMLHttpRequest object. That way, the page can request new content and update the page without triggering a full refresh. And full refreshes are bad, because they download extra data, cause the page to flicker, and scroll the user back to the top. All of these details seem minor, but they make the difference between a website that feels slick and seamless, and one that seems hopelessly clunky and out of date.

To build the example in Figure 11-3, you first need to carve out a spot for the dynamic content. Here it's a <div> element that creates a golden box and has two links underneath:

```
<div id="slide">Click Next to start the show.</div>
<a onclick="return previousSlide()" href="#">&lt; Previous</a>&nbsp;&nbsp;&
<a onclick="return nextSlide()" href="#">Next &gt;</a>
```

**Figure 11-3:**

This page splits its content into separate slides. Click the Previous or Next link to load in a new slide, with different text content and a new picture. To make this work, the page uses the XMLHttpRequest object to request the new content, as it's needed.

The links call `previousSlide()` or `nextSlide()`, depending on whether the visitor is traveling forward or backward in the list of sites. Both functions increment a counter that starts at 0, moves up to 5, and then loops back to 1. Here's the code for the `nextSlide()` function:

```
var slideNumber = 0;

function nextSlide() {
    // Move the slide index ahead.
    if (slideNumber == 5) {
        slideNumber = 1;
    } else {
        slideNumber += 1;
    }

    // Call another function that shows the slide.
    goToNewSlide();

    // Make sure the link doesn't actually do anything (like attempt
    // to navigate to a new page).
    return false;
}
```

And here's the very similar code for `previousSlide()`:

```
function previousSlide() {
    if (slideNumber == 1) {
        slideNumber = 5;
    } else {
        slideNumber -= 1;
    }

    goToNewSlide();
    return false;
}
```

Both functions rely on another function, `goToNewSlide()`, which does the real work. It uses `XMLHttpRequest` to contact the web server and ask for the new chunk of data.

The real question: Where does the `ChinaSites.html` page get its data from? Sophisticated examples might call some sort of web service or PHP script. The new content could be generated on the fly, or pulled out of a database. But this example uses a low-tech solution that works on any web server—it looks for a file with a specific name. For example, the file with the first slide is named `ChinaSites1_slide.html`, the file with the second is `ChinaSites2_slide.html`, and so on. Each file contains a scrap of HTML markup (not an entire page). For example, here's the content in `ChinaSites5_slide.html`:

```
<figure>
  <h2>Wishing Tree</h2>
  <figcaption>Make a wish and toss a red ribbon up into the branches
  of this tree. If it sticks, good fortune may await.</figcaption>
  
</figure>
```

Now that you know where the data is stored, it's easy enough to create an XMLHttpRequest that grabs the right file. A simple line of code can generate the right file name using the current counter value. Here's the `goToNewSlide()` function that does it:

```
var req = new XMLHttpRequest();

function goToNewSlide() {
  if (req != null) {
    // Prepare a request for the file with the slide data.
    req.open("GET", "ChinaSites" + slideNumber + "_slide" + ".html", true);

    // Set the function that will handle the slide data.
    req.onreadystatechange = newSlideReceived;

    // Send the request.
    req.send();
  }
}
```

The last step is to copy the retrieved data in the `<div>` that represents the current slide:

```
function newSlideReceived() {
  if ((req.readyState == 4) && (req.status == 200)) {
    document.getElementById("slide").innerHTML = req.responseText;
  }
}
```

Tip: To give this example a bit more pizzazz, you could create a transition effect. For example, the new picture could fade into the view while the old one fades out of sight. All you need is the opacity property and a snippet of JavaScript that runs on a timer. (See <http://clagnut.com/sandbox/imagefades.php> for the classic approach, or <http://css3.bradshawenterprises.com/cimg2/> for a style-based solution that uses the new and not-yet-completely-supported CSS3 transitions feature.) This is one of the advantages of dynamic pages that use XMLHttpRequest—they can control exactly how new content is presented.

This isn't the last you'll see of this example. In Chapter 12 (page 372), you'll use HTML5's history management to manage the web page's URL, so that the URL changes to match the currently displayed slide. But for now, it's time to move on to two new ways to communicate with the web server.

Server-Sent Events

The XMLHttpRequest object lets your web page ask the web server a question and get an immediate answer. It's a one-for-one exchange—once the web server provides its response, the interaction is over. There's no way for the web server to wait a few minutes and send another message with an update.

However, there are some types of web pages that could use a longer-term web server relationship. For example, think of a stock quote on Google Finance (www.google.com/finance). When you leave that page open on your desktop, you'll see regular

price updates appear automatically. Another example is a news ticker like the one at www.bbc.co.uk/news. Linger here, and you'll find that the list of headlines is updated throughout the day. You'll find similar magic bringing new messages into the inbox of any web-based mail program, like Hotmail (www.hotmail.com).

In both these examples, the web page is using a technique called *polling*. Periodically (say, every few minutes), the page checks the web server for new data. To implement this sort of design, you use JavaScript's `setInterval()` or `setTimeout()` functions (see page 223), which trigger your code after a set amount of time.

Polling is a reasonable solution, but it's sometimes inefficient. In many cases, it means calling the web server and setting up a new connection, only to find out that there's no new data. Multiply this by hundreds or thousands of people using your website at once, and it can add up to an unnecessary strain on your web server.

One possible solution is *server-sent events*, which let a web page hold an open connection to the web server. The web server can send new messages at any time, and there's no need to continually disconnect, reconnect, and run the same server script from scratch. (Unless you want to, because server-sent events *also* support polling.) Best of all, the server-sent event system is simple to use, works on most web hosts, and is sturdily reliable. However, it's relatively new, as Table 11-1 attests, with no support in current versions of Firefox or Internet Explorer.

Table 11-1. Browser support for server-sent events

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	-	6*	5	5	11	4	-

*Currently, this version is available in early beta builds only.

Note: If you're looking for a polyfill that can fake server-sent event support using polling, there are several candidates worth checking out at <http://tinyurl.com/polyfills>.

In the following sections, you'll put together a simple example that demonstrates server-sent events.

The Message Format

Unlike XMLHttpRequest, the server-sent events standard doesn't let you send just any data. Instead, you need to follow a simple but specific format. Every message must start with the text "data:" followed by the actual message text and the *new line* character sequence, which is represented as "\n\n" in many programming languages, including PHP.

Here's an example of what a line of message text looks like, as it travels over the Internet:

```
data: The web server has sent you this message.\n\n
```

It's also acceptable to split a message over multiple lines. You use the end of line character sequence, which is often represented as a single “\n”. This makes it easier to send complex data:

```
data: The web server has sent you this message.\n
data: Hope you enjoy it.\n\n
```

You'll notice that you still need to start each line with “data:” and you still need to end the entire message with “\n\n”.

You could even use this technique to send JSON-encoded data (page 291), which would allow the web page to convert the text into an object in a single step:

```
data: {\n
data: "messageType": "statusUpdate",\n
data: "messageData": "Work in Progress"\n
data: }\n\n
```

Along with the message data, the web server can send a unique ID value (using the prefix “id:”) and a connection timeout (using “retry:”):

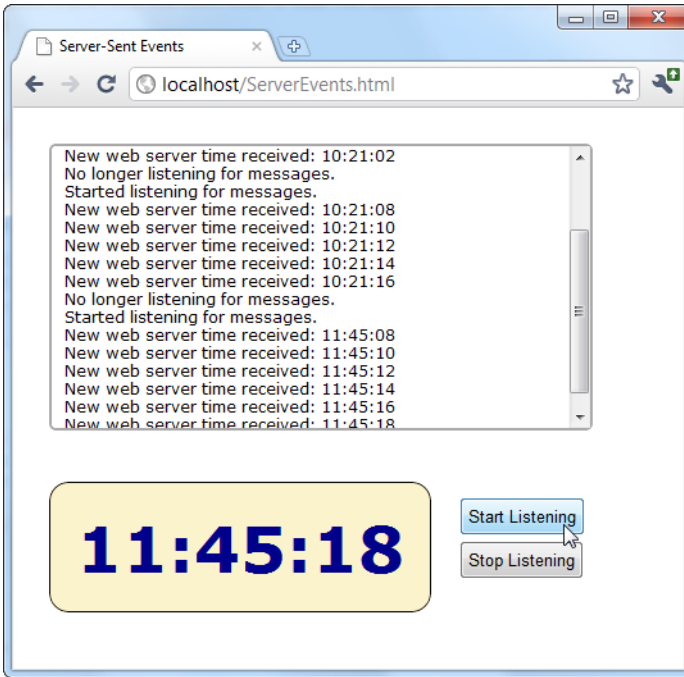

```
id: 495\n
retry: 15000\n
data: The web server has sent you this message.\n\n
```

Your web page pays attention to the message data, but it doesn't deal with the ID and connection timeout information. Instead, the *browser* uses these details. For example, after reading the above message, the browser knows that if it loses its connection to the web server, it should attempt to reconnect after 15,000 milliseconds (15 seconds). It should also send the ID number 495 to help the web server identify it.

Note: A web page can lose its connection to the web server for a variety of reasons, including a brief network outage or a proxy server that times out while waiting for data. If possible the browser will attempt to reopen the connection automatically, after waiting a default 3 seconds.

Sending Messages with a Server Script

Now that you know the message format, it's trivially easy to create some server-side code that spits it out. Once again, it makes sense to turn to PHP to build a straightforward example that virtually all web hosts will support. Figure 11-4 shows a page that gets regular messages from the server. In this case, the messages are simple—they contain the current time, on the web server.

**Figure 11-4:**

When this page is listening, it receives a steady stream of messages from the web server—approximately one every 2 seconds. Each message is added to the scrolling list at the top, and the time display at the bottom shows the time received from the most recent message.

Note: The web server time is a single piece of information that's continuously updated. That makes it a good candidate for creating a simple server-side event demonstration like this one. However, in a real example, you're more likely to send something more valuable, like the most up-to-date headlines for a news ticker.

The server-side part of this example simply reports the time, in regular intervals. Here's the complete script, at a glance:

```
<?php
    header("Content-Type: text/event-stream");
    header('Cache-Control: no-cache');

    // Start a loop that goes forever.
    do {
        // Get the current time.
        $currentTime = date("h:i:s", time());

        // Send it in a message.
        echo "data: " . $currentTime . PHP_EOL;
        echo PHP_EOL;
        flush();
    }
```

```

        // Wait 2 seconds before creating a new message.
        sleep(2);
    } while(true);
?>

```

The beginning of this script sets two important headers. First, it sets the MIME type to *text/event-stream*, which is required by the server-side event standard:

```
header("Content-Type: text/event-stream");
```

Then, it tells the web server (and any proxy servers) to turn off web caching. Otherwise, it's possible that some of the time messages will arrive in uneven batches:

```
header('Cache-Control: no-cache');
```

The rest of the code is wrapped in a loop that continues indefinitely (or at least until the client disappears). Each time the loop runs, it uses the built-in `time()` function to grab the current time (in the format *hours:minutes:seconds*), and it stuffs that into a variable:

```
$currentTime = date("h:i:s", time());
```

Next, the loop uses this information to build a message in the proper format, which it sends using PHP's trusty `echo` command. In this example, the message is single line, starting with "data:" and followed by the time. It ends with the constant `PHP_EOL` (for PHP *end of line*), which is a shorthand way of referring to the "\n" character sequence described earlier:

```

echo "data: " . $currentTime . PHP_EOL;
echo PHP_EOL;

```

Note: If this looks funny, it's probably because PHP uses the dot operator (.) to join strings. It works in the same way as the + operator with text in JavaScript, only there's no way to accidentally confuse it with numeric addition.

The `flush()` function makes sure the data is sent right away, rather than buffered until the PHP code is complete. Finally, the code uses the `sleep()` function to stall itself for 2 seconds before continuing with a new pass through the loop.

Tip: If you wait a long time between messages, your connection might be cut off by a *proxy server* (a server that sits between your web server and the client's computer, directing traffic). To avoid this behavior, you can send a comment message every 15 seconds or so, which is simply a colon (:) with no text.

Processing Messages in a Web Page

The web page that listens to these messages is even simpler. Here's all the markup from the `<body>` section, which divides the pages into three `<div>` sections—one for the message list, one for the big time display, and one for the clickable buttons that start the whole process:

```

<div id="messageLog"></div>
<div id="timeDisplay"></div>

```

```
<div id="controls">
  <button onclick="startListening()">Start Listening</button><br>
  <button onclick="stopListening()">Stop Listening</button>
</div>
```

When the page loads, it looks up these `messageLog` and `timeDisplay` elements and stores them in global variables so they'll be easy to access in all your functions:

```
var messageLog;
var timeDisplay;

window.onload = function() {
  messageLog = document.getElementById("messageLog");
  timeDisplay = document.getElementById("timeDisplay");
};
```

The magic happens when someone clicks the Start Listening button. At this point, the code creates a new `EventSource` object, supplying the URL of the server-side resource that's going to send the messages. (In this example, that's a PHP script named *TimeEvents.php*.) It then attaches a function to the `onMessage` event, which fires whenever the page receives a message.

```
var source;

function startListening() {
  source = new EventSource("TimeEvents.php");
  source.onmessage = receiveMessage;
  messageLog.innerHTML += "<br>" + "Started listening for messages.";
}
```

Tip: To check for server-side event support, you can test if the `window.EventSource` property exists. If it doesn't, you'll need to use your own fallback approach. For example, you could use the `XMLHttpRequest` object to make periodic calls to the web server to get data.

When `receiveMessage` is triggered, you can get the message from the *data* property of the event object. In this example, the data adds a new message in the message list and updates the large clock:

```
function receiveMessage(e) {
  messageLog.innerHTML += "<br>" + "New web server time received: " + e.data;
  timeDisplay.innerHTML = e.data;
}
```

You'll notice that once the message is delivered to your page, the pesky "data:" and "/n/n" details are stripped out, leaving you with just the content you want.

Finally, a page can choose to stop listening for server events at any time by calling the `close()` method of the `EventSource` object. It works like this:

```
function stopListening() {
  source.close();
  messageLog.innerHTML += "<br>" + "No longer listening for messages.";
}
```

Polling with Server-Side Events

The previous example used server-side events in the simplest way. The page makes a request, the connection stays open, and the server sends information periodically. The web browser may need to reconnect (which it will do automatically), but only if there's a problem with the connection or if it decides to temporarily stop the communication for other reasons (for example, low battery in a mobile device).

But what happens if the server script ends and the web server closes the connection? Interestingly, even though no accident occurred, and even though the server deliberately broke off communication, the web page still automatically reopens the connection (after waiting the default 3 seconds) and requests the script again, starting it over from scratch.

You can use this behavior to your advantage. For example, imagine that you create a relatively short server script that sends just one message. Now your web page acts like it's using polling (page 334), by periodically reestablishing the connection. The only difference is that the web server tells the browser how often it should check for new information. In a page that uses traditional polling, this detail is built into your JavaScript code.

The following script uses a hybrid approach. It stays connected (and sends periodic messages) for 1 minute. Then, it recommends that the browser try in again in 2 minutes and closes the connection:

```
<?php
    header("Content-Type: text/event-stream");
    header('Cache-Control: no-cache');

    // Tell the browser to wait 2 minutes before reconnecting,
    // when the connection is closed.
    echo "retry: 120000" . PHP_EOL;

    // Store the start time.
    $startTime = time();

    do {
        // Send a message.
        $currentTime = date("h:i:s", time());
        echo "data: " . $currentTime . PHP_EOL;
        echo PHP_EOL;
        flush();

        // If a minute has passed, end this script.
        if ((time() - $startTime) > 60) {
            die();
        }

        // Wait 5 seconds, and send a new message.
        sleep(5);
    } while(true);
?>
```

Now when you run the page, you'll get a minute's worth of regular updates, followed by a 2-minute pause (Figure 11-5). In a more sophisticated example, you might have the web server send a special message to the web browser that tells it there's no reason to wait for updated data (say, the stock markets have closed for the day). At this point, the web page could call the EventSource's `close()` method.

Note: With complex server scripts, the web browser's automatic reconnection feature might not work out so well. For example, the connection may have been cut off while the web server was in the middle of a specific task. In this case, your web server code can send each client an ID (as described on page 335), which will be sent back to the server when the browser reconnects. However, it's up to your server-side code to generate a suitable ID, keep track of what task each ID is doing (for example, by storing some information in a database), and then attempt to pick up where you left off. All of these steps can be highly challenging if you lack super-black-belt coding skills.

Figure 11-5:

This page uses a combination of streaming (for a batch of messages, over the course of a minute), followed by polling (for the next 2 minutes). This sort of design might make sense as a way to minimize web server traffic, depending on how often your data is updated and how important it is to have up-to-the-minute data.

Web Sockets

Server-sent events are a perfect tool if you want to receive a series of messages from the web server. But the communication is completely one-sided. There's no way for the browser to respond, or to enter into a more complex dialogue.

If you're creating a web application where the browser and the web server need to have a serious conversation, your best bet (without adopting Flash) is to use the XMLHttpRequest object. Depending on the sort of application you're building, this approach may work fine. However, there are stumbling blocks aplenty. First, the XMLHttpRequest object doesn't work well if you need to send multiple messages back and forth very quickly (like you might in a chat application, for example). Second, there's no way to associate one call with the next, so every time the web page makes a request, the web server needs to sort out who you are all over again. If your web page needs to make a chain of related requests, your web server code can become frightfully complicated.

There's a solution to these problems, but it's not quite here yet. That solution is *web sockets*, a standard that lets a browser hold open a connection to a web server, and exchange back-and-forth messages for as long as it wants. The web sockets feature has generated plenty of excitement, but it's still evolving, and it lacks solid browser support. Firefox 4 and Opera 11 initially added support for web sockets, only to disable it a few months later due to concerns about a potential security threat. The feature is scheduled to reappear in Firefox 6, using a slightly tweaked version of the original protocol, and it's likely to follow in future versions of Opera. Microsoft hasn't made any commitment but is openly experimenting with the feature (you can play with its test lab at <http://tinyurl.com/3szzz72>).

Because of these continuous changes, it's difficult to say anything definitive about the web socket standard. In fact, this section doesn't even include the familiar support table, because different browser versions support different versions of the web socket standard, and they're generally not compatible. That means a web socket server that's designed with one version in mind won't work with browsers that are built with a different version in mind.

Note: For now, the best bet is to test web socket pages with Chrome, which provides the most consistent support for them. You can also try out Firefox, if you download the beta version of Firefox 6. (It's technically possible to switch on socket support in older versions, using a hidden setting, but it's awkward and it uses an older, out-of-date version of the socket standard anyway; therefore, it's not really worth the trouble.)

Assessing Web Sockets

If you've made it this far, you know not to be scared off from features so new that they haven't been finished or fully implemented yet. The real question is how much time you should spend learning web sockets right now—in other words, are they destined to be a valuable feature in the future of web programming, and can you expect to plop web sockets into your own applications in a year or two?

To answer these questions, you need to understand two important points. First, web sockets are a specialized tool. They make great sense in a chat application, a massive multiplayer game, or a peer-to-peer collaboration tool. They allow new types of applications, but they probably don't make sense in most of today's JavaScript-powered web applications (like e-commerce websites).

Second, web socket solutions can be fiendishly complex. The web page JavaScript is simple enough. But to build the server-side application, you'll need mad programming skills, including a good grasp of multithreading and networking concepts.

In order to use web sockets, you need to run a program (called a *web socket server*) on the web server for your website. This program has the responsibility of coordinating everyone's communication, and once it's launched it keeps running indefinitely.

Note: Many web hosts won't allow long-running programs, unless you pay for a *dedicated server* (a web server that's allocated to your website, and no one else's). If you're using ordinary shared hosting, you probably can't create web pages that use the web socket feature. Even if you can manage to launch a web socket server that keeps running, your web host will probably detect it and shut it down.

To give you an idea of the scope of a web socket server, consider some of the tasks a web socket server needs to manage:

- Set the message “vocabulary”—in other words, decide what types of messages are valid, and what they mean.
- Keep a list of all the currently connected clients.
- Detect errors sending messages to clients, and stop trying to contact them if they don't seem to be there anymore.
- Deal with any in-memory data—that is, data that all web clients might access—safely. Subtle issues abound—for example, consider what happens if one client is trying to join the party while another is leaving, and the connection details for both are stored in the same in-memory object.

Most developers will probably never create a server-side program that uses sockets; it's simply not worth the considerable effort. The easiest approach will be to install someone else's socket server and design custom web pages that use it. Because the JavaScript part of the web socket standard is easy to use, this won't pose a problem. Another option is to pick up someone else's socket server code and then customize it to get the exact behavior you want. Right now, there are plenty of projects, many of them free and open source, that are developing usable web socket servers for a variety of tasks, and in a variety of server-side programming languages. You'll get the details on page 345.

A Simple Web Socket Client

From the web page's point of view, the web socket feature is easy to understand and use. The first step is to create the WebSocket object. When you do, you supply a URL that looks something like this:

```
var socket = new WebSocket("ws://localhost/socketServer.php");
```

The URL starts with `ws://`, which is the new system for identifying web socket connections. However, the URL still leads to a web application on a server (in this case, the script named `socketServer.php`). The web socket standard also supports URLs that start with `wss://`, which indicates that you want to use a secure, encrypted connection (just as you do when requesting a web page that starts with `https://` instead of `http://`).

Note: Web sockets aren't limited to contacting their home web server. A web page can open a socket connection to a web socket server that's running on another web server, without any extra work.

Simply creating a new WebSocket object causes your page to attempt to connect to the server. You deal with what happens next using one of the WebSocket's four events: `onOpen` (when the connection is first established), `onError` (when there's a problem), `onClose` (when the connection is closed), and `onMessage` (when the page receives a message from the server):

```
socket.onopen = connectionOpen;
socket.onmessage = messageReceived;
socket.onerror = errorOccurred;
socket.onclose = connectionClosed;
```

For example, if the connection has succeeded, it makes sense to send a confirmation message. To deliver a message, you use the WebSocket's `send()` method, which takes ordinary text. Here's a function that handles the `onOpen` event and sends a message:

```
function connectionOpen() {
    socket.send("UserName:jerryCradivo23@gmail.com");
}
```

Presumably, the web server will receive this and then send a new message back.

You can use the `onError` and `onClose` events to notify the web page user. However, the most important event (by far) is the `onMessage` event that fires every time the web server delivers new data. Once again, the JavaScript that's involved is perfectly understandable—you simply grab the text of the message from the `data` property:

```
function messageReceived(e) {
    messageLog.innerHTML += "<br>" + "Message received: " + e.data;
}
```

If the web page decides its work is done, it can easily close the connection with the `disconnect()` method:

```
socket.disconnect();
```

Based on this quick overview, you can see that using someone else's socket server is a breeze—you just need to know what messages to send and what messages to expect.

Note: A lot of behind-the-scenes work takes place to make a web socket connection work. First, the web page makes contact using the well-worn HTTP standard. Then it needs to “upgrade” its connection to a web socket connection that allows unfettered back-and-forth communication. At this point, you could run into a problem if a proxy server sits between your computer and the web server (for example, on a typical company network). The proxy server may refuse to go along with the plan and drop the connection. You can deal with this problem by detecting the failed connection (through the WebSocket's `onError` event) and falling back on one of the socket polyfills described on GitHub at <http://tinyurl.com/polyfills>. They use tricks like polling to simulate a web socket connection, as best as possible.

Web Socket Examples on the Web

Curious to try out web sockets for yourself? There are plenty of places on the web where you can fire up an example on your own.

For starters, try <http://websocket.org/echo.html>, which features the most basic web socket server imaginable: You send a message, and it echoes the same message back to you (Figure 11-6). While this isn't very glamorous, it lets you exercise all the features of the WebSocket class. In fact, there's nothing to stop you from connecting to the echo server in your own page, regardless of whether your page is stored on your own web server (or even on your own computer hard drive).

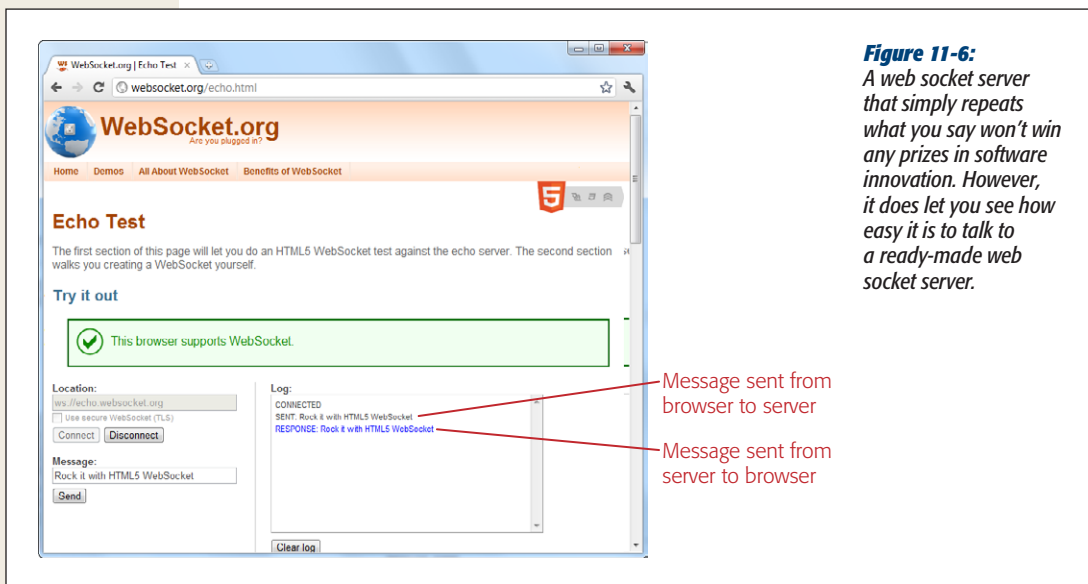

Figure 11-6:
A web socket server that simply repeats what you say won't win any prizes in software innovation. However, it does let you see how easy it is to talk to a ready-made web socket server.

If you want to look at some more exciting examples, check these out:

- **Basic chat.** It's a giant chat free-for-all. Log in to this simple web socket server, send a message, and everyone gets it delivered immediately. Try it out at <http://html5demos.com/web-socket>.
- **Multiuser sketchpad.** This page fuses web sockets with the HTML5 canvas. As other users draw on the canvas, the scribbles they paint appear on your canvas in real-time (and vice versa). It's simple in concept but truly impressive to witness. Try it out at <http://mrdoob.com/projects/multiuserpad>.

POWER USERS' CLINIC

Web Socket Servers

To actually run a practical example of your own, you need a web socket server that your web page can talk to. And although the server code that's required—which is several dozen lines at least—is beyond the scope of this chapter, there are plenty of places where you can find a test server. Here are some of your many options:

- **PHP.** This simple and slightly crude code project gives you a good starting point for building a web socket server with PHP. Get it at <http://code.google.com/p/phpwebsocket>.
- **Ruby.** There's more than one sample web socket server for Ruby, but this one that uses the Event-Machine model is popular. See <http://github.com/igrigorik/em-websocket>.
- **Python.** This Apache extension adds a socket server using Python. Get it at <http://code.google.com/p/pywebsocket>.
- **.NET.** Simple, it isn't. But this comprehensive project contains a complete web socket server using Microsoft's .NET platform and the C# language. Download it from <http://superwebsocket.codeplex.com>.
- **Java.** Similar in scope to the .NET project described above, this web socket server is pure Java. See <http://jwebsocket.org>.
- **node.JS.** Depending on who you ask, node.JS—a web server that runs JavaScript code—is either the next big thing in the making or an overgrown testing tool. Either way, you can get a web socket server that runs on it from <http://github.com/miksago/node-websocket-server>.
- **Kaazing.** Unlike the other items in this list, Kaazing doesn't provide the code for a web socket server. Instead, it provides a mature web socket server that you can license for your website. Adventurous developers who want to go it alone won't be interested. But it may make sense for less-ambitious websites, especially considering the built-in fallback support in its client libraries (which try the HTML5 web socket standard first, then attempt to use Flash, or finally fall back to pure JavaScript polling). Learn more at <http://kaazing.com/products/html5-edition.html>.

More Cool JavaScript Tricks

By now, you know all about the key themes of HTML5. You've used it to write more meaningful and better structured markup. You've seen its rich graphical features, like video and dynamic drawing. And you've used it to create self-sufficient, JavaScript-powered pages that can work even without a web connection.

In this chapter, you'll tackle three features that have escaped your attention so far. As with much of what you've already learned, these features extend the capabilities of what a web page can do—with a scrap of JavaScript code. Here's what awaits:

- **Geolocation.** Although it's often discussed as part of HTML5, geolocation is actually a separate standard that's never been in the hands of the WHATWG (page 13). However, like many of HTML5's features, geolocation lets you power up pages with a bit of JavaScript. Using geolocation, you can grab hold of a single piece of information: the geographic coordinates that pinpoint a web visitor's current location.
- **Web workers.** As web developers make smarter pages that run more JavaScript, it becomes more important to run certain tasks in the background, quietly, unobtrusively, and over long periods of time. You *could* use timers and other tricks. But the web workers feature provides a far more convenient solution for performing background work.

- **Session history.** In the old days of the Web, a page did one thing only: display stuff. As a result, people spent plenty of time clicking links to get from one document to another. But today, a JavaScript-fueled page can load content from another page without triggering a full page refresh. In this way, JavaScript creates a more seamless viewing experience. However, it also introduces a few wrinkles, like the challenge of keeping the browser URL synchronized with the current content. Web developers use plenty of advanced techniques to keep things in order, and now HTML5 adds a session history tool that can help (some of the time).

Note: As you explore these last three features, you'll get a still better idea of the scope of what is now called HTML5. What started as a few good ideas wedged into an overly ambitious standard has grown to encompass a grab bag of new features that tackle a range of different problems, with just a few core concepts (like semantics, JavaScript, and CSS3) to hold it all together.

Geolocation

Geolocation is a feature that lets you find out where in the world your visitors are. And that doesn't just mean what country or city a person's in. The geolocation feature can often narrow someone's position down to a city block, or even determine the exact coordinates of some who's strolling around with a webphone.

The geolocation feature has good support in every browser, as Table 12-1 shows.

Table 12-1. Browser support for geolocation

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	9	3.5	5	5	10.6	3.2	2.1

The obvious weak links are old versions of Internet Explorer, like IE 7 and IE 8. One way to get geolocation support on these browsers is to create a fallback that uses Google Gears (<http://code.google.com/apis/gears>). Google Gears was developed before HTML5 and targets many of the same features, including a similar geolocation system. Although Google Gears is now deprecated (meaning Google has stopped working on it and supporting it for newer browsers), it can still do in a pinch for old browsers. The drawback is that, like all browser plug-ins, Google Gears must be installed on the visitor's computer. If the computer doesn't have Google Gears, you could use Chrome Frame (page 41), or you may just need to ask visitors to type in their locations.

Note: Most of the new JavaScript features you've seen in this book were part of the original HTML5 specification, and were split off when it was handed over to the W3C. But geolocation isn't like that—it was never part of HTML5. Instead, it simply reached maturity around the same time. However, almost everyone now lumps them together as part of the wave of future web technologies.

How Geolocation Works

Geolocation raises quite a lot of questions in people who ordinarily aren't paranoid. Like, how does a piece of software know I'm hanging out at the local coffee shop? Is there some hidden code that's tracking my every move? And who's in that white van parked outside?

Fortunately, geolocation is a lot less Big Brotherish than it seems. That's because even if a browser can figure out your position, it won't tell a website unless you give it explicit permission (see Figure 12-1).

To figure out a person's location, the browser enlists the help of a *location provider*—for example, on Firefox that's Google Location Services. This location provider has the tough job of finding the location, and it can use several different strategies to do it.

For a desktop computer with a fixed (not wireless) Internet connection, the science is simple but imprecise. When someone goes online, her traffic is funneled from her computer or local network through a cable, telephone wire, or (horrors) dial-up connection, until it reaches a high-powered piece of network hardware that brings it onto the Internet. That piece of hardware has a unique *IP address*, a numeric code that establishes its public identity to other computers. It also has a postal address in the real world.

Note: If you have some networking experience, you already know that your computer has its own IP address, like every computer on a network. However, this IP address is your own private one whose purpose is to separate your computer from any other devices that are sharing your connection (like the netbook in your kitchen or the tablet computer in your knapsack). Geolocation doesn't use that IP address.

The location provider combines these two features. First, it figures out the IP address you're connecting through, and then it pinpoints the home of the router that uses it. Because of this indirection, geolocation won't be spot-on when you're using a desktop computer. For example, if you surf from a computer on the west side of Chicago, you might find that your traffic is being funneled through a router that's several miles closer to downtown. Still, even an imprecise result like this is often useful. For example, if you're looking for nearby pizza stores in a mapping tool, you can quickly skip over to the area you're really interested in—your home neighborhood—even if you start a certain distance away.

Note: The IP address technique is the roughest form of geolocation. If there's a better source of location data, the location provider will use that instead.

If you're using a laptop or a mobile device with a wireless connection, a location provider can look for nearby wireless access points. Ideally, the location provider consults a giant database to figure out the exact location of these access points, and then uses that information to triangulate your location.

If you're using a web-enabled phone, the location provider provides a similar triangulation process, but it uses the signals from different cellphone towers. This quick, relatively effective procedure usually gets your position down to less than a kilometer. (More industrialized areas—like downtown city cores—have more cellphone towers, which results in more precise geolocation.)

Finally, many mobile devices also have dedicated GPS hardware, which uses satellite signals to pin your location down to just a few meters. The drawback is that GPS is a bit slower and draws more battery power. It also doesn't work as well in built-up cities, where tall buildings can obscure the signals. As you'll see, it's up to you whether you want to request a high-precision location using GPS, if it's available (page 355).

And of course, other techniques are possible. Nothing stops a location provider from relying on different information, like an RFID chip, nearby Bluetooth devices, a cookie set by a mapping website like Google Maps, and so on.

Tip: You may also be able to correct your starting position with another tool. For example, Firefox fans can use a browser plug-in named Geolocator (<http://addons.mozilla.org/en-us/firefox/addon/geolocator>) to set the position that Firefox should report when you browse a website that uses geolocation. You can even use this technique to fake your address—for example, to pretend your computer in Iowa is actually surfing in from the Netherlands.

The takeaway is this: No matter how you connect to the Internet—even if you’re sitting at a desktop computer—geolocation can get somewhere near you. And if you’re using a device that gets a cellphone signal or has a GPS chip, the geolocation coordinates will be scarily accurate.

UP TO SPEED

How You Can Use Geolocation

Once you’ve answered the big question—how does geolocation work?—you need to resolve another one—namely, why should you use it?

The key point to understand is that geolocation tells your code the approximate geographic coordinates of a person—and that’s it. You need to combine this simple but essential information with more detailed location data. This data could be provided by your web server (typically, fetched out of a huge server-side database) or another geographic web service (like Google Maps).

For example, if you’re a big business with a physical presence in the real world, you might compare the user’s position with the coordinates of your different locations. You could then determine which location is closest. Or, if you’re

building some sort of social networking tool, you might plot the information of a group of people, to show them how close they are to one another. Or, you might take someone else’s location data and use that to provide a service for your visitors, like hunting down the nearest chocolate store, or finding the closest clean toilet in Brooklyn. Either way, the geolocation coordinates of the visitor only become important when they’re combined with more geographic data.

Although other businesses’ mapping and geographic services are outside the scope of this chapter, you’ll get the chance to try out an example with Google Maps on page 356.

Finding a Visitor’s Coordinates

The geolocation feature is strikingly simple. It consists of three methods that are packed into the `navigator.geolocation` object: `getCurrentPosition()`, `watchPosition()`, and `clearWatch()`.

Note: If you aren’t already familiar with the `navigator` object, it’s a relatively minor part of JavaScript, with a few properties that tell you about the current browser and its capabilities. The most useful of these is `navigator.userAgent`, which provides an all-in-one string that details the browser, its version number, and the operating system on which it’s running.

To get a web visitor’s location, you call `getCurrentPosition()`. Of course, the location-finding process isn’t instantaneous, and no browser wants to lock up a page while it’s waiting for location data. For that reason, the `getCurrentPosition()` method is asynchronous—it carries on immediately, without stalling your code.. When the geolocation process is finished, it triggers another piece of code to handle the results.

You might assume that geolocation uses an event to tell you when it's done, in much the same way that you react when an image has been loaded or a text file has been read. But JavaScript is nothing if not inconsistent. Instead, when you call `getCurrentPosition()` you supply the *completion function*.

Here's an example:

```
navigator.geolocation.getCurrentPosition(
  function(position) {
    alert("You were last spotted at (" + position.coords.latitude +
      "," + position.coords.longitude + ")");
  }
);
```

When this code runs, it calls `getCurrentPosition()` and passes in a function. Once the browser determines the location, it triggers that function, which shows a message box. Figure 12-2 shows the result in Internet Explorer.

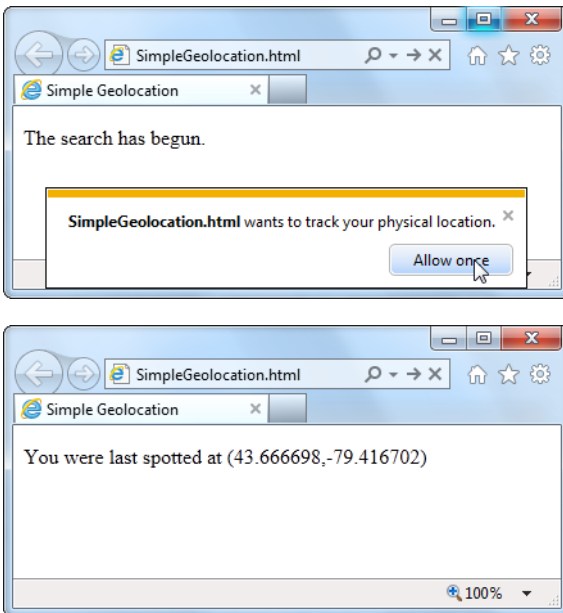

Figure 12-2:

Top: First, you need to agree to let the browser tell the web server about your position.

Bottom: The results are in—your coordinates on the globe.

To keep your code clear and organized, you probably won't define your completion function right inside the `getCurrentPosition()` call (as done in this example). Instead, you can put it in a separate, named function:

```
function geolocationSuccess(position) {
  alert("You were last spotted at (" + position.coords.latitude +
    "," + position.coords.longitude + ")");
}
```

Then you can point to it when you call `getCurrentLocation()`:

```
navigator.geolocation.getCurrentPosition(geolocationSuccess);
```

Remember, you need to use a browser that supports geolocation and let the web page track you. Also, it's a good idea to upload your page to a test server before trying it out. Otherwise, you'll see some quirks (for example, geolocation error-handling won't work) and some browsers will fail to detect your position altogether (like Chrome).

If you're wondering, "What good are geographic coordinates to me?" you've asked a good question. You'll explore how you can use the geolocation data shortly (page 356). But first, you should understand how to catch errors and configure a few geolocation settings.

POWER USERS' CLINIC

Finding Out the Accuracy of a Geolocation Guess

When the `getCurrentPosition()` method meets with success, your code gets a position object that has two properties: *timestamp* (which records when the geolocation was performed) and *coords* (which indicates the geographic coordinates).

As you've seen, the *coords* object gives you the latitude and longitude—the coordinates that pin down your position on the globe. However, the *coords* object bundles up a bit more information that you haven't seen yet. For example, there are more specialized *altitude*, *heading*, and *speed* properties, none of which are currently supported by any browser.

More interesting is the *accuracy* property, which tells you how accurate the geolocation information is, in meters. (Somewhat confusingly, that means the value of the *accuracy* property increases as the accuracy of the location data decreases.) For example, an accuracy of 2,135 meters

converts to about 1.3 miles, meaning the geolocation coordinates have pinpointed the current visitor's position within that distance. To visualize this, imagine a circle with the center at the geolocation coordinates, and a radius of 1.3 miles. Odds are the visitor is somewhere in that circle.

The *accuracy* property is useful for identifying bad geolocation results. For example, if you get an accuracy result that's tens of thousands of meters, then the location data isn't reliable:

```
if (position.coords.accuracy > 50000) {
    results.innerHTML =
        "This guess is all over the map.";
}
```

At this point, you might want to warn the user or offer him the chance to enter the right position information himself.

Dealing with Errors

Geolocation doesn't run so smoothly if the visitor opts out and decides not to share the location data with your page. In the current example, the completion function won't be called at all, and your page won't have any way to tell whether the browser is still trying to dig up the data or has run into an error. To deal with this sort of situation, you supply two functions when you call `getCurrentLocation()`. The first function is called if your page meets with success, while the second is called if your geolocation attempt ends in failure.

Here's an example that uses both a completion function and an error function:

```
// Store the element where the page displays the result.
var results;

window.onload = function() {
    results = document.getElementById("results");

    // If geolocation is available, try to get the visitor's position.
    if (navigator.geolocation) {
        navigator.geolocation.getCurrentPosition(
            geolocationSuccess, geolocationFailure
        );
        results.innerHTML = "The search has begun.";
    }
    else {
        results.innerHTML = "This browser doesn't support geolocation.";
    }
};

function geolocationSuccess(position) {
    results.innerHTML = "You were last spotted at (" +
        position.coords.latitude + ", " + position.coords.longitude + ")";
}

function geolocationFailure(positionError) {
    results.innerHTML = "Geolocation failed.";
}
```

When the error function is called, the browser hands it an error object with two properties: *code* (a numeric code that classifies it as one of four types of problems) and *message* (which provides a short text message reporting the problem). Generally, the message is intended for testing, and your code will use the error code to decide how it should handle the issue.

Here's a revised error function that checks all possible error code values:

```
function geolocationFailure(positionError) {
    if (positionError.code == 1) {
        results.innerHTML =
            "You decided not to share, but that's OK. We won't ask again.";
    }
    else if (positionError.code == 2) {
        results.innerHTML =
            "The network is down or the positioning service can't be reached.";
    }
    else if (positionError.code == 3) {
        results.innerHTML =
            "The attempt timed out before it could get the location data.";
    }
    else {
        results.innerHTML =
            "This the mystery error. We don't know what happened.";
    }
}
```

Note: If you're running the test web page from your computer (not a real web server), the error function won't be triggered when you decline to share your location.

Setting Geolocation Options

So far, you've seen how to call `getCurrentLocation()` with two arguments: the success function and the failure function. You can also supply a third argument, which is an object that sets certain geolocation options.

Currently, there are three options you can set, and each one corresponds to a different property on the geolocation options object. You can set just one or any combination. Here's an example that sets one, named `enableHighAccuracy`:

```
navigator.geolocation.getCurrentPosition(geolocationSuccess,
    geolocationFailure, {enableHighAccuracy: true});
```

And here's an example that sets all three:

```
navigator.geolocation.getCurrentPosition(
    geolocationSuccess, geolocationFailure,
    {enableHighAccuracy: true,
     timeout: 10000,
     maximumAge: 60000}
);
```

Both of these examples supply the geolocation options using a JavaScript object literal. If that looks a bit weird to you, check out the explanatory box on page 356.

So what do these properties mean? The *enableHighAccuracy* property opts into high-precision GPS-based location detection, if the device supports it (and the user allows it). Don't choose this option unless you need exact coordinates, because it can draw serious battery juice. The default for `enableHighAccuracy`, should you choose not to set it, is `false`.

The *timeout* property sets the amount of time your page is willing to wait for location data before throwing in the towel. The timeout is in milliseconds, so a value of 10,000 milliseconds means a maximum wait of 10 seconds. The countdown begins *after* the user agrees to share the location data. By default, timeout is 0, meaning the page will wait indefinitely, without ever triggering the timeout error.

The *maximumAge* property lets you use cached location data. For example, if you set `maximumAge` to 60,000 milliseconds, you'll accept a previous value that's up to a minute old. This saves the effort of repeated geolocation calls, but it also means your results will be less accurate for a person on the move. By default, `maximumAge` is 0, meaning cached location data is never used. (You can also use a special value of Infinity, which means use any cached location data, no matter how old it is.)

UP TO SPEED

Understanding Object Literals

In Chapter 7, you learned about a technique to create objects in JavaScript using a function, which acts as a template. For example, on page 217 you learned how you could use a single `Circle()` function, and then use it to generate dozens of circle objects. On page 226 you did it again to make ball objects.

When you want to formally define the ingredients that make up an object, using a function is the best approach. It leads to well-organized code, and it makes complex coding tasks easier. But sometimes you just need a quick way to create an object for a one-off task. In this case, an *object literal* makes sense, because it requires nothing more advanced than a pair of curly brackets.

To create an object literal, you use the opening curly brace, supply a comma-separated list of properties, and then end with the closing curly brace. You can use spacing and line breaks to make your code more readable, but it's not required. Here's an example:

```
var personObject = {  
  firstName="Joe",  
  lastName="Grapta"  
};
```

For each property, you specify the property name and its starting value. Thus, the above code sets `personObject.firstName` to the text "Joe" and `personObject.lastName` to "Grapta".

The example on page 355 uses object literals to send information to the geolocation system. As long as you use the right property names (the ones the `getCurrentPosition()` method is expecting), then an object literal works perfectly.

If you want to learn more about object literals, object functions, and everything else to do with custom objects in JavaScript, check out the detailed information at www.javascriptkit.com/javatutors/oopjs.shtml.

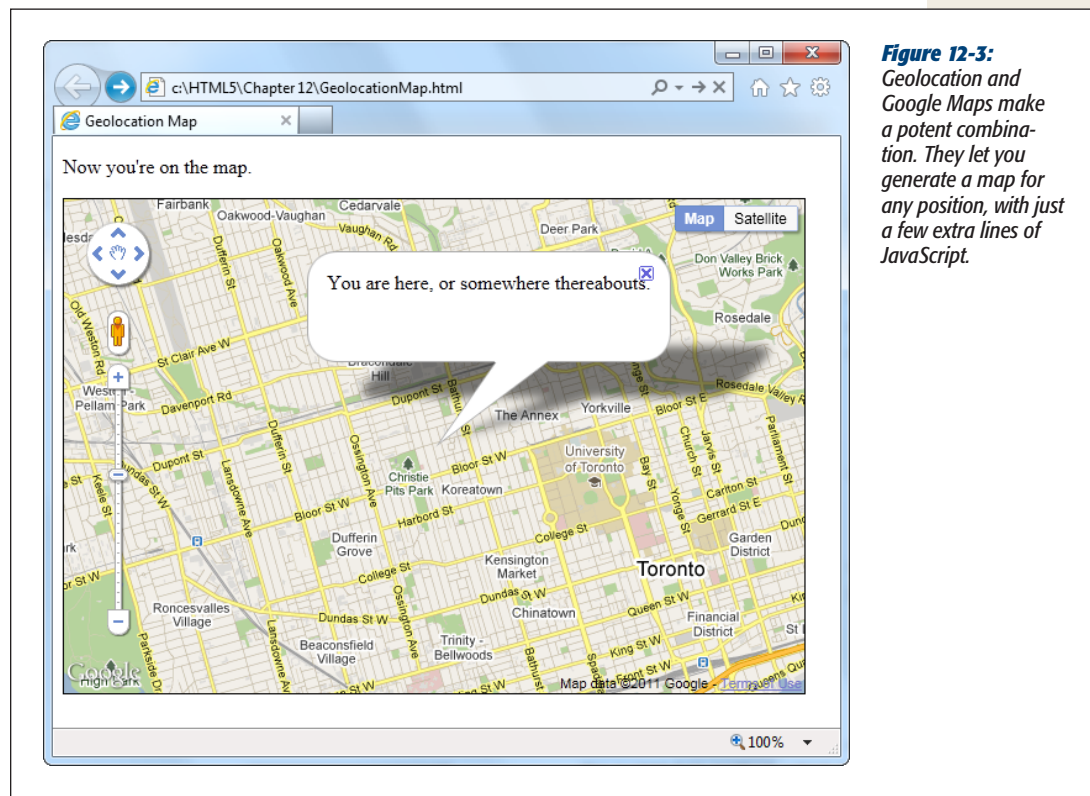

Showing a Map

Being able to grab someone's geographic coordinates is a neat trick. But the novelty wears off fast unless you have something useful to do with that information. Hardcore geo-junkies know that there's a treasure trove of location information out there. (Often, the problem is taking this information and converting it to a form that's useful to your web application.) There are also several web-based mapping services, the king of which is Google Maps. In fact, good estimates suggest that Google Maps is the most heavily used web application service, for any purpose.

Using Google Maps, you can create a map for any portion of the world, at any size you want. You can control how your visitors interact with that map, generate driving instructions, and—most usefully—overlay your own custom data points on that map. For example, a Google Maps-fortified page can show visitors your business locations or flag interesting sights in a Manhattan walking tour. To get started with Google Maps, check out the documentation at <http://code.google.com/apis/maps/documentation/javascript>.

Note: Google Maps is free to use, even for commercial websites, provided you aren't charging people to access your site. (And if you are, Google has a premium mapping service you can pay to use.) Currently, Google Maps does not show ads, although the Google Maps license terms explicitly reserve the right to do that in the future.

Figure 12-3 shows a revised version of the geolocation page. Once it grabs the current user's coordinates, it shows that position in a map.

Creating this page is easy. First, you need a link to the scripts that power the Google Maps API. Place this before any script blocks that use the mapping functionality:

```
<head>
  <meta charset="utf-8">
  <title>Geolocation Map</title>
  <script src="http://maps.google.com/maps/api/js?sensor=true"></script>
  ...
</head>
```

Next, you need a `<div>` element that will hold the dynamically generated map. Give it a unique ID for easy reference:

```
<body>
  <p id="results">Where do you live?</p>
  <div id="mapSurface"></div>
</body>
```

You can then use a style sheet rule to set the size of your map:

```
#mapSurface {
  width: 600px;
  height: 400px;
  border: solid 1px black;
}
```

Now you're ready to start using Google Maps. The first job is to create the map surface. This example creates the map when the page loads, so that you can use it in the success or failure function. (After all, failure doesn't mean the visitor can't use the mapping feature in your page; it just means that you can't determine that visitor's current location. You'll probably still want to show the map, but just default to a different starting point.)

Here's the code that runs when the page loads. It creates the map and then starts a geolocation attempt:

```
var results;
var map;

window.onload = function() {
  results = document.getElementById("results");

  // Set some map options. This example sets the starting zoom level and the
  // map type, but see the Google Maps documentation for all your options.
  var myOptions = {
    zoom: 13,
    mapTypeId: google.maps.MapTypeId.ROADMAP
  };

  // Create the map, with these options.
  map = new google.maps.Map(document.getElementById("mapSurface"), myOptions);

  // Try to find the visitor's position.
  if (navigator.geolocation) {
    navigator.geolocation.getCurrentPosition(geolocationSuccess,
      geolocationFailure);
    results.innerHTML = "The search has begun.";
  }
  else {
    results.innerHTML = "This browser doesn't support geolocation.";
    goToDefaultLocation();
  }
};
```

Tip: The Google Maps documentation at <http://tinyurl.com/36aemmr> shows how to perform geolocation two ways—using the geolocation feature described in this chapter, or falling back to Google Gears (page 348).

Even after you've created the map with this code, you still won't see it in the page. That's because you haven't set a geographic position. To do that, you need to create a specific global *point* using the `LatLng` object. You can then place that point on the map with the map's `setCenter()` method. Here's the code that does that with the visitor's coordinates:

```
function geolocationSuccess(position) {
    // Turn the geolocation position into a LatLng object.
    location = new google.maps.LatLng(
        position.coords.latitude, position.coords.longitude);

    // Map that point.
    map.setCenter(location);
}
```

This code is sufficient for displaying a map, like the one in Figure 12-3. But you can also add adornments to that map, like other places or an info bubble. For the latter, you need to create an `InfoWindow` object. Here's the code that creates the info bubble shown in Figure 12-3:

```
// Create the info bubble and set its text content and map coordinates.
var infowindow = new google.maps.InfoWindow();
infowindow.setContent("You are here, or somewhere thereabouts.");
infowindow.setPosition(location);

// Make the info bubble appear.
infowindow.open(map);

results.innerHTML = "Now you're on the map.";
}
```

Finally, if geolocation fails or isn't supported, you can carry out essentially the same process. Just use the hard-coded coordinates of a place you know:

```
function geolocationFailure(positionError) {
    ...
    goToDefaultLocation();
}

function goToDefaultLocation() {
    // This is the location of New York.
    var newYork = new google.maps.LatLng(40.69847, -73.95144);

    map.setCenter(newYork);
}
```

Monitoring a Visitor's Moves

All the examples you've used so far have relied on the `getCurrentPosition()` method, which is the heart of geolocation. However, the geolocation object has two more methods that allow you to track a visitor's position, so your page receives notifications as the location changes.

It all starts with the `watchPosition()` method, which looks strikingly similar to `getCurrentPosition()`. Like `getCurrentPosition()`, `watchPosition()` accepts three arguments: a success function (which is the only required detail), a failure function, and an options object:

```
navigator.geolocation.watchPosition(geolocationSuccess, geolocationFailure);
```

The difference between `getCurrentPosition()` and `watchPosition()` is that `watchPosition()` may trigger the success function multiple times—when it gets the location for the first time, and again, whenever it detects a new position. (It's not in your control to set how often the device checks for a new position. All you need to know is that the device won't bother you if the position hasn't changed, but it will trigger the success function again if it has.) On a desktop computer, which never moves, the `getCurrentPosition()` and `watchPosition()` methods have exactly the same effect.

Unlike `getCurrentPosition()`, `watchPosition()` returns a number. You can hold onto this number, and pass it in to `clearWatch()` to stop paying attention to location changes. Or, you can ignore this step and keep receiving notifications until the visitor surfs to another page:

```
var watch = navigator.geolocation.watchPosition(geolocationSuccess,
  geolocationFailure);
...

navigator.geolocation.clearWatch(watch);
```

Web Workers

Way back when JavaScript was first created, no one worried too much about performance. JavaScript was built to be a straightforward language for running small bits of script in a web page. JavaScript was a frill—a simplified version of Java for amateur programmers. It certainly wasn't meant to run anyone's business.

Fast forward nearly 20 years, and JavaScript has taken over the Web. Developers use it to add interactivity to almost every sort of page, from games and mapping tools to shopping carts and fancy forms. But in many ways, the JavaScript language is still scrambling to catch up to its high status.

One example is the way JavaScript deals with big jobs that require hefty calculations. In most modern programming systems, work like this would happen quietly in the *background*, while the person using the application carried on, undisturbed. But in JavaScript, code always runs in the *foreground*. So any time-consuming piece of code will interrupt the user and freeze up the page until the job is done. Ignore this problem, and you'll wind up with some seriously annoyed, never-to-return web page visitors.

Note: Crafty web developers have found some partial solutions to the JavaScript freeze-up problem. These involve splitting long-running tasks into small pieces and using `setInterval()` or `setTimeout()` to run one piece at a time. For certain types of tasks, this solution works well (for example, it's a practical way to animate a canvas, as demonstrated on page 222). But if you need to run a single, very long operation from start to finish, this technique adds complexity and confusion.

HTML5 introduces a better solution. It adds a dedicated object, called a *web worker*, that's designed to do background work. If you have a time-consuming job to polish off, you create a new web worker, supply it with your code, and start it on its way. While it works, you can communicate with it in a safe but limited way—by passing text messages.

Table 12-2 shows the current state of web worker support.

Table 12-2. Browser support for web workers

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	10*	3.5	3	4	10.6	-	-

*Currently, this version is available in early beta builds only.

UP TO SPEED

Web Worker Safety Measures

JavaScript's web worker lets your code work in the background, while something else takes place in the foreground. This brings up a well-known theme of modern programming: If an application can do two things at once, one of them has the potential to mess up the other.

The problem occurs when two different pieces of code fight over the same data, at the same time. For example, one piece of code may attempt to read some data, while another attempts to set it. Or both may attempt to set a variable at the same time, causing one change to be overwritten. Or two pieces of code may attempt to manipulate the same object in different ways, pushing it into an inconsistent state. The possible issues are endless, and they're notoriously difficult to discover and solve. Often, a multithreaded application (that's an application that uses several *threads*

of independently executing code) works fine during testing. But when you start using it in the real world, maddeningly inconsistent errors appear.

Fortunately, you won't face these problems with JavaScript's web workers feature. That's because it doesn't allow you to share the same data between your web page and your web workers. You can *send* data from your web page to a web worker (or vice versa), but JavaScript automatically makes a copy of your data and sends that. That means there's no possible way for two threads to get hold of the same memory slot at the same time, and cause subtle issues. Of course, this simplified model also restricts some of the things that web workers can do, but a minor reduction in capabilities is the cost of making sure ambitious programmers can't shoot themselves in the foot.

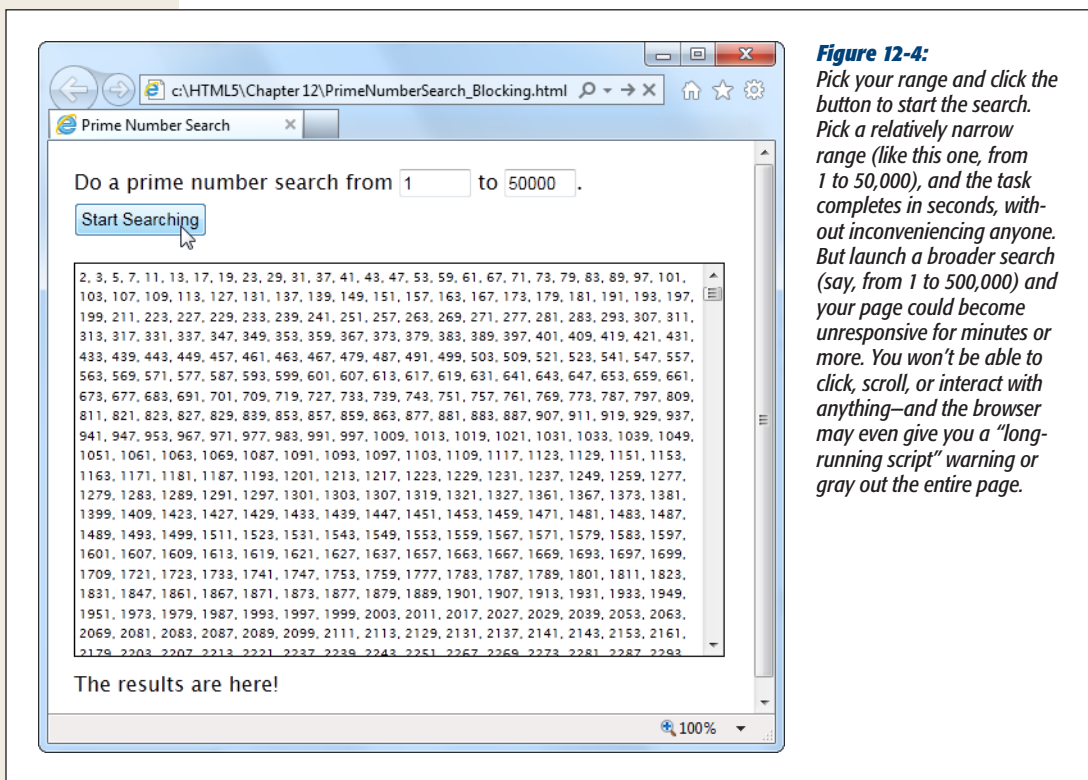

Note: If you're running your web worker page from a local file, Chrome will fail unless you start it with the `--allow-file-access-from-files` parameter. The easiest way to do this is to create a new Chrome shortcut that tacks this parameter onto the end of the command line. See <http://tinyurl.com/3j4dgb> for a blow-by-blow description.

A Time-Consuming Task

Before you can see the benefits of web workers, you need to find a suitable intensive piece of code. There's no point in using web workers for short tasks. But if you plan to run some CPU-taxing calculations that could tie up the web browser for more than a few seconds, web workers make all the difference. Consider, for example, the prime number searcher shown in Figure 12-4. Here, you can hunt for prime numbers that fall in a given range. The code is simple, but the task is *computationally difficult*, which means it could take some serious number-crunching time.

Figure 12-4:

Pick your range and click the button to start the search. Pick a relatively narrow range (like this one, from 1 to 50,000), and the task completes in seconds, without inconveniencing anyone. But launch a broader search (say, from 1 to 500,000) and your page could become unresponsive for minutes or more. You won't be able to click, scroll, or interact with anything—and the browser may even give you a “long-running script” warning or gray out the entire page.

Clearly, this page can be improved with web workers. But before you get to that, you need to take a quick look through the existing markup and JavaScript code.

The markup is short and concise. The page uses two `<input>` controls, one for each text box. It also includes a button to start the search, and two `<div>` elements, one to hold the results and another to hold the status message underneath. Here's the complete markup from inside the `<body>` element:

```
<p>Do a prime number search from <input id="from" value="1"> to
  <input id="to" value="20000">.</p>
<button id="searchButton" onclick="doSearch()">Start Searching</button>

<div id="primeContainer">
</div>

<div id="status"></div>
```

One interesting detail is the styling of the `<div>` element that holds the prime number list. It's given a fixed height and a maximum width, and the `overflow` and `overflow-x` properties work together to add a vertical scroll bar (but not a horizontal one):

```
#primeContainer {
  border: solid 1px black;
  margin-top: 20px;
  margin-bottom: 10px;
  padding: 3px;
  height: 300px;
  max-width: 500px;
  overflow: scroll;
  overflow-x: hidden;
  font-size: x-small;
}
```

The JavaScript code is a bit longer, but not much more complicated. It retrieves the numbers from the text boxes, starts the search, and then adds the prime number list to the page. It doesn't actually perform the mathematical operations that find the prime numbers—this is handled through a separate function, which is named `findPrimes()` and stored in a separate JavaScript file.

Tip: You don't need to see the `findPrimes()` function to understand this example or web workers—all you need is a suitably long task. However, if you're curious to see the math that makes this page work, or if you just want to run a few prime number searches yourself, check out the full code on the try-out site at www.prosetech.com/html5.

Here's the complete code for the `doSearch()` function:

```
function doSearch() {
  // Get the numbers for the search range.
  var fromNumber = document.getElementById("from").value;
  var toNumber = document.getElementById("to").value;

  // Perform the prime search. (This is the time-consuming step.)
  var primes = findPrimes(fromNumber, toNumber);

  // Loop over the array of prime numbers, and paste them together into
  // one long piece of text.
```

```

var primeList = "";
for (var i=0; i<primes.length; i++) {
    primeList += primes[i];
    if (i != primes.length-1) primeList += ", ";
}

// Insert the prime number text into the page.
var displayList = document.getElementById("primeContainer");
displayList.innerHTML = primeList;

// Update the status text to tell the user what just happened.
var statusDisplay = document.getElementById("status");
if (primeList.length == 0) {
    statusDisplay.innerHTML = "Search failed to find any results.";
}
else {
    statusDisplay.innerHTML = "The results are here!";
}
}

```

As you can see, the markup and code is short, simple, and to the point. Unfortunately, if you plug in a large search you'll find that it's also as slow and clunky as riding a golf cart up a steep hill.

Doing Work in the Background

The web worker feature revolves around a new object called the `Worker`. When you want to run something in the background, you create a new `Worker`, give it some code, and send it some data.

Here's an example that creates a new web worker that runs the code in the file named `PrimeWorker.js`:

```
var worker = new Worker("PrimeWorker.js");
```

The code that a worker runs is *always* stored in a separate JavaScript file. This design discourages newbie programmers from writing web worker code that attempts to use global variables or directly access elements on the page. Neither of these operations is possible.

Note: Browsers enforce a strict separation between your web page and your web worker code. For example, there's no way for the code in `PrimeWorker.js` to write prime numbers into a `<div>` element. Instead, your worker code needs to send its data back to JavaScript code on the page, so the web page code can display the results.

Web pages and web workers communicate by exchanging messages. To send data to a worker, you call the worker's `postMessage()` method:

```
worker.postMessage(myData);
```

The worker then receives an `onMessage` event that provides a copy of the data. This is when it starts working.

Similarly, when your worker needs to talk back to the web page, it calls its own `postMessage()` method, along with some data, and the web page receives an `onMessage` event. Figure 12-5 shows this interaction close up.

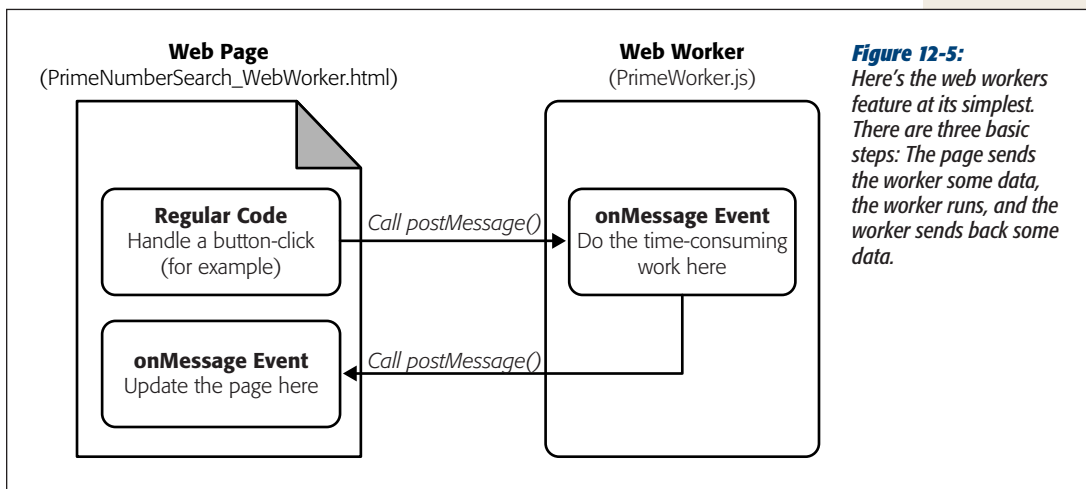

Figure 12-5: Here's the web workers feature at its simplest. There are three basic steps: The page sends the worker some data, the worker runs, and the worker sends back some data.

There's one more wrinkle to consider before you dive in. The `postMessage()` function allows only a single value. This is a stumbling block for the prime number cruncher, because it needs two pieces of data (the two numbers in the range). The solution is to package these two details into an object literal (see page 356). This code shows one example, which gives the object two properties (the first named *from*, and the second named *to*), and assigns values to both of them:

```
worker.postMessage(
  { from: 1,
    to: 20000 }
);
```

Note: Incidentally, you can send virtually any object to a worker. Behind the scenes, the browser uses JSON (page 291) to convert your object to a harmless piece of text, duplicate it, and re-objectify it.

With these details in mind, you can revise the `doSearch()` function you saw earlier. Instead of performing the prime number search itself, the `doSearch()` function creates a worker and gets it to do the real job:

```
var worker;

function doSearch() {
  // Disable the button, so the user can't start more than one search
  // at the same time.
  searchButton.disabled = true;
```

```

// Create the worker.
worker = new Worker("PrimeWorker.js");

// Hook up to the onMessage event, so you can receive messages
// from the worker.
worker.onmessage = receivedWorkerMessage;

// Get the number range, and send it to the web worker.
var fromNumber = document.getElementById("from").value;
var toNumber = document.getElementById("to").value;

worker.postMessage(
  { from: fromNumber,
    to: toNumber }
);

// Let the user know that things are on their way.
statusDisplay.innerHTML = "A web worker is on the job (" +
  fromNumber + " to " + toNumber + ") ...";
}

```

Now, the code in the `PrimeWorker.js` file springs into action. It receives the `onMessage` event, performs the search, and then posts a new message back to the page, with the prime list:

```

onmessage = function(event) {
  // The object that the web page sent is stored in the event.data property.
  var fromNumber = event.data.from;
  var toNumber = event.data.to;

  // Using that number range, perform the prime number search.
  var primes = findPrimes(fromNumber, toNumber);

  // Now the search is finished. Send back the results.
  postMessage(primes);
};

function findPrimes(fromNumber, toNumber) {
  // (The boring prime number calculations go in this function.)
}

```

When the worker calls `postMessage()`, it fires the `onMessage` event, which triggers this function in the web page:

```

function receivedWorkerMessage(event) {
  // Get the prime number list.
  var primes = event.data;

  // Copy the list to the page.
  ...

  // Allow more searches.
  searchButton.disabled = false;
}

```

You can now use the same code you saw earlier (page 364) to convert the array of prime numbers into a piece of text, and insert that text into the web page.

Overall, the structure of the code has changed a bit, but the logic is mostly the same. The result, however, is dramatically different. Now, when a long prime number search is under way, the page remains responsive. You can scroll down, type in the text boxes, and select numbers in the list from the previous search. Other than the message at the bottom of the page, there's nothing to reveal that a web worker is plugging away in the background.

Tip: Does your web worker need access to the code in another JavaScript file? There's a simple solution with the `importScripts()` function. For example, if you want to call functions from the `FindPrimes.js` file in `PrimeWorker.js`, just add this line of code before you do:

```
importScripts("FindPrimes.js");
```

Handling Worker Errors

As you've learned, the `postMessage()` method is the key to communicating with web workers. However, there's one more way that a web worker can notify your web page—with the `onerror` event that signals an error:

```
worker.onerror = workerError;
```

Now, if some dodgy script or invalid data causes an error in your background code, the error details are packaged up and sent back to the page. Here's some web page code that simply displays the text of the error message:

```
function workerError(error) {
    statusDisplay.innerHTML = error.message;
}
```

Along with the `message` property, the error object also includes a *lineno* and *filename* property, which report the line number and file name where the error occurred.

Canceling a Background Task

Now that you've built a basic web worker example, it's time to add a few refinements. First is cancellation support, which lets your page shut down a worker in mid-calculation.

There are two ways to stop a worker. First, a worker can stop itself by calling `close()`. More commonly, the page that created the worker will shut it down by calling the worker's `terminate()` method. For example, here's the code you can use to power a straightforward cancel button:

```
function cancelSearch() {
    worker.terminate();
    statusDisplay.innerHTML = "";
    searchButton.disabled = false;
}
```

GEM IN THE ROUGH

A Web Worker Fallback

By this point, you're probably wondering what you should do when your page runs on a browser that *doesn't* have web worker support.

As with geolocation, you can use Google Gears as a fallback for web workers, as it provides a similar feature called worker pool (http://code.google.com/apis/gears/api_workerpool.html). However, even if you use Gears, you'll *still* need another fallback for computers that don't have it installed. The easiest option is to simply do the same work in the foreground:

```
if (window.Worker) {
    // Web workers are supported.
    // So why not create a web worker
    // and start it?
} else {
```

```
// Web workers aren't available.
// You can just call the prime search
// function, and wait.
}
```

This approach doesn't force you to write any extra code, because the prime-number-searching function is already written, and you can call it with or without a web worker. However, if you have a long task, this approach could lock up the browser for a bit. An alternate (but more tedious) approach is to try to fake a background job using the `setInterval()` or `setTimeout()` methods. For example, you could write some code that tests just a few numbers every interval.

Click this button to stop the current search and re-enable the search button. Just remember that once a worker is stopped in this way, you can't send any more messages, and it can't be used to do any more operations. To perform a new search, you need to create a new worker object. (The current example does this already, so it works perfectly.)

Passing More Complex Messages

The last trick you'll learn to do with a web worker is return progress information. Figure 12-6 shows a revised version of the web worker page that adds this feature.

To build the progress display, the web worker needs to send the progress percentage to the page while it works. But as you already know, web workers have just one way to talk to the pages that owns them—with the `postMessage()` method. So to create this example, the web worker needs to send *two* types of messages: progress notifications (while the work is under way) and the prime number list (when the work is finished). The trick is making the difference between these two messages clear, so the `onMessage` event handler in the page can easily distinguish between the two types.

The best approach is to add a bit of extra information to the message. For example, when the web worker sends progress information, it can slap the text label "Progress" on its message. And when the web worker sends the prime number list, it can add the label "PrimeList."

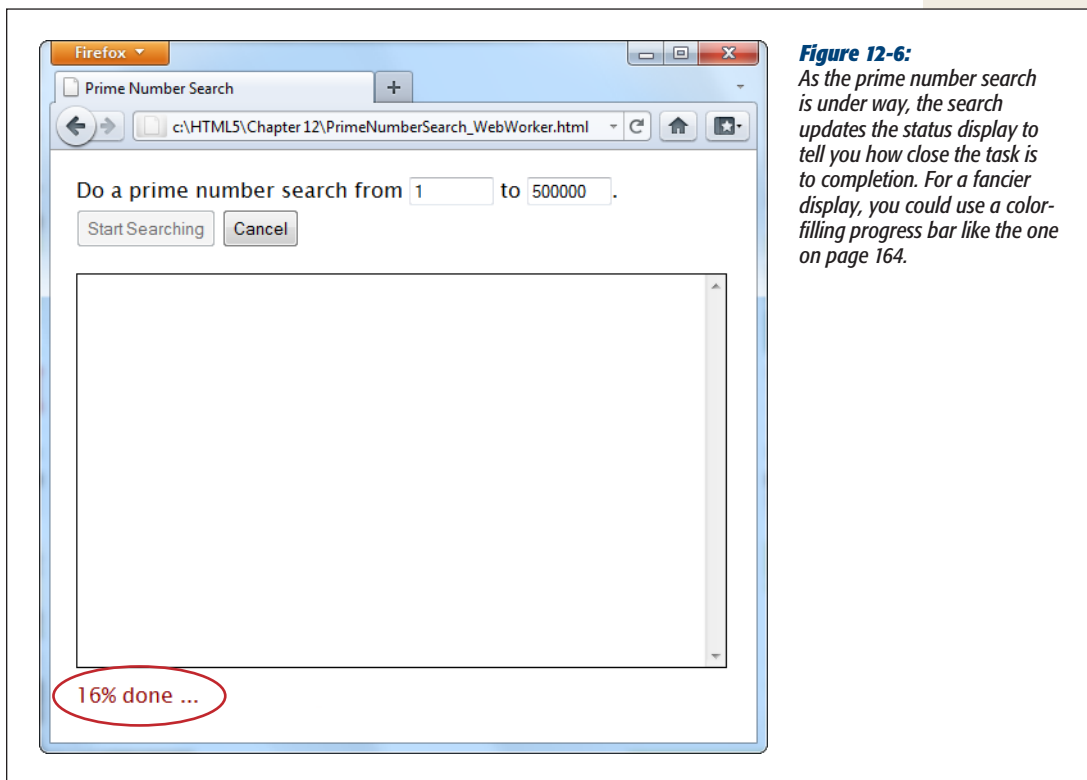

Figure 12-6: As the prime number search is under way, the search updates the status display to tell you how close the task is to completion. For a fancier display, you could use a color-filling progress bar like the one on page 164.

To bundle all the information you want together in one message, you need to create an object literal. This is the same technique the web page used to send the number range data to the web worker. The extra piece of information is the text that describes the type of message, which is placed in a property called *messageType* in this example. The actual data goes in a second property, named *data*.

Here's how you would rewrite the web worker code to add a message type to the prime number list:

```
onmessage = function(event) {
    // Perform the prime number search.
    var primes = findPrimes(event.data.from, event.data.to);

    // Send back the results.
    postMessage(
        {messageType: "PrimeList", data: primes}
    );
};
```

The code in the `findPrimes()` function also uses the `postMessage()` method to send a message back to the web page. It uses the same two properties—`messageType` and `data`. But now the `messageType` indicates that the message is a progress notification, and `data` holds the progress percentage:

```
function findPrimes(fromNumber, toNumber) {
    ...

    // Calculate the progress percentage.
    var progress = Math.round(i/list.length*100);

    // Only send a progress update if the progress has changed at least 1%.
    if (progress !== previousProgress) {
        postMessage(
            {messageType: "Progress", data: progress}
        );
        previousProgress = progress;
    }
    ...
}
```

When the page receives a message, it needs to start by checking the `messageType` property to determine what sort of message it has just received. If it's a prime list, then the results are shown in the page. If it's a progress notification, then the progress text is updated:

```
function receivedWorkerMessage(event) {
    var message = event.data;

    if (message.messageType === "PrimeList") {
        var primes = message.data;

        // Display the prime list. This code is the same as before.
        ...
    }
    else if (message.messageType === "Progress") {
        // Report the current progress.
        statusDisplay.innerHTML = message.data + "% done ...";
    }
}
```

Note: There's another way to design this page. You could get the worker to call `postMessage()` every time it finds a prime number. The web page would then add each prime number to the list and show it in the page immediately. This approach has the advantage of showing results as they arrive. However, it also has the drawback of continually interrupting the page (because the web worker will find prime numbers quite quickly). The ideal design depends on the nature of your task—how long it takes to complete, whether partial results are useful, how quickly each partial result is calculated, and so on.

POWER USERS' CLINIC

More Ways to Use a Web Worker

The prime number search uses web workers in the most straightforward way possible—to perform one well-defined task. Every time the search is started, the page creates a new web worker. That web worker is responsible for a single task. It receives a single message, and sends a single message back.

Your pages don't need to be this simple. Here are a few examples of how you can extend your web-worker designs to do more complicated things:

- **Reuse a web worker for multiple jobs.** When a worker finishes its work and reaches the end of the `onMessage` event handler, it doesn't die. It simply goes idle and waits quietly. If you send the worker another message, it springs back to life and does the work.
- **Create multiple web workers.** Your page doesn't need to stick to one worker. For example, imagine you want to let a visitor launch several prime number searches at a time. You could create a new web worker for each search, and keep track of all your workers in an array. Each time a web worker responds with its list of prime numbers, you add that to the page,

taking care not to overwrite any other worker's result. (However, some words of caution are in order. Web workers have a relatively high overhead, and running a dozen at once could swamp the computer with work.)

- **Create web workers inside a web worker.** A web worker can start its own web workers, send them messages, and receive their messages back. This technique is useful for complex computational tasks that require recursion, like calculating the Fibonacci sequence.
- **Download data with a web worker.** Web workers can use the `XMLHttpRequest` object (page 325) to grab new pages or to send requests to a web service. When they get the information they need, they can call `postMessage()` to send it up to the page.
- **Do periodic tasks with a web worker.** Web workers can use the `setTimeout()` and `setInterval()` functions, just like ordinary web pages. For example, you might create a web worker that checks a website for new data every minute.

History Management

Session history is an HTML5 add-on that extends the capabilities of the JavaScript history object. This sounds simple, but the trick is knowing when and why you should use it.

If you've never noticed the history object before, don't be alarmed. Up until now, it's had very little to offer. In fact, the traditional history object has just one property and three basic methods. The property is *length*, and it tells you how many entries are in the browser's History list (the list of recently visited web pages that the browser maintains as you skip from page to page across the Web). Here's an example that uses it:

```
alert("You have " + history.length +  
      " pages in your browser's history list.");
```

The most useful history method is `back()`. It lets you send a visitor one step back in the browsing history:

```
history.back();
```

This method has the same effect as if the visitor clicked the browser's Back button. Similarly, you can use the forward() method to step forward, or the go() method to move a specified number of steps backward or forward.

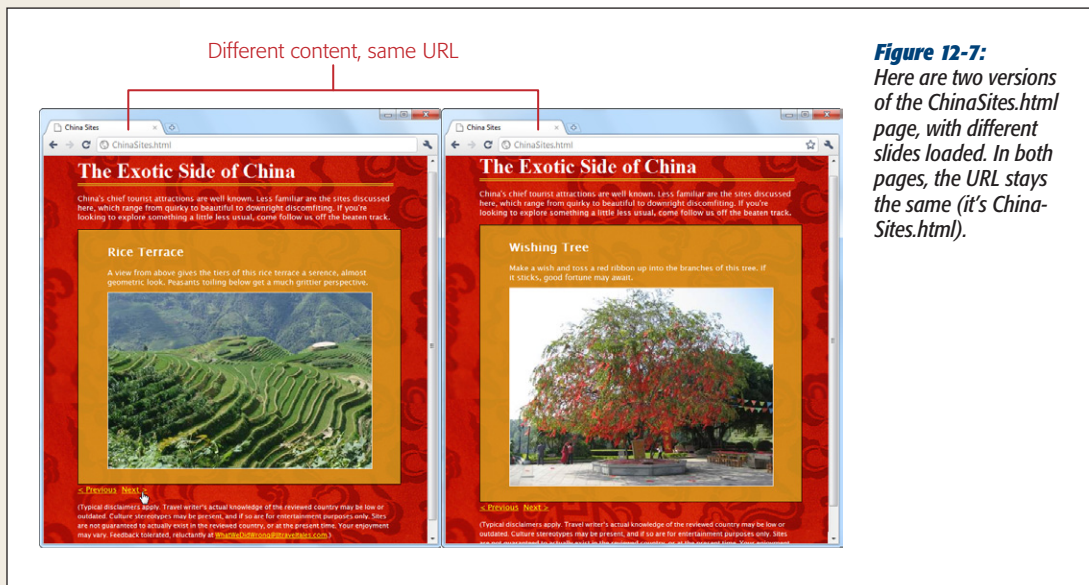

All this adds up to relatively little, unless you want to design your own custom Back and Forward buttons on a web page. But HTML5 adds a bit more functionality, which can be put to far more ambitious purposes. The centerpiece is the pushState() method, which lets you change the URL in the browser window without triggering a page refresh. This comes in handy in a specific scenario—namely, when you're building dynamic pages that quietly load new content and seamlessly update themselves. In this situation, the page's URL and the page's content can become out of sync. For example, if a page loads content from another page, the first page's URL stays in the browser's address box, which can cause all sorts of bookmarking confusion. Session history gives you a way to patch this hole.

If you're having a bit of trouble visualizing this scenario, hold on. In the next section, you'll see a page that's a perfect candidate for session history.

The URL Problem

In the previous chapter, you considered a page about Chinese tourism that had a built-in slideshow (page 330). Using the Previous and Next buttons on this page, the viewer could load different slides. But the best part about this example is that each slide was loaded quietly and unobtrusively and without reloading the page, thanks to the trusty XMLHttpRequest object.

Pages that include dynamic content and use this sort of design have a well-known limitation. Even though the page changes when it loads in new content, the URL stays the same in the browser's address bar (Figure 12-7).

To understand the problem, imagine that Joe reads the article shown in Figure 12-7, looks at the different sights, and is excited by the wishing tree in the fifth slide. Joe bookmarks the page, sends the URL to his friend Claire via email, and promotes it to the whole world with a Twitter message (“Throwing paper into a tree beats dropping coins in a fountain. Check it out at <http://...>”). The problem is that when Joe returns to his bookmark, or when Claire clicks the link in the email, or when any of Joe’s followers visit the link in the tweet, they all end up at the first slide. They may not have the patience to click through to the fifth slide, or they may not even know where it is. And this problem grows worse if there are more than just five slides—for example, a Flickr photo stream could have dozens or hundreds of pictures.

The Traditional Solution: Hashbang URLs

To deal with this problem, some web pages tack extra information onto the end of the URL. One of the most common (and controversial) strategies is the hashbang technique, which sticks on the characters `#!` followed by some text of your choosing. Here’s an example:

```
http://jjtraveltales.com/ChinaSites.html#!/Slide5
```

The reason the hashbang approach works is because browsers treat everything after the `#` character as the *fragment* portion of a URL. So in the example shown here, the web browser knows that you’re still referring to the same `ChinaSites.html` page, just with an extra fragment added to the end.

On the other hand, consider what happens if your JavaScript code changes the URL without using the `#` character:

```
http://jjtraveltales.com/ChinaSites.html/Slide5
```

Now the web browser will immediately send this request to the web server and attempt to download a new page. This isn’t what you want.

So how would you implement the hashbang technique? First, you need to change the URL that appears in the browser whenever your page loads a new slide. (You can do this by setting the `location.href` property in your JavaScript code.) Second, you need to check the URL when the page first loads, retrieve the fragment, and fetch the corresponding bit of dynamic content from the web server. All of this adds up to a fair bit of juggling, but you can use a JavaScript library like `PathJS` (<https://github.com/mtrpcic/pathjs>) to make life much easier.

The hashbang approach is widely used but deeply controversial. Web designers have started to back away from it for a number of reasons:

- **Complex URLs.** Facebook is a good example of the problem. In the past, it wouldn’t take much browsing before the browser’s URL would be polluted with extra information, as in `http://www.facebook.com/profile.php?id=1586010043#!/pages/Haskell/401573824771`. Now designers use session history, if the browser supports it.

- **Inflexibility.** Hashbang pages store a lot of information in the URL. If you change the way a hashbanged page works, or the way it stores information, old URLs could stop working, which is a major website fail.
- **Search engine optimization.** Search engines may treat different hashbanged URLs as essentially the same page. In the `ChinaSites.html` page, that means you won't get a separately indexed page for each tourist site—in fact, search engines might ignore this information altogether. This means that if someone searches for “china wishing tree,” the `ChinaSites.html` page won't turn up as a match. Google made its own attempt to solve the problem with a special hashbang syntax (<http://code.google.com/web/ajaxcrawling/docs/getting-started.html>) but web developers have unanimously criticized it for confusing everyone.
- **Cool URLs matter.** Cool URLs are web page addresses that are short, clear, and—most importantly—never change. Tim Berners-Lee, the creator of the Web, explains the philosophy at www.w3.org/Provider/Style/URI.html. And no matter how strongly you feel about keeping good web content alive, hashbang URLs are difficult to maintain and unlikely to survive the next stage in web evolution.

Although webmasters differ over how much they tolerate the hashbang approach, most agree that it's a short stage of web development that eventually will be replaced by HTML5's session history feature.

The HTML5 Solution: Session History

HTML5's session history feature provides a different solution to the URL problem. It gives you a way to change the URL to whatever you want, without needing to stick in funny characters like the hashbang. For example, when the `ChinaSites.html` page loads the fifth slide, you could change the URL to look like this:

```
http://jjtraveltales.com/ChinaSites4.html
```

When you do this, the browser won't actually attempt to request a page named `ChinaSites4.html`. Instead, it keeps the current page, with the newly loaded slide, which is exactly what you want. The same is true if the visitor goes back through the browser history. For example, if a visitor moves to the next slide (and the URL changes to `ChinaSites5.html`) and then clicks the Back button (returning the URL to `ChinaSites4.html`), the browser sticks with the current page and raises an event that gives you the chance to load the matching slide and restore the right version of the page.

So far, this sounds like a perfect solution. However, there's a significant drawback. If you want this system to work the way it's intended, you actually need to create a page for every URL you use. In this example, that means you need to create `ChinaSites1.html`, `ChinaSites2.html`, `ChinaSites3.html`, and so on. That's because surfers might go directly to those pages—for example, when returning through a bookmark, typing the link in by hand, clicking it in an email message, and so on. For big web outfits

(like Facebook or Flickr), this is no big deal, because they can use a scrap of server-side code to serve up the same slide content in a different package. But if you're a small-scale web developer, it might be a bit more work. For some options on how to handle the challenge, see the box on page 378.

Now that you understand how session history fits into your pages (the hard part), actually using it is easy. In fact, session history consists of just two methods and a single event, all of which are added to the history object.

The most important of these is the `pushState()` method, which lets you change the web page portion of the URL to whatever you want. For security reasons, you can't change the rest of the URL. (If you could, hackers would have a powerful tool for faking other people's websites—including, say, the Gmail sign on a bank transaction form.)

Here's an example that changes the web page part of the URL to `ChinaSites4.html`:

```
history.pushState(null, null, "ChinaSites4.html");
```

The `pushState()` method accepts three arguments. The third one is the only essential detail—it's the URL that appears in the browser's address bar.

The first argument is any piece of data you want to store to represent the current state of this page. As you'll see, you can use this data to restore the page state if the user returns to this URL through the browser's History list. The second argument is the page title you want the browser to show. All browsers are currently unified in ignoring this detail. If you don't want to set either the state or the title, just supply a *null* value, as shown above.

Here's the code you'd add to the `ChinaSites.html` page to change the URL to match the currently displayed slide. You'll notice that the current slide number is used for the page state. That detail will become important in a moment, when you consider the `onPopState` event:

```
function nextSlide() {
  if (slideNumber == 5) {
    slideNumber = 1;
  } else {
    slideNumber += 1;
  }

  history.pushState(slideNumber, null, "ChinaSites" + slideNumber + ".html");
  goToNewSlide();
  return false;
}

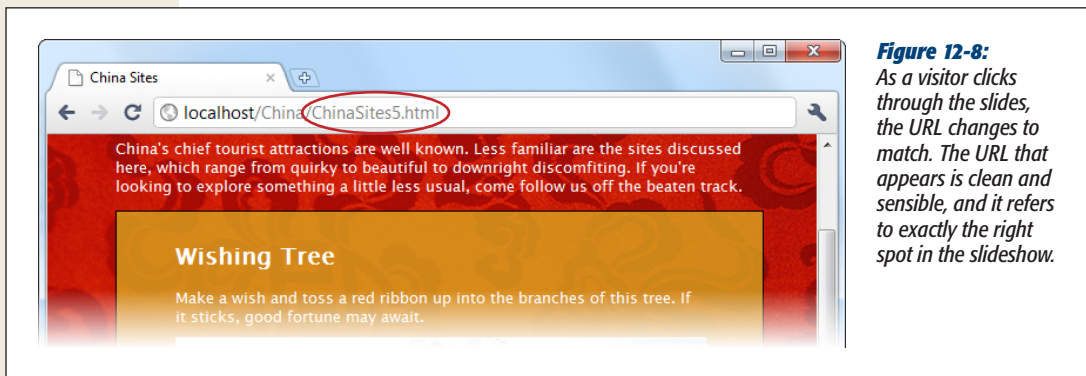

function previousSlide() {
  if (slideNumber == 1) {
    slideNumber = 5;
  } else {
    slideNumber -= 1;
  }
}
```

```

    history.pushState(slideNumber, null, "ChinaSites" + slideNumber + ".html");
    goToNewSlide();
    return false;
}

```

Figure 12-8 shows the result.

If you use the `pushState()` method, you'll also need to think about the `onPopState` event, which is its natural counterpart. While the `pushState()` method puts a new entry into the browser's History list, the `onPopState` event gives you the chance to deal with it when the user returns.

To understand how it works, consider what happens if a visitor works through all the slides. As she clicks through, the URL in the address bar changes from `ChinaSites.html` to `ChinaSites1.html`, then `ChinaSites2.html`, `ChinaSites3.html`, and so on. Even though the page hasn't actually changed, all of these URLs are added to the browser's history. If the user clicks back to get to a previous slide (for example, moving from `ChinaSites3.html` to `ChinaSites2.html`), the `onPopState` event is triggered. It provides your code with the state information you stored earlier, with `pushState()`. Your job is to use that to restore the page to its proper version. In the current example, that means loading the corresponding slide:

```

window.onpopstate = function(e) {
    if (e.state != null) {
        // What's the slide number for this state?
        // (You could also snip it out of the URL, using the location.href
        // property, but that's more work.)
        slideNumber = e.state;

        // Request this slide from the web server.
        goToNewSlide();
    }
};

```

You'll notice that this example checks to see if there is any state object before it does its work. That's because some browsers (including Chrome) fire the `onPopState` event the first time a page is loaded, even if you haven't yet called `pushState()`.

Note: There's one more new history method, but it's used a lot less frequently—`replaceState()`. You can use `replaceState()` to change the state information that's associated with the current page, without adding anything to the History list.

Browser Compatibility for Session History

Session history is a relatively new feature, although you'll find it in the latest versions of all desktop browsers except Internet Explorer (see Table 12-3).

Table 12-3. Browser support for session history

	IE	Firefox	Chrome	Safari	Opera	Safari iOS	Android
Minimum version	-	4	8	5	11.5	4.2	-

There are several ways you can handle a browser that doesn't support session history. If you do nothing at all, the fancy URLs just won't appear. This is what you get if you load the previous example in Internet Explorer—no matter what slide you load up, the URL stays fixed at `ChinaSites.html`. Flickr also uses this approach with its photo streams (to see an example, view <http://tinyurl.com/6hnvanw> with Internet Explorer).

Another choice is to trigger a full page refresh when the user loads new content on a browser that doesn't support session history. This makes sense if providing a good, meaningful URL is more important than providing the slick experience of dynamically loaded content. For example, the code hosting website <http://github.com> uses this strategy to keep the URL up to date when you browse through the folders of a project. But use a browser that supports session history, and you'll not only get dynamically loaded content, but you'll also see a neat slide-in effect, which is described at <http://github.com/blog/760-the-tree-slider>.

The most complex option is to use session history where possible, but fall back to the hashbang syntax. (Facebook uses this method.) The drawback is that you'll need to juggle two different approaches in the same page. You can also use a JavaScript patch that tries to paper over the difference—it's available at <http://github.com/balupton/history.js>.

Creating Extra Pages to Satisfy Your URLs

Session history follows the original philosophy of the Web: Every piece of content should be identified with a unique, durable URL. Unfortunately, this means you'll need to make sure that these URLs lead visitors back to the content they want, which is a much stickier affair. For example, when someone types in a request for `ChinaSites3.html`, you need to grab the main content from `ChinaSites.html` and the slide content from `ChinaSites3_slide.html` and somehow stick it together.

If you're a hard-core web programmer, you can write code that runs on the web server, intercepts web request, and carries out this assembly process on the fly. But if you don't have serious codemaster skills, you'll need to use a different approach.

The simplest option is to make a separate file for each URL—in other words, actually create the files `ChinaSites1.html`, `ChinaSites2.html`, `ChinaSites3.html`, and so on. Of course, you don't want to duplicate the slide content in more than one place (for example, in both the `ChinaSites3.html` and `ChinaSites3_slide.html`), because that would create a maintenance nightmare. Fortunately, there are two simple approaches that can simplify your life:

- **Use server-side includes.** If your web server supports this technique (and most do), you can use a special coded instruction like the following:

```
<!--#include file="footer.html" -->
```

Although it looks like a comment, this tells the web server to open the file and insert its contents at that position in the markup. Using this technique, you can insert the main content and the slide content into each slide-specific page. In fact, each slide-specific web page file (`ChinaSites1.html`, `ChinaSites2.html`, and so on) will need just a few lines of markup to create a basic shell of a page.

- **Use templates in a web design tool.** Both Adobe Dreamweaver and Microsoft Expression Web allow you to create web templates that can be copied, with exact detail, to as many pages as you want. So if you create a template that has the main content and style details, you can reuse it to create all the slide-specific pages you need, quickly and easily.

Part Four: Appendixes

Appendix A: A Very Short Introduction to CSS

Appendix B: A Very Short Introduction to JavaScript

A Very Short Introduction to CSS

It's no exaggeration to say that modern web design wouldn't be possible without CSS, the Cascading Style Sheet standard. CSS allows even the most richly formatted, graphically complex web pages to outsource the formatting work to a separate document—a *style sheet*. This keeps the web page markup clean, clear, and readable.

To get the most out of HTML5 (and this book), you need to be familiar with the CSS standard. If you're a CSS pro, don't worry about this appendix—carry on with the material in the rest of the book, and pay special attention to Chapter 8, which introduces the new style features that are being added to CSS3. But if your CSS skills are a bit rusty, this appendix will help to refresh your memory before you go any further.

Note: This appendix gives a very quick (and not comprehensive) rundown of CSS. If you're still overwhelmed, consult a book that deals with CSS in more detail, like *CSS: The Missing Manual*.

Adding Styles to a Web Page

There are three ways to use styles in a web page.

The first approach is to embed style information directly into an element using the *style* attribute. Here's an example that changes the color of a heading:

```
<h1 style="color: green">Inline Styles are Sloppy Styles</h1>
```

This is convenient, but it clutters the markup terribly.

The second approach is to embed an entire style sheet in a `<style>` element, which you must place in the `<head>` section of your page:

```
<head>
  <title>Embedded Style Sheet Test</title>
  <style>
    ...
  </style>
</head>
```

This code separates the formatting from your web page markup but still keeps everything together in one file. This approach makes sense for one-off formatting tasks (when you don't want to reuse your formatting choices in another page), and it's a good choice for simple tests and examples, like the ones that are included with this book. However, it's not so great for a real-world, professional website, because it leads to long, bloated pages.

The third approach is to link to a separate style sheet file by adding a `<link>` element to the `<head>` section. Here's an example that tells a web browser to apply the styles from the style sheet named `SampleStyles.css`:

```
<head>
  <title>External Style Sheet Test</title>
  <link rel="stylesheet" href="SampleStyles.css">
</head>
```

This approach is the most common, and the most powerful. It also gives you the flexibility to reuse your styles in other pages. If you want, you can further divide your styles into multiple style sheets, and link to as many as you need in any HTML page.

Note: A simple philosophy underpins modern web development. HTML markup is for structuring a page into logical sections (for example, paragraphs, headings, lists, images, and links), while a CSS style sheet is for formatting it (by specifying fonts, colors, borders, backgrounds, and layout). Follow this rule, and your web pages will be easy to edit. You'll also be able to change the formatting and layout of your entire website simply by modifying its linked style sheet. (To see a truly impressive example of style sheet magic, check out www.csszengarden.com, where one website is given more than 200 different faces, simply by swapping in different style sheets.)

The Anatomy of a Style Sheet

A style sheet is a text file, which you'll usually place on a web server alongside your HTML pages. It contains one or more *rules*. The order of the rules doesn't matter.

Each rule applies one or more formatting details to one or more HTML elements. Here's the structure of a simple rule:

```
selector {  
  property: value;  
  property: value;  
}
```

And here's what each part means:

- The **selector** identifies the type of content you want to format. A browser hunts down all the elements in the web page that match your selector. There are many different ways to write a selector, but one of the simplest approaches (shown next) is to identify the elements you want to format by their element name. For example, you could write a selector that picks out all the level-one headings in your page.
- The **property** identifies the type of formatting you want to apply. Here's where you choose whether you want to change colors, fonts, alignment, or something else. You can have as many property settings as you want in a rule—this example has two.
- The **value** sets a value for the property. For example, if your property is color, the value could be light blue or a queasy green.

Now here's a real rule that does something:

```
h1 {  
  text-align: center;  
  color: green;  
}
```

Pop this text into a style sheet and save it (for example, as `SampleStyles.css`). Then, take a sample web page (one that has at least one `<h1>` heading), and add a `<link>` element that refers to this style sheet. Finally, open this page in a browser. You'll see that the `<h1>` headings don't have their normal formatting—instead, they will be centered and green.

CSS Properties

The previous example introduces two formatting properties: *text-align* (which sets how text is positioned, horizontally) and *color* (which sets the text color).

There are many, many more formatting properties for you to play with. Table A-1 lists some of the most commonly used. In fact, this table lists almost all the style properties you'll encounter in the examples in this book (not including the new CSS3 properties that are described in Chapter 8).

Table A-1. Commonly used style sheet properties, by category

	Properties
Colors	color
	background-color
Spacing	margin
	padding
	margin-left, margin-right, margin-top, margin-bottom
	padding-left, padding-right, padding-top, padding-bottom
Borders	border-width
	border-style
	border-color
	border (to set the width, style, and color in one step)
Text alignment	text-align
	text-indent
	word-spacing
	letter-spacing
	line-height
	white-space
Fonts	font-family
	font-size
	font-weight
	font-style
	font-variant
	text-decoration
	@font-face (for using fancy fonts; see page 244)
Size	width
	height
Layout	position
	left, right
	float, clear
Graphics	background-image
	background-repeat
	background-position

Tip: If you don't have a style sheet book on hand, you can get an at-a-glance overview of all the properties listed here (and more) at www.htmldog.com/reference/cssproperties. You can also get more information about each property, including a brief description of what it does and the values it allows.

Formatting the Right Elements with Classes

The previous style sheet rule formatted all the `<h1>` headings in a document. But in more complex documents, you need to pick out specific elements, and give them distinct formatting.

To do this, you need to give these elements a name with the *class* attribute. Here's an example:

```
<h1 class="ArticleTitle">HTML5 is Winning</h1>
```

Now you can write a style sheet rule that formats only this heading. The trick is to write a selector that starts with a period, followed by the class name, like this:

```
.ArticleTitle {  
    font-family: Garamond, serif;  
    font-size: 40px;  
}
```

Now, the `<h1>` that represents the article title is sized up to be 40 pixels tall.

You can use the class attribute on as many elements as you want. In fact, that's the idea. A typical style sheet is filled with class rules, which take web page markup and neatly carve it into stylable units.

Finally, it's worth noting that you can create a selector that uses an element type and a class name, like this:

```
h1.ArticleTitle {  
    font-size: 40px;  
}
```

This selector creates an `ArticleTitle` class that will work only for `<h1>` elements. Sometimes, you may write this sort of style rule just to be clear. For example, you may want to make it obvious that the `ArticleTitle` applies only to `<h1>` headings, and shouldn't be used anywhere else. But most of the time, web designers just create straight classes with no element restrictions.

Note: Different selectors can overlap. If more than one selector applies to the same element, they will both take effect, with the most general being applied first. For example, if you have a rule that applies to all headings and a rule that applies to the class named `ArticleTitle`, the all-headings rule is applied first, followed by the class rule. As a result, the class rule can override the properties that are set in the all-headings rule. If two rules are equally specific, the one that's defined last in the style sheet wins.

Style Sheet Comments

In a complicated style sheet, it's sometimes worth leaving little notes to remind yourself (or let other people know) why a style sheet rule exists, and what it's designed to do. Like HTML, CSS lets you add comments, which the web browser ignores. However, CSS comments don't look like HTML comments. They always start with the characters `/*` and end with the characters `*/`. Here's an example of a somewhat pointless comment:

```
/* The heading of the main article on a page. */
.ArticleTitle {
    font-size: 40px;
}
```

Slightly More Advanced Style Sheets

You'll see an example of a practical style sheet in a moment. But first, you need to consider a few of the finer points of style-sheet writing.

Structuring a Page with <div> Elements

When working with style sheets, you'll often use the <div> element to wrap up a section of content:

```
<div>
  <p>Here are two paragraphs of content.</p>
  <p>In a div container.</p>
</div>
```

On its own, the <div> does nothing. But it gives you a convenient place to apply some class-based style sheet formatting. Here are some examples:

- **Inherited values.** Some CSS properties are *inherited*, which means the value you set in one element is automatically applied to all the elements inside. One example is the set of font properties—set them on a <div>, and everything inside gets the same text formatting (unless you override it in places with more specific formatting rules).
- **Boxes.** A <div> is a natural container. Add a border, some spacing, and a different background color (or image), and you have a way to make select content stand out.
- **Columns.** Professional websites often carve their content up into two or three columns. One way to make this happen is to wrap the content for each column in a <div>, and then use CSS positioning properties to put them in their proper places.

Tip: Now that HTML5 has introduced the semantic elements, the <div> element doesn't play quite as central a role. If you can replace a <div> with another, more meaningful semantic element (like <header> or <figure>), you should do that. But when nothing else fits, the <div> remains the go-to tool. Chapter 2 has a detailed description of all the new semantic elements.

The <div> element also has a smaller brother named . Like the <div> element, the element has no built-in formatting. The difference is that <div> is a block element, designed to wrap separate paragraphs or entire sections of content, while is an inline element that's meant to wrap smaller portions of content inside a block element. For example, you can use to apply custom formatting to a few words inside a paragraph.

Note: CSS encourages good design. How? If you want to use CSS effectively, you need to properly plan the structure of your web page. Thus, the need for CSS encourages even casual web-page writers to think seriously about how their content is organized.

Multiple Selectors

Sometimes, you might want to define some formatting that applies to more than one element or more than one class. The trick is to separate each selector with a comma.

For example, consider these two heading levels, which have different sizes but share the same title font:

```
h1 {
  font-family: Impact, Charcoal, sans-serif;
  font-size: 40px;
}

h2 {
  font-family: Impact, Charcoal, sans-serif;
  font-size: 20px;
}
```

You could pull the *font-family* setting into a separate rule that applies to both heading levels, like this:

```
h1, h2 {
  font-family: Impact, Charcoal, sans-serif;
}

h1 {
  font-size: 40px;
}

h2 {
  font-size: 20px;
}
```

It's important to understand that this isn't necessarily a better design. Often, it's better to duplicate settings because that gives you the most flexibility to change formatting later on. If you have too many shared properties, it's more awkward to modify one element type or class without affecting another.

Contextual Selectors

A contextual selector matches an element *inside* another element. Here's an example:

```
.Content h2 {
  color: #24486C;
  font-size: medium;
}
```

This selector looks for an element that uses the Content class. Then, it looks for `<h2>` elements inside that element, and formats them with a different text color and font size. Here's an example of an element it will format:

```
<div class="Content">
  ...
  <h2>Mayan Doomsday</h2>
  ...
</div>
```

In the first example, the first selector is a class selector, and the second selector (the contextual one), is an element type selector. However, you can change this up any way you want. Here's an example:

```
.Content .LeadIn {
  font-variant: small-caps;
}
```

This selector looks for an element in the LeadIn class, wrapped inside an element in the Content class. It matches this element:

```
<div class="Content">
  <p><span class="LeadIn">Right now</span>, you're probably feeling pretty
  good.
  After all, life in the developed world is comfortable ...</p>
  ...
</div>
```

Once you get the hang of contextual selectors, you'll find that they're quite straightforward, and ridiculously useful.

id Selectors

Class selectors have a closely related cousin called id selectors. Like a class selector, the id selector lets you format just the elements you chose. And like a class selector, the id selector lets you pick a descriptive name. But instead of using a period, you use a number-sign character (#), as shown here:

```
#Menu {
  border-width: 2px;
  border-style: solid;
}
```

As with class rules, browsers don't apply id rules unless you specifically tell them to in your HTML. However, instead of switching on the rules with a *class* attribute, you do so with the *id* attribute. For example, here's a `<div>` element that uses the Menu style:

```
<div id="Menu">...</div>
```

At this point, you're probably wondering why you would use an id selector—after all, the id selector seems almost exactly the same as a class selector. But there's one difference: You can assign a given id to just *one* element in a page. In the current example, that means only one `<div>` can be labeled with the Menu id. This restriction doesn't apply to class names, which you can reuse as many times as you like.

That means the id selector is a good choice if you want to format a single, never-repeated element on your page. The advantage is that the id selector clearly indicates the special importance of that element. For example, if a page has an id selector named Menu or NavigationBar id selector, the web designer knows there's only one menu or navigation bar on that page. Of course, you never *need* to use an id selector. Some web designers use class selectors for everything, whether the section is unique or not. It's really just a matter of personal preference.

Note: The id attribute also plays an important role in JavaScript, allowing web page designers to identify a specific element so it can be manipulated in code. The examples in this book use id rules whenever an element already has an id for JavaScript. (This avoids defining setting both the id attribute and the class attribute.) In every other case, the examples use class rules, regardless of whether the element is unique or not.

Pseudoclass Selectors

So far, the selectors you've seen have been straightforward. They've taken a single, obvious piece of information into consideration, like the element type, class name, or id name. Pseudoclasses are a bit more sophisticated. They take extra information into account—information that might not be set in the markup or might be based on user actions.

For most of CSS history, browsers have supported just a few pseudoclasses, which were mostly designed for formatting links. The `:link` pseudoclass formats any link that points to a new, unvisited location. The `:visited` pseudoclass applies to any link that points to a location the reader has already visited. The `:hover` pseudoclass formats a link when a visitor moves the mouse over it, and the `:active` pseudoclass formats a link as a reader clicks it, before releasing the mouse button. As you can see, pseudoclasses always start with a colon (:).

Here's a style rule that uses pseudoclasses to create a misleading page—one where visited links are blue and unvisited links are red:

```
a:link {
    color: red;
}
a:visited {
    color: blue;
}
```

You can also use pseudoclasses with a class name:

```
.BackwardLink:link {
    color: red;
}
.BackwardLink:visited {
    color: blue;
}
```

Now an anchor element needs to specify the class name to display your new style, as shown here:

```
<a class="BackwardLink" href="...">...</a>
```

Pseudoclasses aren't just a way to format links. The *:hover* pseudoclass is useful for applying animated effects and creating fancy buttons. It's used with CSS3 transitions in Chapter 8 (page 271).

Note: CSS3 also introduces some more advanced pseudoclasses that take other details into consideration, like the position of an element relative to other elements or the state of an input control in a web form. These pseudoclasses aren't described in this book, but you can learn about them from a Smashing Magazine article at <http://tinyurl.com/3p28wau>.

Attribute Selectors

Attribute selection is a new feature offered by CSS3 that lets you format a specific type of element that also has a specific value set for one of its attributes. For example, consider the following style rule, which applies only to text boxes:

```
input[type="text"] {  
    background-color:silver;  
}
```

First, this selector grabs all the `<input>` elements. Then, it filters down its selection to include just those `<input>` elements that have a `type` attribute set to "text," which it then formats. In the following markup, that means the first `<input>` element gets the silver background, but the second doesn't:

```
<label for="name">Name:</label><input id="name" type="text"><br>  
<input type="submit" value="OK">
```

Technically, you don't need to include the `type="text"` attribute in the first `<input>` element, because that's the default value. If you leave it out, the attribute selector still works, because it pays attention to the current *value* of the attribute, and doesn't care how that value is defined in your markup.

Similarly, you could create a rule that formats the caption for this text box but ignores all other labels:

```
label[for="name"] {  
    width: 200px;  
}
```

Note: You can still get a bit fancier with attribute selectors. For example, you can match a combination of attribute values, or match part of an attribute value. These techniques are awfully clever but inject too much complexity into the average style sheet. To get the lowdown, see the CSS3 standard for selectors at www.w3.org/TR/css3-selectors/#selectors.

A Style Sheet Tour

Chapter 2 shows how you can learn to use HTML5's new semantic elements by revising a straightforward, but nicely formatted page called `ApocalypsePage_Original.html` (Figure A-1). This page links to a style sheet named `ApocalypsePage_Original.css`:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <title>Apocalypse Now</title>
  <link rel="stylesheet" href="ApocalypsePage_Original.css">
</head>
...
```

The style sheet is straightforward and relatively brief, weighing in somewhere over 50 lines. In this section, you'll dissect each one of its style rules.

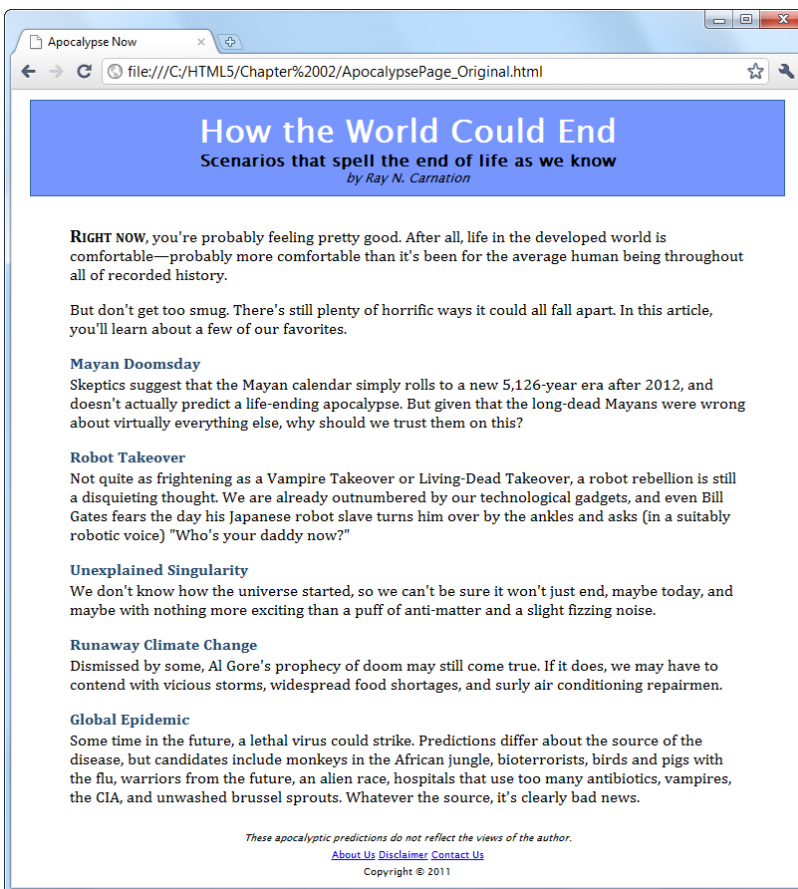

Figure A-1:
The styles in this page are simple, but they follow the basic organizational principles that you'll see put into practice throughout this book.

First, the style sheet begins with a selector that targets the `<body>` element, which is the root of the entire web page. This is the best place to set inherited values that you want to apply, by default, to the rest of the document. Examples include margins, padding, background color, the font, and the width:

```
body {
    font-family: "Lucida Sans Unicode", "Lucida Grande", Geneva, sans-serif;
    max-width: 800px;
}
```

When setting the *font-family* property in CSS, you should follow two rules. First, use a web-safe font—one of the small number of fonts that are known to work on virtually all web-connected computers (see www.fonttester.com/help/list_of_web_safe_fonts.html for the basics, or www.speaking-in-styles.com/web-typography/Web-Safe-Fonts for more exotic, riskier choices). Second, use a font list that starts with the specific variant you want, followed by other possible fallbacks, and ends with *serif* or *sans-serif* (two font instructions that all browsers understand). If you prefer to use a fancy font that the user must download from your web server, check out the CSS3 font embedding feature on page 244.

The body rule also sets a maximum width, capping it at 800 pixels. This rule prevents overly long, unreadable lines when the browser window is made very wide. There are other possible techniques for handling this situation, including splitting the text into columns (page 253), using CSS media queries (page 256), or creating extra columns to soak up the additional space. However, although setting a fixed 800-pixel width isn't the most glamorous solution, it is a common approach.

Next in the style sheet is a class-specific rule that formats the header region at the top of the page:

```
.Header {
    background-color: #7695FE;
    border: thin #336699 solid;
    padding: 10px;
    margin: 10px;
    text-align: center;
}
```

Note: In the original example (used here), the header is simply a `<div>` with the class name `Header`. However, Chapter 2 explains how you might consider replacing that with HTML5's new `<header>` element.

There's a lot of information packed into this rule. The *background-color* property can be set, like all CSS colors, using a color name (which provides relatively few choices), an HTML color code (as done here), or the `rgb()` function (which specifies the red, green, and blue components of the color). The examples in this book use all three approaches, with color names in simple examples and color codes and the `rgb()` function in more realistic examples.

Incidentally, every HTML color code can be written with the `rgb()` function, and vice versa. For example, you can write the color in the above example using the `rgb()` function, like this:

```
background-color: rgb(118,149,254);
```

Tip: To actually get the RGB values for the color you want, try an online color picker, or look the numbers up in your favorite drawing or graphics program.

The header rule also draws a thin border around its edges. It uses the all-in-one *border* property to specify the border thickness, border color, and border style (for example, solid, dashed, dotted, double, groove, ridge, inset, or outset) in one property setting.

With the background color and border details out of the way, the header rule sets 10 pixels of padding (between the content inside and the border) and 10 pixels of margin space (between the border and the surrounding web page). Finally, the text inside the header is centered.

The following three rules use contextual selectors to control how elements are formatted inside the header. The first one formats `<h1>` elements in the header:

```
.Header h1 {
  margin: 0px;
  color: white;
  font-size: xx-large;
}
```

Tip: When setting a font size, you can use keywords (like the *xx-large* value used here). Or if you want precise control, you can supply an exact measurement using pixels or em units.

The next two rules format classes are named `.Teaser` and `.Byline`:

```
.Header .Teaser {
  margin: 0px;
  font-weight: bold;
}

.Header .Byline {
  font-style: italic;
  font-size: small;
  margin: 0px;
}
```

This code works because the header contains two `` elements. One `` has the class name `Teaser`, and contains the subtitle. The second `` has the author information, and uses the class name `Byline`:

```
<div class="Header">
  <h1>How the World Could End</h1>
  <p class="Teaser">Scenarios that spell the end of life as we know</p>
  <p class="Byline">by Ray N. Carnation</p>
</div>
```

Next up is a rule that formats a `<div>` with the class name `Content`. It holds the main body of the page. The accompanying style sheet rule sets the font, padding, and line height:

```
.Content {
  font-size: medium;
  font-family: Cambria, Cochin, Georgia, "Times New Roman", Times, serif;
  padding-top: 20px;
  padding-right: 50px;
  padding-bottom: 5px;
  padding-left: 50px;
  line-height: 120%;
}
```

Whereas the header rule set the padding to be the same on all sides, the content rule sets different padding on each side, adding more space above and the most space on the sides. One way to do that is to specify the expanded padding properties (like *padding-top*, *padding-right*, and so on), as done here. Another option is to use the *padding* property with a series of values—the trick being that you need to remember the right order. (It's top, right, bottom, left.) Here's how you can replace the expanded padding properties with just one property:

```
padding: 20px 50px 5px 50px;
```

Generally, you'll use this form when setting the padding on all sides, but you'll use the expanded padding properties if you just want to change the padding on some sides. Of course, it's really a matter of taste.

The final *line-height* property sets the space between adjacent lines. The value of 120 percent gives some extra spacing, for a more readable feel.

Following the content rule are three contextual selectors that format elements inside. The first rule formats a span with the class name `LeadIn`. It's used to put the first two words in large, bold, small-cap lettering:

```
.Content .LeadIn {
  font-weight: bold;
  font-size: large;
  font-variant: small-caps;
}
```

The next two rules change how the `<h2>` and `<p>` elements are formatted in the content region:

```
.Content h2 {
  color: #24486C;
  margin-bottom: 2px;
  font-size: medium;
}

.Content p {
  margin-top: 0px;
}
```

As you can see, as a style sheet grows longer it doesn't necessarily become more complex. Here, the style sheet simply repeats the same basic techniques (class selectors and contextual selectors), but uses them to format other parts of the document.

Finally, the style sheet ends with the rules that format the footer portion. By now, you can interpret these on your own:

```
.Footer {  
    text-align: center;  
    font-size: x-small;  
}  
  
.Footer .Disclaimer {  
    font-style: italic;  
}  
  
.Footer p {  
    margin: 3px;  
}
```

This rounds out the `ApocalypsePage_Original.css` style sheet. Feel free to download it from the try-out site (www.prostech.com/html5) and try tweaking it to see what happens. Or, check out Chapter 2, which revises this page and the accompanying style sheet to use the HTML5 semantic elements.

A Very Short Introduction to JavaScript

There was a time when the Web was all about markup. Pages held text and HTML tags, and not much more. Really advanced websites used server scripts that could tweak the HTML markup before it made its way to the browser, but the code stopped there.

Crack open a web page today and you're likely to find buckets of JavaScript code, powering everything from vital features to minor frills. Self-completing text boxes, pop-up menus, picture slideshows, and webmail are just a few examples of the many ways crafty developers put JavaScript to work. In fact, it's nearly impossible to imagine a Web *without* JavaScript. While HTML is still the language of the Web, JavaScript is now the brains behind its most advanced pages.

In this appendix, you'll get a heavily condensed JavaScript crash course. This appendix won't provide a complete tutorial on JavaScript, nor does it have enough information to help you get started if you've never written a line of code in any programming language, ever. But if you have some rudimentary programming knowledge—say, you once learned a lick of Visual Basic, picked up the basics of Pascal, or took C out for spin—this appendix will help you transfer your skills to the JavaScript world. You'll get just enough information to identify familiar programming ingredients like variables, loops, and conditional logic. And you'll cover all the basic language elements that are used in the JavaScript-based examples in the rest of this book.

Tip: If you need more help to get started with JavaScript, check out *JavaScript & jQuery: The Missing Manual*, which also introduces jQuery, a popular JavaScript-enhancing toolkit. Or, read Mozilla's detailed but dry JavaScript guide at <http://developer.mozilla.org/en/JavaScript/Guide>.

How a Web Page Uses JavaScript

Before you can run a line of JavaScript, you need to know where to put it in your web page. It all starts with the `<script>` element. The following sections show you how to take a page from quick-and-dirty JavaScript injection to a properly structured example that you can put online, without embarrassment.

Embedding Script in Your Markup

The simplest way to use the `<script>` element is to stick it somewhere in your HTML markup, like this:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>A Simple JavaScript Example</title>
</head>

<body>
  <p>At some point in the processing of this page, a script block
  will run and show a message box.</p>

  <script>
    alert("We interrupt this web page with a special JavaScript announcement.");
  </script>

  <p>If you get here, you've already seen it.</p>
</body>
</html>
```

This script block contains just one line of code, although you could just as easily pack it with a sequence of operations. In this case, the single line of code triggers JavaScript's built-in `alert()` function. The `alert()` function accepts a piece of text, and shows that text in a message box (see Figure B-1). To move on, the user must click the OK button.

Note: This example introduces a JavaScript convention that you'll see throughout this book, and on good websites everywhere: the semicolon. In JavaScript, semicolons indicate the end of each programming statement. Strictly speaking, semicolons aren't necessary (unless you want to cram multiple statements on a single line). However, they're considered good style.

If you want to run some JavaScript right away (as in this example), you'll probably put it at the end of the `<body>` section, just before the final `</body>` tag. That way, it runs only after the browser has processed all the page markup.

**Figure B-1:**

When the web browser comes across JavaScript code, it runs it immediately. In fact, it even halts the page processing, temporarily. In this case, the code is held up until the web page user closes the message box, by clicking OK. This allows the code to continue and the script block to end. The web browser then processes the rest of the markup.

GEM IN THE ROUGH

Dealing with Internet Explorer's Paranoia

If you run the alert example above in Firefox or Chrome, you'll find that everything works seamlessly. If you run it in Internet Explorer, you won't get the same satisfaction. Instead, you'll see a security warning in a yellow bar at the top of the page (depending on the version of IE). Until you go to that bar and click Allow Blocked Content, your JavaScript code won't run.

At first glance, IE's security warning seems like a surefire way to scare off the bravest web visitor. But you don't need to worry; the message is just part of the quirky way Internet Explorer deals with web pages that you store on your hard drive. When you access the same page over the Web, Internet Explorer won't raise the slightest objection.

That said, the security warning is still an annoyance while you're testing your web page, because it forces you to keep

explicitly telling the browser to allow the page to run JavaScript. To avoid the security notice altogether, you can tell Internet Explorer to pretend you downloaded your page from a web server. You do this by adding a special comment called the *mark of the Web*. You place this comment in the <head> section of your page:

```
<head>
<meta charset="utf-8">
<!-- saved from url=(0014)about:internet -->
...
</head>
```

When IE sees the mark of the Web, it treats the page as though it came from a web server, skipping the security warning, and running your JavaScript code without hesitation. To all other browsers, the mark of the Web just looks like an ordinary HTML comment.

Using a Function

The problem with the previous example is that it encourages you to mingle code and markup in an unseemly mess. To keep things organized, you should wrap each code “task” in a *function*—a named unit of code that you can call into action whenever you need it.

When you create a function, you should give it a logical name. Here’s one named `showMessage`:

```
function showMessage() {
    // Code goes here ...
}
```

Right now, this function contains a single comment, but no code. (A JavaScript comment is a line that starts with two slash characters, which the browser ignores.)

To add some code, just put all the statements you need between the curly brackets:

```
function showMessage() {
    alert("We interrupt this web page with a special JavaScript announcement.");
}
```

Of course, this whole shebang needs to go in a `<script>` block. The best place to put JavaScript functions is in the `<head>` section of the page. This imposes some basic organization on your page, by moving the code out of the markup and into a separate section.

Here’s a revamped version of the earlier example, which now uses a function:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <title>A Simple JavaScript Example</title>
    <script>
        function showMessage() {
            alert("We interrupt this web page with a special JavaScript announcement.");
        }
    </script>
</head>
...
```

Functions, on their own, don’t do anything. To trigger a function, you need another piece of code that *calls* the function.

Calling a function is easy—in fact, you’ve already seen how to do it with the built-in `alert()` function. You simply write the function name, followed by a set of parentheses. Inside the parentheses, you put whatever data the function needs. Or, if the function doesn’t accept any data, like `showMessage()`, you simply include parentheses with nothing inside them:

```
...
<body>
    <p>At some point in the processing of this page, a script block
    will run and show a message box.</p>
    <script>
```

```

showMessage();
</script>
<p>If you get here, you've already seen it.</p>
</body>
</html>

```

Because this new-and-improved design now has two script blocks, it seems more complicated than before. But it's actually a dramatic step forward, for several reasons:

- **The bulk of the code is out of the markup.** You need just one line of code to call a function. However, a realistic function will contain a pile of code, and a realistic page will contain a pile of functions. You definitely want to separate all those details from your markup.
- **You can reuse your code.** Once code is in a function, you can call that function at different times, from different places in your code. This isn't obvious in this simple example, but it becomes an important factor in more complex applications, like the painting application in Chapter 6.
- **You're ready to use external script files.** Moving your code out of the markup is a precursor to moving it right out of the HTML file, as you'll see in the next section, for even better organization.
- **You can add events.** An event is a way for you to tell the page to run a specific function when a specific occurrence takes place. Web pages are event-driven, which means most code is fired up when an event happens (rather than being launched through a script block). Events need functions, and events let you trigger functions without using an extra script block, as you'll see on page 402.

Note: You can place as many `<script>` blocks in a web page as you want.

Moving the Code to a Script File

Pulling your JavaScript code together into a set of functions is the first step in good organization. The second step is to take that script code and put it in an entirely separate file. Do this with all your scripts, and you'll get smaller, simpler web pages—and the ability to reuse the same functions in different web pages. In fact, putting script code in an external file is analogous to putting CSS style rules in an external file. In both cases, you gain the ability to reuse your work and you leave simpler pages behind.

Note: Virtually every well-designed web page that uses JavaScript puts the code in one or more script files. The only exceptions are if you have a few lines of very simple code that you're certain not to use anywhere else, or if you're creating a one-off example.

Script files are always plain text files. Usually, they have the extension `.js` (for JavaScript). You put all your code inside a script file, but you don't include the `<script>` element. For example, here are the complete contents of a script file named `MessageScripts.js`:

```
function showMessage() {
    alert("We interrupt this web page with a special JavaScript announcement.");
}
```

Now save the file, and put it in the same folder as your web page. In your web page, define a script block, but don't supply any code. Instead, add the `src` attribute and indicate the script file you want to link to:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>A Simple JavaScript Example</title>
  <script src="MessageScripts.js"></script>
</head>

<body>
  <p>At some point in the processing of this page, a script block
  will run and show a message box.</p>
  <script>
  showMessage()
  </script>
  <p>If you get here, you've already seen it.</p>
</body>
</html>
```

When a browser comes across this script block, it requests the `MessageScripts.js` file and treats it as though the code were right inside the page. That means you can call the `showMessage()` function in exactly the same way you did before.

Note: Even though the script block doesn't actually contain any code when you use external script files, you must still include the closing `</script>` tag. If you leave that out, the browser assumes everything that follows—the rest of the page—is part of your JavaScript code.

You can also link to JavaScript functions on another website—just remember that the `src` attribute in the `<script>` element needs to point to a full URL (like `http://SuperScriptSite.com/MessageScript.js`) instead of just a file name. This technique is necessary for plugging into other companies' web services, like Google Maps (page 356).

Responding to Events

So far, you've seen how to run script right away—by weaving a script block into your HTML markup. But it's far more common to trigger code after the page is finished processing but when the user takes a specific action, like clicking a button or moving the mouse pointer over an element.

To do so, you need to use JavaScript *events*, which are notifications that an HTML element sends out when specific things happen. For example, JavaScript gives every element an event named `onMouseOver` (a compressed version of “on mouse over”). As the name suggests, this event takes place (or *fires*, to use programmer-speak) when a visitor moves his mouse pointer over an HTML element like a paragraph, link, image, table cell, or text box. That action triggers the `onMouseOver` event and your code flies into action.

This discussion brings up one key question: How do you link your code to the event you want to use? The trick is to add an event attribute to the appropriate element. So if you want to handle the `onMouseOver` event of an `` element, you need markup like this:

```

```

Note: In JavaScript, function, variable, and object names are case-sensitive, meaning `showMessage` is not the same as `showMESSAGE` (and the latter fails). However, the event attribute names are not case sensitive, because they are technically a part of HTML markup, and HTML tolerates any combination of uppercase and lowercase letters. It's common to write event attributes with no capitals (as shown here) because this matches the old rules of XHTML, and most programmers are too lazy to reach for the Shift key anyway.

Now, when the mouse moves over the image, and the `onMouseOver` event fires, the browser will automatically call the `showMessage()` function, which shows a rather unremarkable message box (Figure B-2). When an event triggers a function in this way, that function is called an *event handler*.

Figure B-2:
In this example, the alert box doesn't pop up until you move your mouse pointer over the link.

To use events effectively, you need to know which events JavaScript supports. In addition, you need to know which events work on which HTML elements. Table B-1 provides a list of commonly used events and the HTML elements that they apply to (and you can find a more complete reference at <http://developer.mozilla.org/en/DOM/element>).

Table B-1. Common HTML object events

Event name	Description	Applies to
onClick	Triggered when you click an element.	Virtually all elements
onMouseOver	Triggered when you move your mouse pointer over an element.	Virtually all elements
onMouseOut	Triggered when you move your mouse pointer away from an element.	Virtually all elements
onKeyDown	Triggered when you press a key.	<select>, <input>, <textarea>, <a>, <button>
onKeyUp	Triggered when you release a pressed key.	<select>, <input>, <textarea>, <a>, <button>
onFocus	Triggered when a control receives focus (in other words, when you position the cursor on the control so you can type something in). Controls include text boxes, checkboxes, and so on—see page 112 to learn more.	<select>, <input>, <textarea>, <a>, <button>
onBlur	Triggered when focus leaves a control.	<select>, <input>, <textarea>, <a>, <button>
onChange	Triggered when you change a value in an input control. In a text box, this event doesn't fire until you move to another control.	<select>, <input type="text">, <textarea>
onSelect	Triggered when you select a portion of text in an input control.	<input type="text">, <textarea>
onError	Triggered when your browser fails to download an image (usually due to an incorrect URL).	
onLoad	Triggered when your browser finishes downloading a new page or finishes loading an object, like an image.	, <body>
onUnload	Triggered when a browser unloads a page. (This typically happens after you enter a new URL or when you click a link. It fires just <i>before</i> the browser downloads the new page.)	<body>

A Few Language Essentials

A brief appendix isn't enough to cover any language, even one as straightforward as JavaScript. However, the following sections will fill you in on a few language essentials that you'll need to digest the examples elsewhere in this book.

Variables

Every programming language has the concept of *variables*—containers that you can use to store bits of information in memory. In JavaScript, every variable is created the same way, by declaring it with the *var* keyword followed by the variable name. This example creates a variable named *myMessage*:

```
var myMessage;
```

Note: JavaScript variables are case-sensitive, which means a variable named *myMessage* differs from one named *MyMessage*. If you try to use them interchangeably, you'll wind up with an error message (if your browser is nice) or a bizarre mistake in the page (which is usually what happens).

To store information in a variable, you use the equal sign (=), which copies the data on the right side of the equal sign into the variable on the left. Here's a one-step example that defines a variable and puts a text value (which is known as a *string*) inside:

```
var myMessage = "Everybody loves variables";
```

You can then use your variable:

```
// Show the variable text in a message box.  
alert(myMessage);
```

Note: JavaScript is a notoriously loose language, and it lets you use variables even if you don't specifically declare them with the *var* keyword. However, doing so is considered extremely bad form and is likely to lead to sloppy mistakes.

Null Values

One special value you may run into is *null*, which is programmer-speak for nothing. If a variable is null, it indicates that a given object doesn't exist. Depending on the context, this may signal that a specific feature is unavailable. For example, Modernizr (page 38) uses null value tests to determine whether the browser supports certain HTML5 features. You may also check for null values in your scripts—for example, to determine if you haven't yet created or stored an object:

```
if (myObject == null) {  
    // There is no myObject in existence.  
    // Now might be a good time to create one.  
}
```

Variable Scope

There are two basic places you can create a variable—inside or outside a function. The following code snippet has one of both:

```
<script>
var outsideVariable;

function doSomething() {
    var insideVariable;
    ...
}
</script>
```

If you create a variable inside a function (called a *local variable*), that variable exists only while that function is running. Here, `insideVariable` is a local variable. As soon as the `doSomething()` method ends, the variable is tossed out of memory. That means the next time the page calls `doSomething()`, the `insideVariable` is created from scratch, with none of its previous data.

On the other hand, if you create a variable outside a function (called a *global variable*), its value lasts as long as the page is loaded in the browser. Furthermore, every function can use that variable. In the previous example, `outsideVariable` is a `globalVariable`.

Tip: The rule of thumb is to use a local variable, unless you specifically need to share your variable with multiple functions, or to retain its value after the function ends. That's because it's more trouble to keep track of global variables, and if you use too many, your code becomes messy.

Variable Data Types

In JavaScript, variables can store different data types, such as text, integers, floating point numbers, arrays, and objects. However, no matter what you want to store in your variable, you define it with the same `var` keyword. You do *not* set the data type of your variable.

That means you can take the `myMessage` variable, with its piece of text, and replace that with a numeric value, like this:

```
myMessage = 27.3;
```

This behavior makes JavaScript easy to use, because any variable can hold any type of content. It can also let JavaScript mistakes slip past undetected. For example, you might want to grab the text out of a text box, and put that in a variable, like this:

```
var = inputElement.value;
```

But if you're not careful, you can accidentally end up putting the entire text box *object* into the variable, like this:

```
var = inputElement;
```

JavaScript allows both actions, so it won't complain. But a few lines into your code, this mistake will probably lead to some sort of unrecoverable problem. At that point, the browser simply stops running the rest of your code, without giving you any error message to explain what happened.

Operations

One of the most useful things you can do with numeric variables is perform *operations* on them to change your data. For example, you can use arithmetic operators to perform mathematical calculations:

```
var myNumber = (10 + 5) * 2 / 5;
```

These calculations follow the standard order of operations (parentheses first, then multiplication and division, then addition and subtraction). The result of this calculation is 6.

TROUBLESHOOTING MOMENT

Identifying Errors in JavaScript Code

In order to deal with problems (like the variable mistake shown on page 406), you need to master *debugging*—the fine art of hunting down the problems in your code and stamping them out. Unfortunately, the way you go about debugging depends on the browser you're using. Different browsers have different debugging tools (or support different debugging extensions). And while they all serve the same purpose, they don't work in exactly the same way.

Fortunately, all the information you need is on the Web. Here are some links that can explain how to debug JavaScript mistakes, based on your browser of choice:

- **Internet Explorer.** To sort out problems with IE, press F12 to pop up the Developer Tools window. To learn how to use it, visit <http://msdn.microsoft.com/ie/aa740478>.
- **Firefox.** Serious Firefox developers use a Firefox add-in called Firebug (<http://getfirebug.com/javascript>) to see what their code is doing at all times. You can also get a quick overview of Firefox debugging

options from the Mozilla documentation at http://developer.mozilla.org/en/Debugging_JavaScript.

- **Google Chrome.** Chrome has a respectable built-in debugger. To get started, read Google's debugging tutorial at http://code.google.com/chrome/extensions/tut_debugging.html.
- **Opera.** Opera's debugging tool of choice is Dragonfly (www.opera.com/dragonfly), and it provides a good overview about basic debugging techniques at <http://tinyurl.com/39nv7w>.
- **Safari.** Safari has a powerful set of built-in debugging tools, although tracking down the documentation that explains them can be tricky. You can start with a fairly technical article from the Safari Developer Library at <http://tinyurl.com/63om77c>.

Remember, it doesn't matter what browser and debugging tool you use to correct problems. Once they're fixed, they're fixed for everyone.

You can also use operations to join together multiple pieces of text into one long string. In this case, you use the plus (+) operator:

```
var firstName = "Sarah";
var lastName = "Smithers";
var fullName = firstName + " " + lastName;
```

Now the *fullName* variable holds the text “Sarah Smithers.” (The “ ” in the code above tells JavaScript to leave a space between the two names).

When making simple modifications to a variable, there’s a shortcut you’re likely to use. For example, if you have this basic addition operation:

```
var myNumber = 20;
myNumber = myNumber + 10;
// (Now myNumber is 30.)
```

You can rewrite it like this:

```
var myNumber = 20;
myNumber += 10;
// (Now myNumber is 30.)
```

This trick of moving the operator to the left side of the equal sign works with pretty much any operator. Here are some examples:

```
var myNumber = 20;
myNumber -= 10;
// (Now myNumber is 10.)
myNumber *= 10;
// (Now myNumber is 100.)

var myText = "Hello";
var myText += " there.";
// (Now myText is "Hello there.")
```

And if you want to add or subtract the number 1, there’s an even more concise shortcut:

```
var myNumber = 20;
myNumber++;
// (Now myNumber is 21.)

myNumber--;
// (Now myNumber is 20.)
```

Conditional Logic

All conditional logic starts with a *condition*: an expression that is either true or false. Based on the result, you can decide to run some code or to skip over it.

To create a condition, you need to rely on JavaScript’s *logical operators*, which are detailed in Table B-2.

Table B-2. Logical operators

Operator	Description
<code>==</code>	Equal to.
<code>!=</code>	Not equal to.
<code>!</code>	Not. (This reverses the condition, so if it would ordinarily be true, it is now false, and vice versa.)
<code><</code>	Less than.
<code>></code>	Greater than.
<code><=</code>	Less than or equal to.
<code>>=</code>	Greater than or equal to.
<code>&&</code>	Logical and (evaluates to true only if both expressions are true). If the first expression is false, the second expression is not evaluated.
<code> </code>	Logical or (evaluates to true if either expression is true). If the first expression is true, the second expression is not evaluated.

Here's an example of a simple condition:

```
myNumber < 100
```

To use this condition to make decisions, you need to put it with an *if* statement. Here's an example:

```
if (myNumber < 100) {
    // (This code runs if myNumber is 20, but not if it's 147.)
}
```

Note: Technically, you don't need the curly brackets around your conditional code, unless you have more than one statement. However, including the brackets is always clearer and avoids potential errors if you do have multiple statements.

When testing equality, make sure you use two equal signs. A single equal sign sets a variable's value, rather than performing the comparison you want:

```
// Right:
if (myName == "Joe") {
}

// Wrong:
if (myName = "Sarah") {
}
```

If you want to evaluate more than one condition, one after the other, you can use more than one *if* block (naturally). But if you want to look at a series of conditions, and find the first one that matches (while ignoring the others), you need the *else* keyword. Here it is at work:

```
if (myNumber < 100) {
    // (This code runs if myNumber is less than 100.)
}
else if (myNumber < 200) {
```

```
// (This code runs if myNumber is less than 200 but greater than or equal to
100.)
}
else {
  // (In all other cases, meaning myNumber is 200 or more, this code runs.)
}
```

You can include as many or as few conditions as you like in an if block, and adding a final else without a condition is also optional.

Loops

A loop is a basic programming tool that lets you repeat a block of code. The king of JavaScript loops is the *for* loop. It's essentially a loop with a built-in counter. Most programming languages have their own version of this construct.

When creating a for loop, you set the starting value, the ending value, and the amount to increment the counter after each pass. Here's one example:

```
for (var i = 0; i < 5; i++){
  // (This code executes five times.)
  alert("This is message: " + i);
}
```

At the beginning of the for loop is a set of brackets with three important pieces of information. The first portion (in this example, *var i = 0*) creates the counter variable (*i*) and sets its initial value (0). The second portion (*i < 5*) sets a termination condition. If it's not true (for example, *i* is increased to 5), the loop ends and the code inside is not repeated again. The third portion (*i++*), increments the counter variable. In this example, the counter is incremented by 1 after each pass. That means *i* will be 0 for the first pass, 1 for the second pass, and so on. The end result is that the code runs five times and shows this series of messages:

This is message: 0

This is message: 1

This is message: 2

This is message: 3

This is message: 4

Arrays

The for loop pairs naturally with the *array*—a programming object that stores a list of values.

JavaScript arrays are remarkably flexible. Unlike in many other programming languages, you don't define the number of items you want an array to store in JavaScript. Instead, you simply begin by creating an empty array with square brackets, like this:

```
var colorList = [];
```

You can then add items using the array's `add()` method:

```
colorList.add("blue");  
colorList.add("green");  
colorList.add("red");
```

Or you can place an array item in a specific position. If this memory slot doesn't already exist, JavaScript creates it for you, happily:

```
colorList[3] = "magenta";
```

And you can pull it out yourself, also by position:

```
var color = colorList[3];
```

Note: Just remember that JavaScript arrays use zero-based counting: The first item in an array is in slot 0, the second is in slot 1, and so on.

Once you have an array stocked with items, you can process each of them using a for loop like this:

```
for (var i = 0; i < colorList.length; i++) {  
    alert("Found color: " + colorList[i]);  
}
```

This code moves from the first item (the item at position 0) to the last item (using the array's `length` property, which reports its total item count). It shows each item in a message box, although you could surely think of something more practical to do with your array items.

Using a for loop to process an array is a basic technique in JavaScript. You'll use it often in this book, with arrays that you create yourself and ones that are provided to you by other JavaScript functions.

Functions that Receive and Return Data

Earlier, you saw a simple function, `showMessage()`. When you called `showMessage()`, you didn't need to supply any data, and when it finished, it didn't provide you with any additional information.

Functions aren't always that simple. In many cases, you need to send specific information to a function, or take the results of a function and use them in another operation. For example, imagine you want to create a version of the `showMessage()` function that you can use to show different messages. To do so, you need to make the `showMessage()` function accept a single *parameter*. This parameter represents the customized text you want to incorporate into your greeting.

To add the parameter, you must first give it a name, say *customMessage*, and put it in parentheses after the function name, like so:

```
function showMessage(customMessage) {  
    alert(customMessage);  
}
```

Note: There's no limit to how many pieces of information a function can accept. You just need to separate each parameter with a comma.

Inside the function, it can work with the parameters just like normal variables. In this example, the function simply takes the supplied text and shows it in a message box.

Now, when calling the `showMessage()` function, you need to supply one value (called an *argument*) for each of the function's parameters:

```
showMessage("Nobody likes an argument.");
```

Parameters let you send information *to* a function. You can also create functions that send information *back* to the script code that called them. The key to doing this is the *return* command, which you put right at the end of your function. The return command ends the function immediately, and spits out whatever information your function generates.

Of course, a sophisticated function can accept *and* return information. For example, here's a function that multiplies two numbers (the `numberA` and `numberB` parameters) and returns the result to anyone who's interested:

```
function multiplyNumbers(numberA, numberB) {
    return numberA * numberB;
}
```

Here's how you use this function elsewhere on your web page:

```
// Pass in two numbers, and get the result.
var result = multiplyNumbers(3202, 23405);

// Use the result to create a message.
var message = "The product of 3202 and 23405 is " + result;

// Show the message.
showMessage(message);
```

Of course you don't really need a function to multiple numbers (an ordinary JavaScript calculation can do that), nor do you need a function to show a message box (because the built-in `alert()` function can handle that job). But both examples do a good job of showing you how functions tick, and you'll use parameters and return values in the same way in more complex functions.

Interacting with the Page

So far, you've seen the right way to put JavaScript in a page, but you haven't done anything impressive (in fact, you haven't done anything but pop up a message box). Before going ahead, you need to know a bit more about the role JavaScript typically plays.

First, it's important to understand that JavaScript code is *sandboxed*, which means its capabilities are carefully limited. Your page can't perform any potentially risky tasks on your visitor's computer, like sending orders to a printer, accessing files, running other programs, reformatting a hard drive, and so on. This design ensures good security, even for careless visitors.

Instead, JavaScript spends most of its time doing one of these tasks:

- **Updating the page.** Your script code can change elements, remove them, or add new ones. In fact, JavaScript has complete flexibility to change every detail about the currently displayed HTML, and can even replace the whole document.
- **Retrieving data from the server.** JavaScript can make new web requests from the same web server that sent the original page. By combining this technique with the one above, you can create web pages that seamlessly update important information, like a list of news stories or a stock quote.
- **Sending data to the server.** HTML already has a way to send data to a web server, called web forms (Chapter 4). But JavaScript can take a much more subtle approach. It can grab bits of information out of your form controls, validate them, and even transmit them to the web server, all without forcing the browser to refresh the page.

The last two techniques require the XMLHttpRequest object, a JavaScript extension that's described on page 325. In the following sections, you'll take a look at the first of these, which is a fundamental part of almost every JavaScript-powered page.

Manipulating an Element

In the eyes of JavaScript, your page is much more than a static block of HTML. Instead, each element is a live object that you can examine and modify with JavaScript code.

The easiest way to get a hold of an object is to identify it with a unique name, which you apply through the *id* attribute. Here's an example:

```
<h1 id="pageTitle">Welcome to My Page</h1>
```

Once you give your element a unique ID, you can easily locate that object in your code and have JavaScript act on it.

JavaScript includes a handy trick for locating an object: the *document.getElementById()* method. Basically, a *document* is an object that represents your whole HTML document. It's always available, and you can use it any time you want. This document object, like any object worthy of the name, gives you some handy properties and methods. The *getElementById()* method is one of the coolest—it scans a page looking for a specific HTML element.

Note: If you're familiar with the basics of object-oriented programming, properties and methods are old hat. If not, you can think of *properties* as data that's attached to an object, and you can think of *methods* as functions that are built into an object.

When you call the `document.getElementById()` method, you supply the ID of the HTML element you're looking for. Here's an example that digs up the object for an HTML element with the ID *pageTitle*:

```
var titleObject = document.getElementById("pageTitle");
```

This code gets the object for the `<h1>` element shown earlier and stores it in a variable named *titleObject*. By storing the object in a variable, you can perform a series of operations on it without having to look it up more than once.

So what, exactly, can you do with HTML objects? To a certain extent, the answer depends on the type of element you're working with. For example, if you have a hyperlink, you can change its URL. If you have an image, you can change its source. And there are some actions you can take with almost all HTML elements, like changing their style or modifying the text that appears between the beginning and ending tags. As you'll see, you'll find these tricks useful in making your pages more dynamic—for example, you can change a page when a visitor takes an action, like clicking a link. Interactions like these make visitors feel as though they're using an intelligent, responsive program instead of a plain, inert web page.

Here's how you modify the text inside the just-mentioned `<h1>` element, for example:

```
titleObject.innerHTML = "This Page Is Dynamic";
```

This script works because it uses the *property* named *innerHTML*, which sets the content that's nested inside an element (in this case, an `<h1>` element with the page title). Like all properties, *innerHTML* is just one aspect of an HTML object you can alter. To write code statements like this, you need to know what properties JavaScript lets you play with.

Obviously, some properties apply to specific HTML elements only, like the *src* attribute that's used to load a new picture into this `` element:

```
var imgObject = document.getElementById("dayImage");
dayImage.src = "cloudy.jpg";
```

You can also tweak CSS properties through the style object:

```
titleObject.style.color = "rgb(0,191,255)";
```

Modern browsers boast a huge catalog of DOM properties you can use with just about any HTML element. Table B-3 lists some of the most useful.

Table B-3. Common HTML object properties

Property	Description
className	Lets you retrieve or set the class attribute (see page 385). In other words, this property determines what style (if any) this element uses. Of course, you need to define this style in an embedded or linked style sheet, or you'll end up with the plain-Jane default formatting.
innerHTML	Lets you read or change the HTML inside an element. The innerHTML property is insanely useful, but it has two quirks. First, you can use it on all HTML content, including text and tags. So if you want to put bold text inside a paragraph, you can set innerHTML to <code>Hi</code> . Second, when you set innerHTML, you replace all the content inside this element, including any other HTML elements. So if you set the innerHTML of a <code><div></code> element that contains several paragraphs and images, all these items disappear, to be replaced by your new content.
parentElement	Provides the HTML object for the element that contains this element. For example, if the current element is a <code></code> element in a paragraph, this gets the object for the <code><p></code> element. Once you have this element, you can modify it too.
style	Bundles together all the CSS attributes that determine the appearance of the HTML element. Technically, the style property returns a full-fledged style object, and you need to add another dot (.) and the name of the style attribute you want to change, as in <code>myElement.style.fontSize</code> . You can use the style object to dictate colors, borders, fonts, and even positioning.
tagName	Provides the name of the HTML element for this object, without the angle brackets. For example, if the current object represents an <code></code> element, this returns the text "img".

Tip: HTML elements also provide a smaller set of useful methods, including some for modifying attributes, like `getAttribute()` and `setAttribute()`; and some for adding or removing elements, like `insertChild()`, `appendChild()`, and `removeChild()`. To learn more about the properties and methods that a specific HTML element supports, check out the reference at <http://developer.mozilla.org/en/DOM/element>.

Connecting to an Event Dynamically

On page 403, you saw how to wire up a function using an event attribute. However, it's also possible to connect an event to a function using JavaScript code.

Most of the time, you'll probably stick to event attributes. However, there are cases where that isn't possible or convenient. One of the most common examples is when you create an HTML object in your code and then add it to the page dynamically. In this situation, there's no markup for the new element, so there's no way to use an event attribute. (You'll see this technique in the canvas drawing example in Chapter 6.) Another case is when you're attaching an event to a built-in object rather than an element. (You'll see this example when you handle storage events in Chapter 9.) For all these reasons, it's important to understand how to wire up events with code.

Note: There are several different ways to attach events, but they aren't all supported by all browsers. This section uses the *event property* approach, which is. Incidentally, if you decide to use a JavaScript toolkit like jQuery, you'll probably find that it adds yet another event-attaching system, which *will* work on all browsers and may provide a few extra features.

Fortunately, attaching events is easy. You simply set an event property that has the same name as the event attribute you would normally use. For example, say you have an `` element like this somewhere on your page:

```

```

Here's how you tell the browser to call the `swapImage()` method when that image is clicked:

```
var imgObject = document.getElementById("dayImage");
imgObject.onclick = swapImage;
```

However, don't make this mistake:

```
imgObject.onclick = swapImage();
```

This runs the `swapImage()` function, takes the result (if it returns one), and uses that to set the event handler. This is almost certainly not what you want.

To understand what really happens when the `` element is clicked, you need to look at the code in the `swapImage()` function. It grabs the `` element and modifies the `src` attribute to point to a new picture (see Figure B-3):

```
// Keep track of whether the picture has been swapped from day to night.
var dayTime = true;

// This function runs when the onClick event happens.
function swapImage() {
    var imgObject = document.getElementById("dayImage");

    // Flip from day to night or night to day, and update the picture to match.
    if (dayTime == true) {
        dayTime = false;
        imgObject.src = "cloudy.jpg";
    }
    else {
        dayTime = true;
        imgObject.src = "sunny.jpg";
    }
}
```

Sometimes, an event passes valuable information to your event-handling function. To capture this information, you need to add a single parameter to your function. By convention, this parameter is usually named *event* or just *e*:

```
function swapImage(e) {
    ...
}
```

The properties of the event object depend on the event. For example, the `onMouseMove` event supplies the current mouse coordinates (which you'll use when creating the painting program on page 188).

**Figure B-3:**

Click this picture, and the page fires an event. That event triggers a function, and that function loads a new image.

There's one more fine point to note. When you use code to connect an event, you *must* put the entire event name in lowercase letters. This is different from when you wire up an event using an attribute in HTML. Unlike JavaScript, HTML doesn't care one whit about case.

Note: This book refers to events using an easy-to-read convention called Pascal case, which uses uppercase letters to indicate each new word (for example, *onLoad* and *onMouseOver*). However, the code listings use all lowercase letters (for example, *onload* and *onmouseover*) because JavaScript requires it.

Inline Events

In order for the previous example to work, the `swapImage()` function must be defined somewhere else in your code. Sometimes, you may want to skip this step and define the function code in the same place where you attach the function to the event. This slick technique is called an *inline function*.

Here's an example that connects an inline function to the `onClick` event:

```
var imgObject = document.getElementById("dayImage");
imgObject.onclick = function() {
    // The code that went in the swapImage() function
    // now goes here.
    if (dayTime == true) {
        dayTime = false;
        imgObject.src = "cloudy.jpg";
    }
}
```

```
    else {  
        dayTime == true;  
        imgObject.src = "sunny.jpg";  
    }  
};
```

This shortcut approach to event handling is less common than using a separate, named function to handle the event. However, it's still a useful convenience, and the examples in this book use it occasionally.

Note: Inline functions are sometimes useful when you're dealing with an *asynchronous task*—a task that the browser handles in the background. When an asynchronous task is finished, the browser fires an event to notify your code. Sometimes, the clearest way to deal with this situation is to put the code that handles the *completion* of a task right next to the code that triggered the *start* of the task. (Page 201 shows an example with a picture that's loaded asynchronously and then processed.)

Finally, there's one sort of inline function that's used in many of the examples of this book. It's the event handler for the window's `onLoad` event, which fires after the entire page is rendered, displayed, and ready to go. This makes it a logical point for your code to take over. If you try to run code before this point, you might run into trouble if an object hasn't been created yet for the element you want to use:

```
<script>  
window.onload = function() {  
    alert("The page has just finished loading.");  
}  
</script>
```

This approach frees you from worrying about the position of your script block. It lets you place the initialization code in the `<head>` section, where it belongs, with the rest of your JavaScript functions.

Colophon

HTML5: The Missing Manual was composited in Adobe InDesign CS4 by Dessin Designs (www.dessindesigns.com).

The cover of this book is based on a series design originally created by David Freedman and modified by Mike Kohnke, Karen Montgomery, and Fitch (www.fitch.com). Back cover design, dog illustration, and color selection by Fitch.

David Futato designed the interior layout, based on a series design by Phil Simpson. The text font is Adobe Minion; the heading font is Adobe Formata Condensed; and the code font is LucasFont's TheSansMonoCondensed. The illustrations that appear in the book were produced by Robert Romano using Adobe Photoshop and Illustrator CS.
